1 **S1. Instrumentation**

2 **S1.1 Aerosol Mass Spectrometry: set up and operation**

3 Online measurements of organic and sulfate mass concentrations measured in this study
4 were made by a High-Resolution Time-of-Flight Aerosol Mass Spectrometer (AMS, Aerodyne
5 Research Inc.) (DeCarlo et al., 2006; Canagaratna et al., 2007). The AMS provided real-time
6 measurements of bulk non-refractory particle chemical composition (organic, sulfate, nitrate,
7 ammonium, chloride) and chemically resolved mass-diameter distribution. Air was sampled
8 through a critical orifice and enters an aerodynamic lens, which focused the submicron particles
9 into a narrow beam (Zhang et al., 2004). Particles traveled through a sizing chamber to reach a
10 porous tungsten inverted-cone vaporizer at 600 °C, and non-refractory components volatilized.
11 The gaseous molecules were then ionized through electron impact (70 eV), and the ions were
12 measured by time-of-flight mass spectrometry. The high mass resolution allowed for the
13 distinction of ions having the same nominal mass but different elemental composition. Data
14 analysis was performed using standard AMS software (*SQUIRREL* 1.56D, *PIKA* 1.14G)
15 (webpage: [http://cires1.colorado.edu/jimenez-](http://cires1.colorado.edu/jimenez-group/ToFAMSResources/ToFSoftware/index.html)
16 [group/ToFAMSResources/ToFSoftware/index.html](http://cires1.colorado.edu/jimenez-group/ToFAMSResources/ToFSoftware/index.html)).

17 Aerosol particles were sampled through a cyclone (URG-2000-30EH) which had a size
18 cut of 2.5 μm for a flow of 16.7 L min^{-1} . The sampled flow (14.9 to 16.3 L min^{-1}) traveled
19 through a stainless steel tube for about 1.5 m. The flow was then split in two: a 4-m line for
20 sampling (1.2 or 2.6 L min^{-1}) and a line (13.7 L min^{-1}) for exhaust. The sampling flow changed
21 between 1.2 and 2.6 L min^{-1} according to the flow set up of the Scanning Mobility Particle Sizer
22 (SMPS), which was sampling in parallel to the AMS. The sampling flow then entered a poly-
23 tube Nafion dryer (Perma Pure, model PD-100T). Drying prior to entering the instrument

24 container aimed at avoiding water condensation in the line inside the container, which was
25 always kept at lower temperatures than outside (i.e., trailer temperature was around 23 °C during
26 daytime). RH measured after the poly-tube dryer and inside the container was at 40 to 80%.
27 Within the container, a subflow (0.6 or 3 L min⁻¹) was passed through a mono-tube Nafion dryer
28 (Perma Pure, model MD-110) to reach RH < 40%. A flow of 0.09 L min⁻¹ was sampled by the
29 AMS, and the remaining flow of 0.5 or 2.9 L min⁻¹ was sampled by the SMPS. The ambient air
30 sampling line was integrated to a valve switching system, which alternated the AMS/SMPS
31 sampling between the unprocessed ambient air and air processed by oxidation flow reactors or a
32 thermal denuder. The unprocessed ambient air (used for this analysis) was sampled for 4 out of 8
33 min, constituting half of the total acquired data set.

34 Due to expected low mass concentrations and to secondary need for the low-sensitivity
35 high-resolution data, the AMS was operated for most of the time in medium-resolution V-mode
36 ($\Delta m/m = 2200$ at m/z 44), which was used for mass quantification. High-resolution W-mode
37 ($\Delta m/m = 4000$ at m/z 44) was acquired for one of every six days. These data were used to aid
38 choice of ions to fit. When only V-mode data were acquired, the instrument was operated in
39 “mass spectrum” sub-mode for 180 s and in “particle-time-of-flight” sub-mode for 60 s. When
40 W-mode data were also collected, the “W-mass-spectrum” sub-mode was operated for 60 s, the
41 “V-mass-spectrum” sub-mode ran for 120 s, and “V-particle-time-of-flight” sub-mode ran for 60
42 s. Both ways of operation corresponded to 4 min for each cycle, allowing for synchronization to
43 the valve switching system.

44 The AMS sensitivity and the ammonium relative ionization efficiency (RIE) were
45 calibrated every five days using dried ammonium nitrate particles having a mobility diameter of
46 400 nm. An interpolated curve of the obtained values, corresponding to $RIE = 4.3 \pm 0.2$, was

47 used for mass calculation corrections. The sulfate RIE was calibrated using ammonium sulfate a
48 few times during the campaign, and the average value of 0.9 ± 0.1 was applied to the entire
49 campaign. The collection efficiency (CE) was determined as 1.0 for IOP1 according to volume
50 comparison to the two co-located Scanning Mobility Particle Sizers (Figure S6). Volume of
51 black carbon (BC) accounted for 8 ± 6 % of the total volume measured by SMPS, for an
52 assumed density of 1.8 g cm^{-3} for BC. Since BC data were limited, the abscissa of Figure S6 was
53 not subtracted by BC contribution. This CE value was consistent with that used for the AMAZE-
54 08 in the wet season of 2008 (Chen et al., 2009).

55 **S1.2 Semi-Volatile Thermal desorption Aerosol Gas Chromatography: set up and** 56 **operation**

57 Online measurements of organic tracer compounds in the particle and gas phases were
58 made by a Semi-Volatile Thermal desorption Aerosol Gas chromatograph (SV-TAG). This
59 instrument is described in detail elsewhere (Isaacman et al., 2014). Its operation is briefly
60 presented here.

61 Air was sampled at 20 L min^{-1} from the center stream of a flow of 200 L min^{-1} through a
62 15.24 cm (OD) stainless steel duct at a height of approximately 5 m above ground level. The
63 flow was then divided into two channels, passing through a PM1 cyclone at 10 L min^{-1} , each
64 containing a custom Filter Collection and Thermal Desorption cell (F-CTD). The F-CTD
65 quantitatively collected and retained both particle- and gas-phase compounds. A multi-channel
66 carbon denuder (MAST Carbon) was used to remove all gases upstream of one collection cell. In
67 this way, two samples were simultaneously collected: a “particle” sample and a “total” gas-plus-
68 particle sample. Samples were thermally desorbed from the cells subjected to a ramping
69 temperature from 30 to $310 \text{ }^\circ\text{C}$ ($35 \text{ }^\circ\text{C min}^{-1}$) into a helium stream that was 80% saturated with

70 MSTFA (N-Methyl-N-(trimethylsilyl) trifluoroacetamide). Hydroxyl groups were converted into
71 silyl esters and ethers. Analytes were transferred to the GC column, and the sample was analyzed
72 through a commercially available GC/MS (7890A/5975C; Agilent Technologies). The
73 chromatographic data were analyzed using the publicly available software *TAG ExploreR and*
74 *iNtegration* (Isaacman-VanWertz and Sueper).

75 Compounds were quantified using isotopically labeled internal standards to correct for
76 run-to-run variability in sample transfer efficiency and instrument response. Regular multi-point
77 calibrations were made of approximately 100 authentic standards. Pentaerythritol-2-¹³C was used
78 for 2-methyltetrols and C₅-alkene triols. The uncertainty in mass concentration was
79 approximately 15% (Isaacman et al., 2014). C₅-alkene triols were quantified using the calibration
80 factor of 2-methyltetrols under the assumption of an identical total ion response. An absence of
81 an authentic standard results in unconstrained uncertainty in mass concentration of 30 of 50%
82 (Jaoui et al., 2005).

83 **S1.3 NO_y measurements**

84 The NO_y measured included the following species: NO, NO₂, HNO₃, particle nitrate,
85 RNO₃, and PAN. Measurements were made by a custom analyzer designed by Air Quality
86 Design (AQD; <http://www.airqualitydesign.com>). The analyzer was based on two commercial
87 oxides of nitrogen detectors made by Thermo Scientific (Model 42i TLE) and extensively
88 modified by AQD. An external, temperature-controlled inlet box was mounted at 10 m above
89 ground level.

90 The instrument contained both a research grade LED photolysis cell for converting NO₂
91 into NO and a heated molybdenum converter for converting total NO_y into NO. One channel,
92 leading from the photolysis cell to one 42i TLE detector, alternated every minute between NO

93 and NO_x by switching the LED photolysis cell on/off. The other channel, leading from the
94 molybdenum converter to the second 42i TLE detector, measured total NO_y . The detectors
95 internally measured zero based on pre-reaction of the sample with ozone. Instrument response
96 was measured by addition of NO in zero air at the sampling point (10 m). Converter efficiency
97 was measured by gas-phase titration of the NO standard to NO_2 . An HNO_3 source was sampled
98 every other day. The calibration unit was a Thermo Scientific Model 146i calibrator equipped
99 with gas-phase titration and a permeation oven. The raw NO_y measurements, reported at a
100 resolution of 10 s, were averaged into bins of 30 min to filter for local events not representative
101 of the larger scale chemical processes that form the scope of this study.

102 **S2. Positive Matrix Factorization and the IEPOX-SOA factor**

103 The time series of mass spectra of organic material measured by the AMS was analyzed
104 by positive matrix factorization (PMF) using a standard analysis toolkit (Ulbrich et al., 2009).
105 High-resolution, V-mode data were used. The PMF solution was based on minimization of the
106 “Q-value” or “PMF quality-of fit parameter”, meaning the sum of the weighed squared residuals
107 for a chosen number of factors. The interpretation of the physical significance of the AMS PMF
108 factors took into account correlations with quantities simultaneously measured by other
109 instruments. The solution consisted of six factors, and the present study focuses on one of the
110 derived factors, labeled “IEPOX-SOA”. de Sá (in preparation) focuses on presentation of the
111 other factors.

112 The profile of the resolved IEPOX-SOA factor is shown in Figure S1. A key
113 characteristic is intensity at $\text{C}_5\text{H}_6\text{O}^+$ (m/z 82) (Hu et al., 2015). In addition, a prominent signal at
114 C_4H_5^+ (m/z 53) is observed, which has also been reported as characteristic of the IEPOX-SOA
115 factor (Hu et al., 2015). The IEPOX-SOA factor is also relatively highly oxidized, as expressed

116 by $f_{44} = 0.15$ and oxygen to carbon atomic ratio O:C = 0.80, applying the calibration described in
117 Canagaratna et al. (2015).

118 Technical diagnostics of the six-factor solution are presented in Figure S2 and more
119 extensively described in (de Sá, in preparation). Panel b shows the quality of fit parameter
120 $Q/Q_{expected}$ (Ulbrich et al., 2009) as a function of the number of factors, suggesting that the
121 solution should have at least three factors. Panel a shows a great reduction in the structure of the
122 total residuals when going from the five-factor to the six-factor solution. The six-factor solution
123 also offered more meaningful factor profiles (“mass spectra”) (de Sá, in preparation). Panel c
124 shows $Q/Q_{expected}$ as a function of the rotational ambiguity parameter f_{peak} (Ulbrich et al., 2009)
125 for the six-factor solution. A plausible range for f_{peak} was determined according to the best
126 practice of limiting $Q/Q_{expected}$ to a value that does not exceed 0.1% of the minimum value
127 (occurring at $f_{peak} = 0$). The default value of $f_{peak} = 0$ was chosen for the final six-factor solution,
128 since no significant improvements in the external validation of the factors were observed.
129 Moreover, the IEPOX-SOA factor resolved in the six-factor solution had a very robust time trend
130 across a range of rotations in the solution (Figure S2d). As f_{peak} varied, the correlation of factor
131 loading with C5-alkene triols concentrations remained approximately constant, even as some
132 features of the factor profile changed significantly, such as the relative signals of $C_5H_6O^+$ and
133 CO_2^+ , respectively $f(C_5H_6O)$ and $f(CO_2)$, as well as the magnitude of factor loadings and
134 consequently the ratio f .

135 The loading of the IEPOX-SOA factor may be an overestimate or an underestimate of the
136 atmospheric concentration of the IEPOX-derived PM (brown dashed lines in Figure 1). In
137 respect to overestimate, the AMS mass spectrum observed in laboratory studies for the uptake of
138 IEPOX by acidic sulfate particles is statistically equal to that obtained for the uptake of isoprene

139 photo-oxidation products, yet IEPOX accounted for only half of those products (Liu et al., 2015).
140 The implication is that the uptake of non-IEPOX species can lead to a similar AMS spectrum.
141 Pathways of PM production from condensation of multifunctional hydroperoxides lead to a
142 distinct mass spectrum from IEPOX pathways, and are not expected to be highly active under the
143 acidic particle conditions of these experiments (Riva et al., 2016), leaving a large mass fraction
144 of produced PM unexplained. The combination of AMS vaporization at 600 °C and ionization by
145 electron impact at 70 eV may convert IEPOX-derived and non-IEPOX-derived molecules into
146 similar groups of ions, which then give rise to a similar mass spectrum. The SV-TAG, which
147 uses desorption temperatures up to 310 °C and thus can also induce thermal decomposition of
148 some molecules, might also result in an in-common analyte (i.e., tracer) between IEPOX-derived
149 and non-IEPOX-derived molecules, thereby precluding a constraint on any possible overestimate
150 by the AMS factor (Isaacman-VanWertz et al., 2016; Lopez-Hilfiker et al., 2016). For these
151 reasons, the loading of the IEPOX-SOA factor might overestimate IEPOX-derived PM
152 concentrations by accounting for other isoprene oxidation products that are not produced through
153 the IEPOX intermediate.

154 In respect to underestimate, the loading of the IEPOX-SOA factor may not capture the
155 entire particle-phase carbon footprint that originated from IEPOX uptake. Extensive atmospheric
156 processing, such as reactions with hydroxyl radicals or photolysis, can partly eliminate the initial
157 products of IEPOX uptake (Kroll et al., 2009; Bateman et al., 2011; Epstein et al., 2014; Hu et
158 al., 2015; Hu et al., 2016). The IEPOX-originated carbon can still be inside the particle, yet it no
159 longer contributes to the loading of the IEPOX-SOA factor because of an altered mass spectrum
160 for some molecules. Atmospheric reactions gradually homogenize particle composition and
161 properties, and the AMS spectra can become more uniform (Jimenez et al., 2009). Specifically,

162 the ratio of signal intensity at m/z 44 to that at m/z 43 increases, and the relative intensity of m/z
163 82 decreases (Ng et al., 2011; Hu et al., 2015). This modified organic material, which originally
164 entered the particle phase through IEPOX uptake, may then contribute to the loading of PMF
165 factors other than IEPOX-SOA, such as the oxidized organic factors broadly labeled as “OOA”
166 (Zhang et al., 2005). For these several reasons, the IEPOX-SOA factor loading might be an
167 underestimate of IEPOX-derived PM concentrations.

168 **S3. Comparison of background and polluted cases**

169 The presence of a pollution plume at T3 is indicated by a combination of several external
170 measured variables, including particle number, ozone, and NO_y concentrations. The definition of
171 background and polluted cases aimed at selecting afternoons that were associated with extreme
172 values of those variables. Conditions entailing concentration of ozone at around 10 ppb or less,
173 particle number concentration of less than 500 cm^{-3} , and NO_y concentrations of less than 1 ppb
174 were collectively a strong indicative of a background case. Conditions including ozone
175 concentrations upward of 30 ppb, particle number concentration above 2000 cm^{-3} , and NO_y
176 concentrations around 1.5 ppb or above indicated pollution. Measurements of these variables
177 onboard the G-1 aircraft confirmed what the ground measurements suggested on the several days
178 that the G-1 flew overhead.

179 Examples of these supporting data are illustrated in Figure 3 for the chosen background
180 and polluted days (March 3 and 13, 2014, respectively) composing the primary case study
181 analyzed in the main text. A few other afternoons, representative of these two extremes of
182 background and polluted cases, were selected from the campaign time series and are depicted in
183 Figure S4. The top panel shows cases of background conditions, and the bottom panel shows
184 cases of polluted conditions. The local wind direction observed for the polluted cases generally

185 characterized by easterlies, as consistent with Manaus direction, whereas for the background
186 cases it tends to diverge from that prevailing direction. The cases within each category are
187 ordered from left to right in ascending order of IEPOX-SOA factor loadings.

188 Sulfate concentrations had a wide range of values, even for background conditions
189 (Figure S4), as discussed in the main text. Meteorological conditions such as overcast (lower
190 photooxidation activity) and rain events (higher wet deposition), as seen on March 20 and March
191 23, are some of the factors that control particle number and mass concentration (sulfate and
192 organic compounds). These factors help to explain the natural variability in sulfate mass
193 concentration. By comparison, on a sunny day, with winds mostly coming from the northeast
194 direction, as exemplified by February 16 and March 3, sulfate mass concentrations can be around
195 $0.3 \mu\text{g m}^{-3}$ or more, values which are also typical of some polluted days (bottom panel). Both the
196 factor loading and the ratio f increased with increasing sulfate (rows 2 and 3 of top panel), when
197 NO_y levels were approximately the same. A comparison of February 16 and March 3 shows in
198 addition the importance of NO_y concentration: for similar concentrations of sulfate and organic
199 PM and similar meteorological conditions, the case having lower NO_y concentrations (0.4 to 0.5
200 ppb on March 3 as compared to 0.7 to 0.8 ppb on February 16) was associated with considerably
201 higher absolute and relative factor loadings.

202 For the polluted cases shown in Figure S4, NO_y concentrations were variable between
203 and within cases, ranging from 1 ppb up to 7 ppb. Larger sulfate mass concentrations (from left
204 to right) were associated with larger absolute and relative factor loadings, analogous to what was
205 observed for background cases. A comparison between March 3 and 13 (i.e., background and
206 polluted; Figure 4) shows that for similar sulfate concentrations but higher NO_y levels March 13
207 had considerably lower factor loadings. The case of February 9 (polluted) illustrates that the

208 factor loadings did not exceed $0.4 \mu\text{g m}^{-3}$ and f did not exceed 0.2 even at rarely high sulfate
209 concentrations in the wet season, reaching $0.9 \mu\text{g m}^{-3}$. This finding is attributed to the high NO
210 concentrations, as implied by NO_y concentrations of 3 ppb and greater, that suppressed IEPOX
211 production.

212 These cases illustrate the possible wide range of observed sulfate mass concentrations
213 under background conditions, in great part overlapping with typical values of polluted
214 conditions. The cases also demonstrate that the trend in observed IEPOX-SOA factor loadings
215 and ratio f , both within each category (background or polluted conditions) and between them, can
216 be consistently explained by the roles that sulfate and NO exert on the production of IEPOX-
217 derived PM.

218 **S4. Sulfate and particle acidity estimates in the context of field studies**

219 The underlying relative importance of direct compared to indirect roles of sulfate on the
220 formation of IEPOX-derived PM is not well understood. Sulfate can play a direct role as a
221 nucleophile in the reaction of formation of organosulfates from IEPOX (Surratt et al., 2007b;
222 Nguyen et al., 2014). Organosulfates, however, are believed to constitute only a fraction of the
223 IEPOX-derived PM (Hu et al., 2015). Particle acidity, an indirect effect of sulfate, has been
224 shown to drive IEPOX-derived PM production in several lab studies (Surratt et al., 2007a;
225 Kuwata et al., 2015; Lewandowski et al., 2015). Nevertheless, the acidity effect observed in
226 laboratories is not as clearly observed in field studies, wherein pH estimates have typically been
227 employed as a proxy for acidity (Budisulistiorini et al., 2013; Lin et al., 2013; Worton et al.,
228 2013; Budisulistiorini et al., 2015; Xu et al., 2015). The present study corroborates those findings
229 and further argues that this apparent conflict can be reasoned by taking into account that both the
230 estimate and the end-use of pH may be problematic in the context of field studies.

231 Firstly, a reliable estimate of pH is often hard to obtain. In the case of the present study,
232 some difficulties were imposed by data availability. Gas-phase measurements of NH_3 or HNO_3
233 were not available for performing “forward” mode calculations in thermodynamic models or gas-
234 particle phase partitioning calculations, which have been suggested as the best method to predict
235 pH (Hennigan et al., 2015). Co-located independent measurements of ion concentrations (e.g., by
236 chromatograph) were not available to confirm the ion balance obtained by AMS measurements
237 (Figure S7).

238 Bearing these caveats in mind, the analysis presented in the main text using sulfate as a
239 predictor for IEPOX-SOA was replicated here using pH in place of sulfate. Figure S8 is
240 analogous to Figure 6a. pH was estimated for IOP1 using AMS measurements of mass
241 concentrations of inorganic ions (sulfate, ammonium, nitrate, and chloride) and measurements of
242 RH and temperature. The E-AIM model II (Clegg et al., 1998) was employed. The final pH was
243 calculated taking into account both the inorganic water predicted by the model and the organic
244 water estimated from organic hygroscopicity κ_{org} values (Thalman, in preparation), in a similar
245 fashion as described by Guo et al. (2015). Figure S8 shows that pH, as calculated herein and for
246 the caveats herein, does not work well as a predictor for IEPOX-SOA factor loading. Figure S9
247 is analogous to Figure 7. Figure S9 shows that, although the overall dependencies on NO_y are
248 similar to analysis of the data by sulfate, the separation by pH yields groups that have less
249 distinct trends and ranges among them.

250 In addition to difficulties associated with generating accurate estimates of pH, there is an
251 inconsistency between the timescales of estimated particle acidity and IEPOX-SOA factor
252 loadings that may preclude underlying correlations to emerge. The estimated pH makes use of
253 instantaneous RH and temperature values and is therefore an instantaneous estimate of pH. They

254 can change in timescales of 15 min or less giving mixing in the boundary layer, for example. On
255 the other hand, sulfate mass concentrations and IEPOX-SOA factor loadings are variables
256 representative of processes of longer time scales of hours and days. By not containing any
257 information on the particle acidity history in the past hours or days, the calculated instantaneous
258 pH may fail in capturing the true effect of acidity on the chemical formation of IEPOX-derived
259 PM. The RH cycling history of sulfate particles has been demonstrated to mediate the extent of
260 IEPOX-derived PM production (Wong et al., 2015). Moreover, sulfate, by being intrinsically
261 related to particle acidity and at the same time a species of congruent lifetime with secondary
262 organic material, may in fact be a better proxy to capture the history of particle acidity than
263 estimates of pH. For these different reasons, sulfate rather than pH is used in the analysis herein.
264 The understanding, however, is that sulfate represents effects beyond those of the direct chemical
265 role of sulfate. In analogy to pH, this discussion also extends to the use of sulfate rather than
266 instantaneous particle water content as the predictor of IEPOX-SOA factor loadings.

267 **S5. Five subsets of data based on NO_y concentrations**

268 The data subsets and fits shown in Figure 6 are shown in separate panels in Figure S5.
269 Once a trend of decreasing fit slope with increasing NO_y concentration was identified, the
270 number of data subsets was defined as the minimum necessary to have subsets of at least 100
271 data points (of a total of 888) to allow for robust statistics and that were also cohesive (as
272 measured by R^2) and non-redundant (i.e., of different fit lines).

273 The coloring by date in Figure S5 shows that there is no apparent correlation between
274 levels of NO_y concentration or goodness of fit with different time periods within IOP1.
275 Meteorological variables such as solar radiation, temperature, and RH (not shown) are also not
276 able to delineate any clear pattern in the data, either within or among groups.

277 Although a linear bivariate statistical analysis for the IEPOX-SOA factor in sulfate and
278 NO_y concentrations at first appears attractive, the underlying chemical processes were not linear,
279 as reflected in the relationship between IEPOX-derived PM and NO_y concentrations. Moreover,
280 sulfate and NO_y concentrations were not independent variables. For these reasons, a linear
281 bivariate analysis is not appropriate, and a subset analysis was pursued instead.

282 **S6. Details and assumptions of the model**

283 The solution to the differential Equation 1 is as follows:

$$284 \quad M(t) = \frac{\alpha_P k_P}{\alpha_L k_L} + e^{\alpha_L k_L t} \left(M_0 - \frac{\alpha_P k_P}{\alpha_L k_L} \right) \quad (S1)$$

285 for which the subscript 0 indicates initial (background) conditions, i.e., immediately before the
286 air mass passes over Manaus. For the transport from Manaus to T3, $t = \tau_{tr}$, and the variable M
287 represents the IEPOX-derived PM mass concentrations at T3.

288 The zero-order production rate coefficient k_P and the first-order loss rate coefficient k_L
289 are lumped parameters representative of several production and loss processes, respectively. A
290 first assumption is that they are constant over the course of four hours. In hand with that
291 assumption, a constant boundary layer height throughout the integration time is assumed. The τ
292 values represent the time required under afternoon conditions to significantly affect the IEPOX-
293 derived PM mass concentration by the corresponding processes. For afternoon time periods,
294 observations show that $dM/dt > 0$ over tropical forests in the absence of pollution (Chen et al.,
295 2009; Chen et al., 2015). The parameter τ_P , corresponding to a first order process, therefore
296 represents an instantaneous quantity in the transient system. For simplicity of presentation, τ_P is
297 defined in reference to M_0 , although defining it in relation to M_{bg} or M_{pol} does not alter the main
298 conclusions presented herein.

299 In terms of loss processes, represented by the rate coefficient k_L , IEPOX-derived PM may
300 be lost by three main mechanisms: heterogeneous oxidation against OH, condensed-phase
301 reactions, and dry deposition. The lifetime of IEPOX-derived PM against heterogeneous
302 oxidation is estimated at around two weeks for an OH concentration of 10^6 molecules cm^{-3} (Hu et
303 al., 2016). Lifetime of IEPOX products against particle-phase reactions has not yet been reported
304 but is expected to be at least several days. A value of one week is used here. The lifetime of PM
305 against deposition is on the order of a week. The overall loss process is then approximated in the
306 model as the sum of these three processes, which leads to an estimate of overall loss rate
307 coefficient $k_L = 0.015 \text{ h}^{-1}$ (overall characteristic time of 2.8 days).

308 In respect to wet deposition along the track from Manaus to the T3 site, strong convection
309 imports background regional air, and for this reason strong wet deposition is mathematically
310 equivalent in the model developed herein to a trajectory that does not pass over Manaus, i.e.,
311 background conditions. Weak wet deposition represents a mixing of polluted and background air
312 masses, giving rise to intermediate NO_y concentrations. Entrainment on the plume edges as well
313 as with the free troposphere is mathematically similar to wet deposition in the model framework.
314 Thus entrainment and wet deposition, without directly contributing to k_L , are indirectly
315 incorporated in the developed model based on their effects on NO_y concentration.

316 In terms of production processes, represented by the rate coefficient k_p , IEPOX-derived
317 PM is produced by multigenerational chemistry of isoprene photooxidation and reactive uptake.
318 Model Case 1 investigated the sensitivity of pollution enhancement ratio and absolute mass
319 concentration of IEPOX-derived PM to its production rate coefficient. After constrained by
320 observations, the estimated interval for k_p was $[0.07, 0.13] \mu\text{g m}^{-3} \text{ h}^{-1}$. In addition, values of $k_p >$
321 $0.2 \mu\text{g m}^{-3} \text{ h}^{-1}$ are unlikely given the rare observation ($<1\%$) of $M_{bg} > 1 \mu\text{g m}^{-3}$.

322 The obtained range can be compared to estimates of total production rate of organic
323 material from diameter growth rates. Firstly, a relative production rate of 1:3 for IEPOX-derived
324 PM to total organic PM is assumed based on the following. IEPOX-derived PM is estimated to
325 contribute 34% on average to total organic PM in central Amazonia under background
326 conditions (Chen et al., 2015). For assumptions of equal first order loss rate coefficients for all
327 organic material, a mass concentration ratio of 1:3 for IEPOX-derived PM to total organic
328 material implies a ratio of 1:3 in their production rate coefficients k_p . As a consequence, the
329 estimated range for total organic material is $[0.21, 0.39] \mu\text{g m}^{-3} \text{h}^{-1}$. For the estimate of organic
330 material production based on growth rates, an average growth rate of 10 nm h^{-1} (Kulmala et al.,
331 2004) is assumed. Further assumptions are a range of particle number concentration of 500 to
332 1000 cm^{-3} and of initial diameter of 20 to 100 nm, typical of background conditions in the
333 Amazon. The obtained range of organic material production from growth rate estimates is
334 therefore 0.02 to $0.32 \mu\text{g m}^{-3} \text{h}^{-1}$, which is comparable to the range constrained by the model.

335 In terms of the influence of Manaus plume on the production and loss processes, the
336 following assumptions were made. The acceleration of the oxidant cycle in the plume implies
337 that $\alpha_L > 1$. Under plume conditions, OH concentrations observed at the T3 site increased by a
338 factor of three compared to background conditions (Martin et al., 2016a; Kim, in preparation). A
339 proportional increase in the loss rate of IEPOX-derived PM by OH heterogeneous chemistry in
340 the plume is expected. While the OH loss mechanism (of characteristic time of two weeks) is
341 accelerated by three fold in the plume, dry deposition and condensed phase reactions (both of
342 assumed characteristic times of a week) are held constant. As a result, the overall loss rate is
343 enhanced by two fold, i.e., $\alpha_L = 2$ is assumed.

344 Concerning the production enhancement factor, the interception of ISOPOO radicals by
345 NO in the pollution plume as well as the faster consumption of intermediate gas-phase species by
346 the enhanced OH and O₃ concentrations implies $\alpha_P < 1$. The assumption is that the production of
347 IEPOX almost halts in the plume, and $\alpha_P = 0.1$. This assumption is supported by measured gas-
348 phase concentrations of ISOPOOH at the T3 site, which dropped by 90% when NO_y
349 concentrations increased from 0.5 ppb to 2 ppb (Liu et al., 2016). This observation and the
350 associated model assumption are a reflection of the lifetimes of the chemical species discussed:
351 in contrast to the abovementioned lifetimes on order of a week for organic particle material
352 against loss processes, the lifetimes of the gaseous species are significantly shorter. Isoprene and
353 ISOPOOH have a lifetime on the order of a few hours (Eddingsaas et al., 2010; St. Clair et al.,
354 2015), and IEPOX has a lifetime of a few hours to a day for an OH concentration of 10^6
355 molecules cm⁻³ (Jacobs et al., 2013; Bates et al., 2014).

List of Supplementary Figures

Figure S1. Profile of the IEPOX-SOA factor resolved by PMF analysis of the time series of AMS organic mass spectra collected in the wet season of 2014 (IOP1) at the T3 site (red), and in the wet season of 2008 (green) as part of AMAZE-08 experiment at the T0t site (Chen et al., 2015). Also plotted is the mass spectrum of secondary organic material produced in the Harvard Environmental Chamber from β -IEPOX photooxidation onto acidic ammonium sulfate seed particles under HO_2 -dominant conditions and $\text{RH} < 5\%$ (blue) (Liu et al., 2015). Pearson correlation coefficients R between the PMF factor of this study and the other spectra were: $R = 0.99$ for the AMAZE-08 PMF factor, $R = 0.81$ for the chamber spectrum with all ions included, and $R = 0.95$ for the chamber spectrum with m/z 44 and 28 excluded.

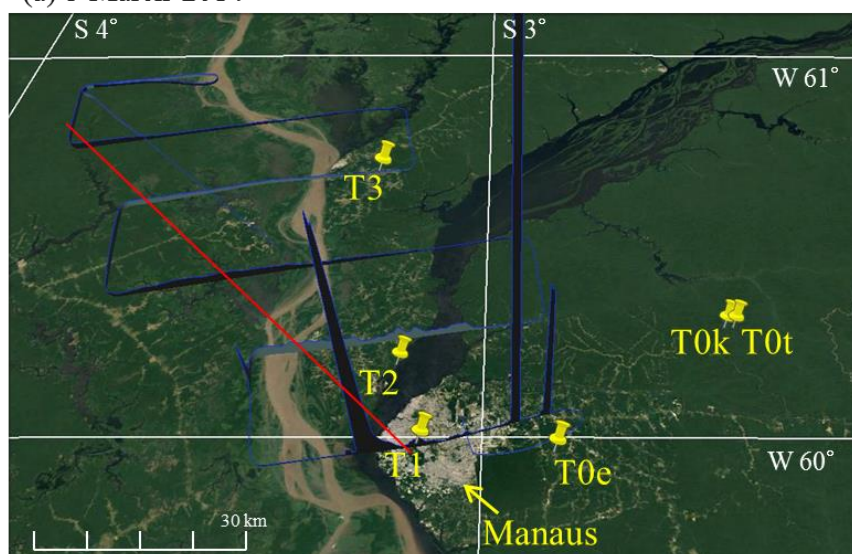

Figure S2. (a) Time series of total ion residuals of PMF solutions from one to six factors, (b) Dependence of the quality-of-fit parameter $Q/Q_{expected}$ on the number of factors for $f_{peak} = 0$, (c) Dependence of the quality-of-fit parameter $Q/Q_{expected}$ on f_{peak} for number of factors = 6. The red line represents $Q/Q_{expected}$ that exceeds in 0.1% the minimum value at $f_{peak} = 0$. This limit determines the range of plausible f_{peak} values as indicated by the dashed black lines, (d) For the six-factor solution, dependence on the f_{peak} parameter of the Pearson correlation coefficient R between the IEPOX-SOA factor loadings and independently measured C_5 -alkene triols (on the right vertical axis), the mean f ratio of IEPOX-SOA factor loading to total organic PM mass concentration, and the relative intensities $f(CO_2)$ and $f(C_5H_6O)$ of the ions CO_2^+ and $C_5H_6O^+$, respectively (on the left vertical axis).

(a) 3 March 2014

(b) 13 March 2014

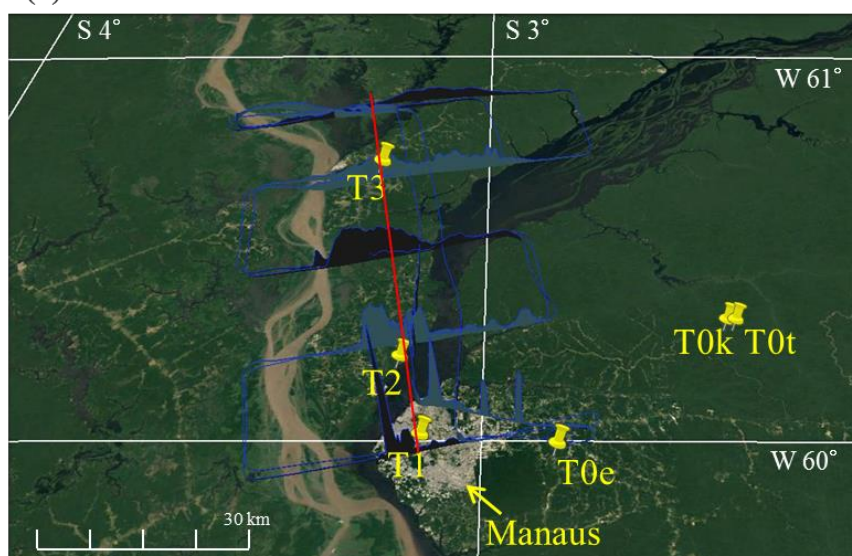

Figure S3. Visualization of the Manaus pollution plume for (a) March 3, 2014, 17:45 – 19:26 UTC, and (b) March 13, 2014, 14:14 – 17:21 UTC. The direction and extent of the plume observed within the boundary layer in the Manaus environs by the G-1 aircraft is represented by plotting NO_y concentrations on a vertical axis (0.13 to 369 ppb on March 3 and 0.10 to 75 ppb on March 13). The red lines guide the eye through the central axis of the plume. An image of land cover is in the horizontal plane. Yellow pins indicate the locations of some of the GoAmazon2014/5 research sites, including T3 (Martin et al., 2016b).

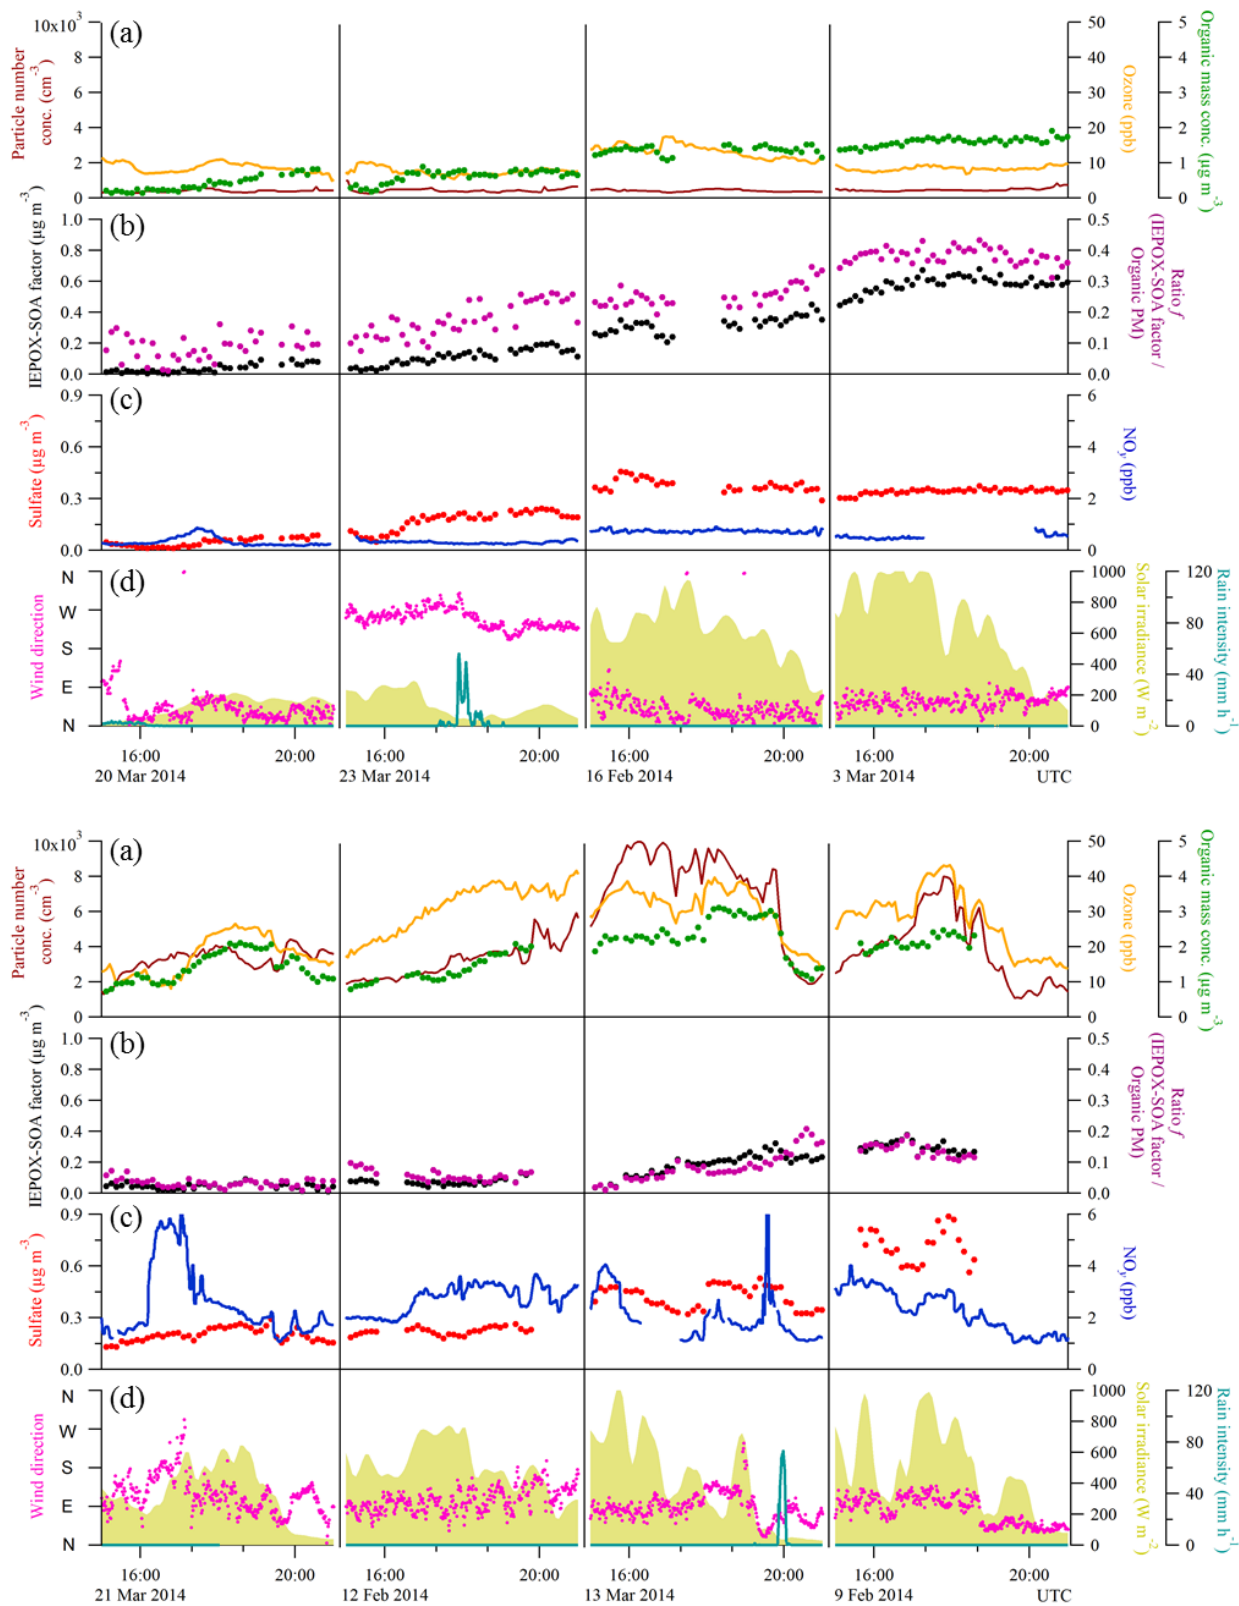

Figure S4. Selected cases of data sets collected during background and polluted conditions (top and bottom panels, respectively) as observed during afternoons at the T3 site.

Figure S5. Scatter plots of sulfate mass concentration and IEPOX-SOA factor loading for local afternoon (12:00-16:00 local time; 16:00-20:00 UTC) for five different ranges of NO_y concentrations. Panels a-e correspond to groups labeled 1-5 according to Table 1. Table 1 presents the parameters of the six least-squares linear fits represented by the lines in the figure. Data is colored by date.

Figure S6. Scatter plot of AMS PM volume concentrations and SMPS PM volume concentrations. SMPS1 measured particles having mobility diameters of 10 to 461 nm from February 7 to March 28, 2014. SMPS2 measured particles having mobility diameters of 10 to 510 nm from February 24 to March 30. Material densities used in the calculation of AMS volume from AMS mass were based on a mixing rule for the five AMS-measured species. The material density of the organic component was calculated following the method of Kuwata et al. (2011) based on O:C and H:C values, which in turn were calculated following the method of Canagaratna et al. (2015).

Figure S7. Ion balance for AMS measured species. A scatter plot is shown of mass concentrations of cations on the ordinate and of anions on the abscissa. Solid gray lines indicate relationships of 1:1 and 0.5:1.

Figure S8. Scatter plot of estimated pH and IEPOX-SOA factor loading for local afternoon (12:00-16:00 local time; 16:00-20:00 UTC). The data sets were collected into five subsets, colored and labeled 1 to 5, based on NO_y concentration (analogous to analysis shown in Figure 6a).

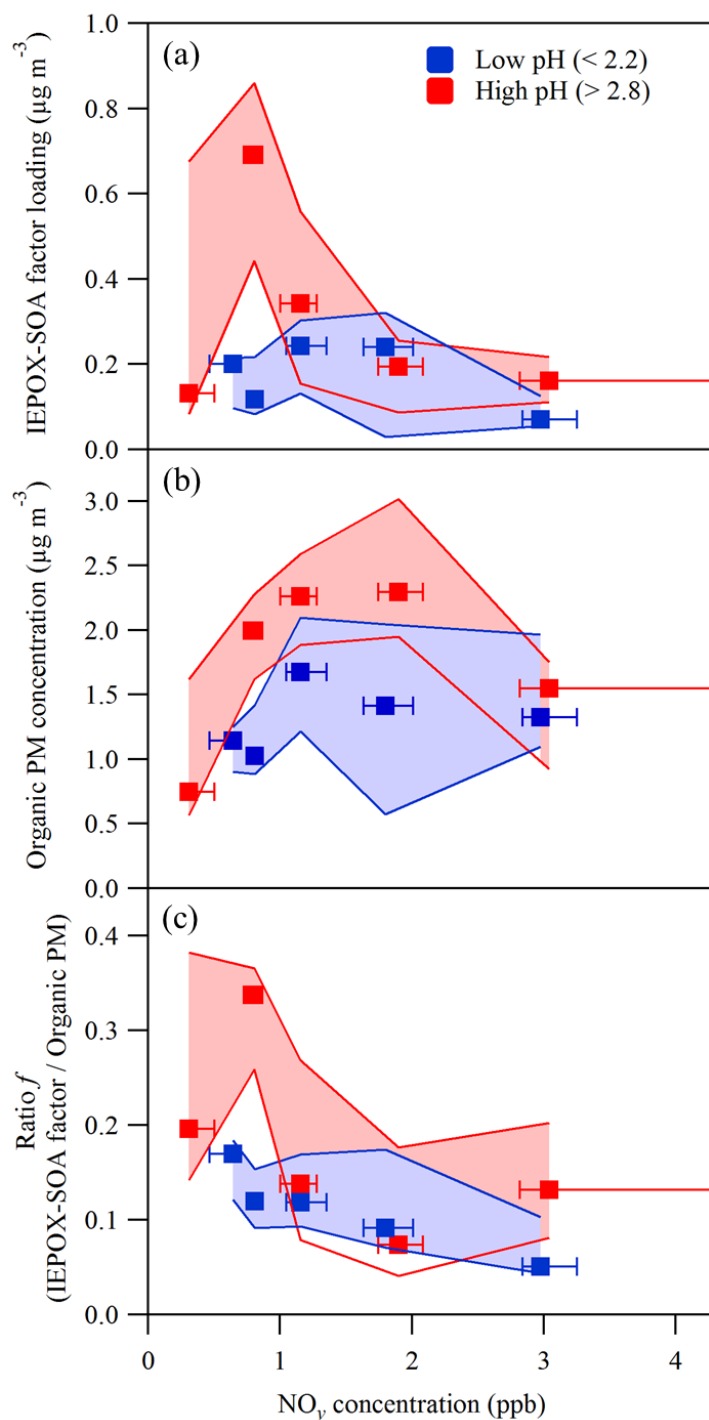

Figure S9. Dependence on NO_y concentration of (a) IEPOX-SOA factor loading, (b) organic mass concentration, and (c) the ratio f of the IEPOX-SOA factor loading to the organic PM concentration. Data are segregated by low (< 2.2) and high (> 2.8) pH and grouped into five levels of NO_y concentration (Figure 7). Squares represent medians of each group. Interquartile ranges are represented by whiskers along the abscissa and shading along the ordinate. The plotted data sets were recorded during local afternoon (12:00-16:00 local time; 16:00-20:00 UTC).
