18 **Abstract**

19       The source attributions for mass concentration, haze formation, transport, and  
20 direct radiative forcing of black carbon (BC) in various regions of China are quantified  
21 in this study using the Community Earth System Model (CESM) with a source-tagging  
22 technique. Anthropogenic emissions are from the Community Emissions Data System  
23 that is newly developed for the Coupled Model Intercomparison Project Phase 6  
24 (CMIP6). Over North China where the air quality is often poor, about 90% of  
25 near-surface BC concentration is contributed by local emissions. 35% of BC  
26 concentration over South China in winter can be attributed to emissions from North  
27 China and 19% comes from sources outside China in spring. For other regions in  
28 China, BC is largely contributed from non-local sources. We further investigated  
29 potential factors that contribute to the poor air quality in China. During polluted days, a  
30 net inflow of BC transported from non-local source regions associated with  
31 anomalous winds plays an important role in increasing local BC concentrations.  
32 BC-containing particles emitted from East Asia can also be transported across the  
33 Pacific. Our model results show that emissions from inside and outside China are  
34 equally important for the BC outflow from East Asia, while emissions from China  
35 account for 8% of BC concentration and 29% in column burden in western United  
36 States in spring. Radiative forcing estimated shows that 65% of the annual mean BC  
37 direct radiative forcing ( $2.2 \text{ W m}^{-2}$ ) in China results from local emissions, and the  
38 remaining 35% are contributed by emissions outside of China. Efficiency analysis  
39 shows that reduction in BC emissions over eastern China could benefit more on the  
40 regional air quality in China, especially in winter haze season.

## 41 **1. Introduction**

42 Black carbon (BC), as a component of atmospheric fine particulate matter  
43 ( $PM_{2.5}$ ), is harmful to human health (Anenberg et al., 2011; Janssen et al., 2012). In  
44 addition to its impact on air quality, as the most efficient light-absorbing  
45 anthropogenic aerosols, BC is thought to exert a substantial influence on climate  
46 (Bond et al., 2013; IPCC, 2013; Liao et al., 2015). It can heat the atmosphere through  
47 absorbing solar radiation (Ramanathan and Carmichael, 2008), influence cloud  
48 microphysical and dynamical processes (Jacobson, 2006; McFarquhar and Wang,  
49 2006), and reduce surface albedo through deposition on snow and ice (Flanner et al.,  
50 2007; Qian et al., 2015).

51 Due to accelerated urbanization and rapid economic growth, emissions of BC in  
52 China increased dramatically during recent decades. It contributed to about one  
53 fourth of the global emissions of BC in recent decades (Bond et al., 2007). Strong  
54 emissions lead to high concentrations of BC over China. Zhang et al. (2008) collected  
55 aerosol samples at eighteen stations spread over China during 2006 and reported BC  
56 concentrations in a range of 9–14  $\mu\text{g m}^{-3}$  at urban sites, 2–5  $\mu\text{g m}^{-3}$  at rural sites, and  
57 about 0.35  $\mu\text{g m}^{-3}$  at remote background sites. BC also exerts significant positive  
58 direct radiative forcing (DRF) at the top of the atmosphere (TOA) in China. Using the  
59 Regional Climate Chemistry Modeling System (RegCCMs), Zhuang et al. (2013)  
60 reported an annual mean BC DRF of 2–5  $\text{W m}^{-2}$  at TOA over eastern China and  
61 about 6  $\text{W m}^{-2}$  over Sichuan Basin in year 2006. Li et al. (2016) also showed a strong  
62 DRF of BC over the North China Plain and Sichuan Basin in most seasons except for  
63 spring when the strongest BC DRF with values of 4–6  $\text{W m}^{-2}$  shifted to southern  
64 China.

65 BC is the product of incomplete combustion of fossil fuels, biofuels, and open  
66 burning, such as forest and grassland fires and agricultural waste burning on fields. In  
67 the atmosphere the average lifetime of BC is only a few days, due to both wet  
68 removal and dry deposition, which is much shorter than that of long-lived greenhouse  
69 gases. In addition, BC lifetime is region dependent. BC in East Asia has a shorter  
70 lifetime than the global mean value due to a faster regional removal (H. Wang et al.,

71 2014), probably associated with strong precipitation during monsoon season. BC  
72 emission reductions may benefit both mitigation of global climate change and  
73 regional air quality (Shindell et al., 2012; Bond et al., 2013; Smith and Mizrahi, 2013),  
74 especially in East Asia where fuel combustion emits substantial BC along with other  
75 pollutant species. Many previous observational and/or modeling studies have  
76 examined the source sector contributions of BC over China (Zhuang et al., 2014;  
77 Y.-L. Zhang et al., 2015; Li et al., 2016). They found that residential heating and  
78 industry sectors were the largest contributors to BC concentrations in China, while  
79 biomass burning emissions from outside China were important to BC in western  
80 China. An effective BC reduction in a receptor region would require knowing not only  
81 the source sector that contributes the most to BC levels, but also the source  
82 contributions from various locations within and outside the region. However, very few  
83 previous studies have focused on the source attribution of BC concentrations in  
84 various regions of China. Li et al. (2016) examined the contributions of emissions  
85 inside and outside China to BC over China (with only two source regions) but did not  
86 divide the source contributions from different regions inside China.

87 Pollution levels also show substantial daily to weekly variation. In recent years,  
88 extreme wintertime hazy conditions occurred frequently in China and caused serious  
89 air pollution, affecting more than half of the 1.3 billion people (Ding and Liu, 2014).  
90 During one winter haze episode in 2013, BC concentrations increased up to about 20  
91 and  $8 \mu\text{g m}^{-3}$  in Xi'an and Beijing over northern China, and 6 and  $4 \mu\text{g m}^{-3}$  in  
92 Guangzhou and Shanghai over southern China, respectively (Y.-L. Zhang et al.,  
93 2015). The transport of pollutants from upwind was reported to be one of the most  
94 important contributors to local high aerosol concentrations during haze days (L. T.  
95 Wang et al., 2014; Y. Yang et al., 2016). L. T. Wang et al. (2014) found that emissions  
96 from northern Hebei and Beijing-Tianjin were the major contributor to particulate  
97 matter ( $\text{PM}_{2.5}$ ) pollution in Shijiazhuang in January 2013. Yang et al. (2016) confirmed  
98 a connection between wind fields and  $\text{PM}_{2.5}$  concentrations during winter hazy days  
99 through model simulations and statistical analysis. They also found that weakened  
100 winds contributed to increases in winter aerosol concentrations and hazy days over

101 eastern China during recent decades. As a chemically inert species, atmospheric BC  
102 is a good tracer to investigate the source region contributions from local and non-local  
103 emissions during polluted conditions that are related to long-range transport.

104 BC particles originating from East Asia can also be transported across the North  
105 Pacific, reaching North America (Hadley et al., 2007; Ma et al., 2013a; Matsui et al.,  
106 2013; H. Wang et al., 2014; Yang et al., 2015). Matsui et al. (2013) simulated outflow  
107 of BC from East Asia using the Community Multiscale Air Quality (CMAQ) model and  
108 found that anthropogenic emissions from China, biomass burning emissions from  
109 Southeast Asia, and biomass burning emissions from Siberia and Kazakhstan  
110 contributed 61%, 17%, and 6%, respectively, to the eastward BC flux at 150°E  
111 averaged over 2008–2010. Hadley et al. (2007) estimated the trans-Pacific transport  
112 of BC during April of 2004 using the Chemical Weather Forecast System (CFORS)  
113 model and reported that, across 130°W, 75% of BC transported into North America  
114 originated from Asia. Huang et al. (2012) simulated BC using the Sulfur Transport  
115 and Deposition Model (STEM), and found emissions outside North America  
116 contributed to 30–80% of column BC over North America in summer 2008. H. Wang  
117 et al. (2014) examined the long-term (1995–2005) average global source-receptor  
118 relationship of BC and found that BC emitted from the entire East Asia only contribute  
119 less than 5% to the total BC burden in North America, although the contribution is up  
120 to 40% near the west coast region. Few studies have examined the outflow from East  
121 Asia and inflow into North America contributed from source regions in and outside  
122 China. In addition, the emissions of BC from China increased dramatically during the  
123 last few years, with the annual total anthropogenic emissions estimated to have  
124 almost doubled in year 2014 compared to year 2000, shown in the newly developed  
125 Community Emissions Data System (CEDS; Hoesly et al. 2017). Therefore, the  
126 long-range transport of BC and source-receptor relationships could be quite different  
127 from previous studies.

128 Due to its warming effect in the climate system, BC is potentially important for  
129 climate mitigation and has drawn much attention recently. Source attribution of the  
130 direct radiative effect of BC is likely to be different from that of near-surface

131 concentration and column burden due to the dependence of radiative forcing on the  
132 vertical distribution of BC and its mixing state with other species that are influenced  
133 by different regional sources. In this study, we use the Community Earth System  
134 Model (CESM) with improved representations of aerosol transport and wet removal (H.  
135 Wang et al., 2013) and a BC source-tagging technique (H. Wang et al., 2014).  
136 Anthropogenic emissions from the newly developed CEDS inventory (Hoesly et al.,  
137 2017), as released for the Coupled Model Intercomparison Project Phase 6 (CMIP6),  
138 are used to examine the source attributions for mass concentration, long-range  
139 transport, and direct radiative forcing of BC in various regions of China. We aim to  
140 quantify: (1) source region contributions to concentrations of BC over various receptor  
141 regions in China; (2) contributions to changes in BC concentrations under polluted  
142 conditions; (3) source contributions to trans-boundary and trans-Pacific transport of  
143 BC; and (4) source contributions to direct radiative forcing of BC in China.

144 The CESM model, emissions, and numerical experiment are described in  
145 Section 2. Section 3 provides evaluation of the simulated concentration and aerosol  
146 absorption optical depth of BC in China. Section 4 investigates source contributions  
147 to near-surface concentrations, long-range transport and direct radiative forcing of BC  
148 over various receptor regions using the BC source-tagging technique in CESM.  
149 Section 5 summarizes these results.

150

## 151 **2. Methods**

152 We simulate the evolution and direct radiative forcing (DRF) of BC using CESM  
153 version 1.2 (Hurrell et al., 2013). The atmospheric model in CESM is version 5 of the  
154 Community Atmosphere Model (CAM5), with horizontal grid spacing of 1.9° latitude  
155 by 2.5° longitude and 30 vertical layers ranging from the surface to 3.6 hPa used in  
156 this study. The model treats the properties and processes of major aerosol species  
157 (sea salt, mineral dust, sulfate, black carbon, primary organic matter and secondary  
158 organic aerosol) using a three-mode modal aerosol module (MAM3), in which aerosol  
159 size distributions are represented by three lognormal modes: Aitken, accumulation,  
160 and coarse modes. BC is emitted to the accumulation mode. Mass mixing ratios of

161 different aerosol species and the number mixing ratio are predicted for each mode. A  
162 more detailed description of the MAM3 representation can be found in Liu et al.  
163 (2012). Aerosol dry deposition velocities are calculated using the Zhang et al. (2001)  
164 parameterization. The wet deposition of aerosols in our CAM5 model includes  
165 in-cloud wet removal (i.e., activation of interstitial aerosols to cloud-borne particles  
166 followed by precipitation scavenging) and below-cloud wet removal (i.e., capture of  
167 interstitial aerosol particles by falling precipitation particles) for both stratiform and  
168 convective clouds. Aerosol activation is calculated with the parameterization of  
169 Abdul-Razzak and Ghan (2000) for stratiform cloud throughout the column and  
170 convective cloud at cloud base, while the secondary activation above convective  
171 cloud base has a simpler treatment with an assumed maximum supersaturation in  
172 convective updrafts (H. Wang et al., 2013). The unified treatment for convective  
173 transport and aerosol wet removal along with the explicit aerosol activation above  
174 convective cloud base was developed by H. Wang et al. (2013) and included in the  
175 CAM5 version being used in this study. This implementation reduces the excessive  
176 BC aloft and better simulates observed BC concentrations in the mid- to  
177 upper-troposphere. Aerosol optical properties for each mode are parameterized  
178 according to Ghan and Zaveri (2007). Refractive indices for aerosols are taken from  
179 the OPAC (optical properties for aerosols and clouds) software package (Koepke and  
180 Schult, 1998), but for BC at solar wavelengths the values are updated from Bond and  
181 Bergstrom (2006). In MAM3, the aging process of BC is neglected by assuming the  
182 immediate mixing of BC with other aerosol species. Direct radiative forcing of BC is  
183 calculated as the difference in the top-of-the-atmosphere net radiative fluxes with and  
184 without BC for the all-sky condition following Ghan (2013).

185 Anthropogenic emissions used in this study are from the CEDS dataset, as  
186 released for the CMIP6 model experiments (Hoesly et al. 2017). This newly released  
187 emission inventory includes aerosol (black carbon, organic carbon) and aerosol  
188 precursor and reactive compounds (sulfur dioxide, nitrogen oxides, ammonia, carbon  
189 monoxide, and non-methane volatile organic compounds). The emissions are  
190 provided at monthly resolution for each year of 1750–2014 on a  $0.5^\circ \times 0.5^\circ$  grid and

191 include agricultural, energy, industry, residential, international shipping, solvents,  
192 surface transportation, waste treatment, and aircraft sectors. The biomass burning  
193 emissions used in this study are also developed for CMIP6 based on Global Fire  
194 Emission Database (GFED) version 4, Fire Model Intercomparison Project (FireMIP),  
195 visibility-observations and Global Charcoal Database (GCD) data (van Marle et al.  
196 2016).

197 Figure 1a shows the horizontal spatial distribution of annual emissions of BC  
198 averaged over the most recent 5 years (2010–2014) and the seven geographical  
199 source regions tagged in continental China, including North China (NC), South China  
200 (SC), Southwest China (SW), Central-West China (CW), Northeast China (NE),  
201 Northwest China (NW), and Tibetan Plateau (TP). Figure 1b summarizes the total  
202 seasonal BC emissions in each of these source regions. North China has the largest  
203 annual emissions of BC in China, with maximum emission larger than  $1.2 \text{ g C m}^{-2}$   
204  $\text{year}^{-1}$  and a regional total emission of  $1089 \text{ Gg C year}^{-1}$  (44% of total emissions from  
205 continental China). Annual emissions of BC also have large values over South and  
206 Southwest China, with maximum values in the range of  $0.8\text{--}1.2 \text{ g C m}^{-2} \text{ year}^{-1}$ ,  
207 followed by Central-West and Northeast China. Over the less economically developed  
208 Northwest China and remote region Tibetan Plateau, emissions of BC are much  
209 lower than other regions in China. The seasonal mean emissions of BC also show the  
210 same spatial pattern as the annual means. BC had the largest emissions over North,  
211 South, and Southwest China in all seasons, among which emissions are strongest in  
212 December-January-February (DJF), especially over North China, resulting from  
213 domestic heating. The total seasonal emissions of BC in continental China are 797,  
214 586, 537, and 577 Gg C in DJF, March-April-May (MAM), June-July-August (JJA),  
215 and September-October-November (SON), respectively, which add up to a total  
216 annual BC emissions of 2497 Gg C averaged over years 2010–2014. The  
217 anthropogenic emissions of BC in China in 2010–2014 are larger than those used in  
218 the previous studies for earlier years (Table S1), partly as a result of a higher estimate  
219 of BC emissions from coal coking production. The higher emissions likely lead to  
220 higher concentrations and direct radiative forcing, and source contributions of BC in

221 China, compared to the values reported in these studies. The DJF emissions account  
222 for 26–35% of annual total whereas emissions in JJA only account for 17–24% over  
223 the seven source regions in continental China. Total BC emissions from neighboring  
224 regions including rest of East Asia (REA, with China excluded), South Asia (SAS),  
225 Southeast Asia (SEA), and Russia/Belarus/Ukraine (RBU) are shown in Figure 1c.  
226 These source regions outside China are consistent with source regions defined in the  
227 second phase of Hemispheric Transport of Air Pollution (HTAP2). South Asia and  
228 Southeast Asia have relatively high emissions. They may dominate the contribution to  
229 concentrations and direct radiative forcing of BC in China, especially southern and  
230 western China, from foreign sources through long-range transport.

231 An explicit BC source tagging capability was originally implemented in CAM5 by H.  
232 Wang et al. (2014), through which emissions of BC from independent source regions  
233 and/or sectors can be explicitly tracked. This method quantifies the source–receptor  
234 relationships of BC in any receptor region within a single model simulation without  
235 perturbing emissions from individual source regions or sectors. R. Zhang et al.  
236 (2015a,b) used this method to quantify the source attributions of BC in western North  
237 America, Himalayas, and Tibetan Plateau. The same BC source tagging technique is  
238 implemented to a newer model version (CAM5.3) and applied in this study to quantify  
239 the source attributions of concentration, transport and direct radiative forcing of BC in  
240 various regions of China. BC emissions (anthropogenic plus biomass burning) from  
241 seven geographical source regions, including North China, South China, Southwest  
242 China, Central-West China, Northeast China, Northwest China, Tibetan Plateau in  
243 China, and from rest of the world (RW) are tagged. Transport and physics tendencies  
244 are calculated separately for each tagged BC in the same way as the original BC  
245 simulation in CESM. We choose the seven individual regions (North China, South  
246 China, Southwest China, Central-West China, Northeast China, Northwest China, and  
247 Tibetan Plateau) and all seven regions combined (hereafter continental China) as  
248 receptor regions in this study to examine the source-receptor relationships of BC.  
249 While all emissions, including sulfur dioxides, organic carbon and BC, were used in  
250 the model simulation, tagging was only applied to BC emissions.

251 The CAM5 simulation is performed at  $1.9^\circ \times 2.5^\circ$  horizontal grid spacing using the  
252 specified-dynamics mode (Ma et al., 2013b), in which large-scale circulations (i.e.,  
253 horizontal winds) are nudged to 6-hourly reanalysis data from the Modern Era  
254 Retrospective-Analysis for Research and Applications (MERRA) reanalysis data set  
255 (Rienecker et al., 2011) with a relaxation time scale of 6 hours (K. Zhang et al., 2014).  
256 The use of nudged winds allows for a more accurate simulation so that the key role of  
257 large-scale circulation patterns matches observations over the specified years. The  
258 simulation is run from year 2009 to 2014, with both time-varying aerosol emissions  
259 and meteorological fields. The first year is for spin-up and the last five years are used  
260 for analysis.

261

### 262 **3. Model evaluation**

263 The simulations of aerosols, especially BC, using CAM5 have been extensively  
264 evaluated against observations including aerosol mass and number concentrations,  
265 vertical profiles, aerosol optical properties, aerosol deposition, and cloud-nucleating  
266 properties in several previous studies (e.g., Liu et al., 2012, 2016; H. Wang et al.,  
267 2013; Ma et al., 2013b; Jiao et al., 2014; Qian et al., 2014; R. Zhang et al., 2015a,b).  
268 Here we focus on the evaluation of model performance in China using measurements  
269 of near-surface BC concentrations, vertical profiles, aerosol index derived from  
270 satellite, and aerosol absorption optical depth from the Aerosol Robotic Network  
271 (AERONET).

#### 272 **3.1 Mass concentrations and column burden of BC**

273 Figure 2 presents spatial distributions of simulated seasonal mean near-surface  
274 concentrations and column burden of BC, both of which show a similar spatial pattern  
275 to emissions of BC (Figure 1a) with the largest values over North China and the lowest  
276 values over Northwest China and Tibetan Plateau. Near-surface model results are  
277 taken to be the lowest model layer (from surface to 985 hPa in average). Among all  
278 seasons, DJF has the highest BC levels, with values in the range of 6–12, 2–8, and 1–  
279  $8 \mu\text{g m}^{-3}$  for near-surface concentrations and 6–12, 2–8, 1–12  $\text{mg m}^{-2}$  for column  
280 burden over North, South, and Southwest China, respectively. In contrast, JJA has

281 the lowest BC concentrations over China due to the lower emissions and larger wet  
282 scavenging associated with East Asian summer monsoon (Lou et al., 2016).  
283 Averaged over continental China, near-surface BC concentrations are 2.5, 1.1, 0.8,  
284 and 1.4  $\mu\text{g m}^{-3}$  in DJF, MAM, JJA, and SON, respectively, with seasonal variability of  
285 50%. The column burden of BC shows smaller seasonal variability (40%), with  
286 area-weighted average of 2.5, 1.4, 1.0, and 1.4  $\text{mg m}^{-2}$  in DJF, MAM, JJA, and SON,  
287 respectively, in China. The magnitude, spatial distribution, and seasonal variations of  
288 simulated near-surface BC concentrations over China are similar to those in Fu et al.  
289 (2012) and X. Wang et al. (2013) using Intercontinental Chemical Transport  
290 Experiment-Phase B (INTEX-B) emission inventory (Zhang et al., 2009) and those in  
291 Li et al. (2016) using HTAP emission inventory (Janssens-Maenhout et al., 2015)  
292 together with a global chemical transport model.

293 The simulated near-surface BC concentrations are evaluated here using  
294 measurements at fourteen sites of the China Meteorological Administration  
295 Atmosphere Watch Network (CAWNET) (Zhang et al., 2012). The locations of  
296 CAWNET sites are shown in Figure S1a. The observational data include monthly BC  
297 concentrations in years 2006–2007. Note that the simulated BC concentrations are  
298 for years 2010–2014. Figure 3a compares the simulated seasonal mean near-surface  
299 BC concentrations with those from CAWNET observations and Table S2 summarizes  
300 the comparison in different regions, using modeled values from the grid cell  
301 containing each observational site. Simulated BC concentrations at most sites are  
302 within the range of one third to three times of observed values, except for Dunhuang  
303 (94.68°E, 40.15°N) and Lhasa (91.13°E, 29.67°N) sites over western China, where  
304 BC concentrations appear to be underestimated in the model (up to 20 times lower).  
305 The possible bias is discussed in the following part. Over North China, simulated  
306 concentrations are similar to observations in DJF, but underestimated in other  
307 seasons. Over South China, the simulations do not have large biases compared to  
308 the observed BC. However, simulated BC is underestimated in all seasons over  
309 Southwest, Central-West, Northeast, Northwest China, and Tibetan Plateau.  
310 Compared to the CAWNET data, the modeled near-surface BC concentrations have

311 a normalized mean bias (NMB) of  $-48\%$ . Note that anthropogenic BC emissions went  
312 up by a factor of 1.18 between 2006–2007 and 2010–2014. An emissions adjusted  
313 comparison would result in an even larger underestimation. There are several  
314 reasons that might cause low bias in this comparison. Liu et al. (2012) and H. Wang  
315 et al. (2013) have previously found underestimation of BC concentrations over China  
316 in CAM5 model and suggested the BC emissions may be significantly  
317 underestimated. Using the global chemical transport model GEOS-Chem together  
318 with emissions in 2006, Fu et al. (2012) found the simulated BC concentrations in  
319 China were underestimated by 56%. With HTAP emissions at the year 2010 level, Li  
320 et al. (2016) showed a low bias of 37% in simulated BC concentration in China.  
321 Larger wet removal rate and shorter lifetime of aerosols along with the instantaneous  
322 aging of BC in the MAM3 can also lead to the lower concentrations of BC (e.g., Wang  
323 et al., 2011; Liu et al., 2012; H. Wang et al., 2013; Kristiansen et al., 2016).

324 Another potential cause for a bias in this comparison is spatial sampling bias.  
325 Half of the CAWNET sites are located in urban areas, which will tend to have high  
326 values near sources, whereas the modeled values represent averages over large grid  
327 cells (R. Wang et al., 2014), as further discussed below.

328 The model captures well the spatial distribution and seasonal variation of BC  
329 concentrations in China, having a statistically significant correlation coefficient of  
330  $+0.56$  between simulated and observed seasonal BC concentrations over CAWNET  
331 sites.

332 Figure S2 compares the observed and simulated vertical profiles of BC  
333 concentrations in the East-Asian outflow region. The model successfully reproduces  
334 the vertical profile of BC that was measured in March–April 2009 during the  
335 A-FORCE field campaign and reported by Oshima et al. (2012).

### 336 **3.2 Aerosol absorption optical depth of BC**

337 To evaluate the simulated aerosol absorption optical depth (AAOD) of BC, the  
338 AAOD data from AERONET (Holben et al., 2001) are used here. The locations of  
339 AERONET sites in China are shown in Figure S1b. The observed AAOD are averaged  
340 over years of 2010–2014 over seven sites and 2005–2010 over three sites with data

341 available. Most AERONET sites are over eastern and central China. AAOD of BC at  
342 550nm are calculated by interpolating AAOD at 440 and 675 nm and removing AAOD  
343 of dust from the retrieved AERONET AAOD following Bond et al. (2013). Figure 3b  
344 compares the observed and simulated seasonal mean AAOD of BC at 550nm and  
345 Table S3 summarizes the comparisons in different regions. The model has a low bias  
346 in simulating AAOD of BC in China, smaller than the bias in near-surface  
347 concentrations, with a NMB of  $-6\%$ . As is the case with surface concentrations, this  
348 bias could be due to model issues, such as BC transport or optical parameterization;  
349 an underestimate in emissions; or spatial sampling bias. Simulated AAOD of BC are  
350 within the range of one third to three times of observed values at most sites, with the  
351 spatial distribution and seasonal variation broadly captured by the model. All but one  
352 of the observations are located in the North and South China regions, and simulated  
353 BC AAOD are, on average, similar to observations there. The AAOD from one  
354 observation site in Central-West China is higher than the modeled value in DJF and  
355 lower in other seasons. Note that, the observed AAOD of BC is derived from  
356 AERONET measurements using the absorption Ångström exponent. A recent study  
357 (Schuster et al., 2016) reported that absorption Ångström exponent is not a robust  
358 parameter for separating out carbonaceous absorption in the AERONET database,  
359 which could cause biases in the AAOD estimates.

360 Figure 4 shows the spatial distribution of simulated seasonal mean AAOD of total  
361 aerosols and Aerosol Index (AI) derived from Ozone Monitoring Instrument (OMI)  
362 measurements over years of 2010–2014. AI is a measure of absorbing aerosols  
363 including BC and dust. Compared to satellite AI data, the model roughly reproduces  
364 spatial distribution of total AAOD in China, with large values over North, South, and  
365 Southwest China in all seasons. AI derived from Total Ozone Mapping Spectrometer  
366 (TOMS) measurements (Figure S3) also shows similar pattern as simulated AAOD. It  
367 should be noted that, besides BC, dust particles also largely contribute to AI and  
368 produces large AI values over Northwest China.

369 To examine the potential model bias more broadly we compared the difference of  
370 AAOD and AI between western and eastern China (Fig. 4). Averaging AI and AAOD

371 broadly over eastern and western China, we find that AAOD/AI is 0.055 over eastern  
372 China and 0.027 over western China. If we assume that the simulated AAOD do not  
373 have large biases over eastern China based on the evaluation against observations  
374 shown above (Fig. 3b and Table S3), then this difference hints a possible  
375 underestimation of BC column burden in the model over the western regions.  
376 However, it is difficult to draw a firm conclusion, given the likely differential role of dust  
377 in eastern vs western China. This differential likely also contributes to AAOD biases in  
378 modeling dust and may also impact biases in the satellite derived AI values.

379

#### 380 **4. Source contributions to BC concentrations, transport and direct radiative** 381 **forcing**

##### 382 **4.1. Source contributions to seasonal mean BC concentrations**

383 Figure 5 shows the simulated spatial distribution of seasonal near-surface BC  
384 concentrations originating from the seven tagged source regions in continental China  
385 and all other sources from outside China (rest of the world, RW) and Table S4  
386 summarizes these source-receptor relationships. It is not surprising that regional  
387 emissions largely influence BC concentrations in the same region. For example,  
388 emissions of BC from North China give  $6.3 \mu\text{g m}^{-3}$  of BC concentrations over North  
389 China in DJF, whereas they only account for less than  $1.8 \mu\text{g m}^{-3}$  over other regions  
390 in China. However, the relatively small amount of BC from upwind source regions can  
391 also be a large contributor to receptor regions near the strong sources. BC emissions  
392 from North China contribute large amount to concentrations over South, Southwest,  
393 Central-West, and Northeast China. BC emissions from South and Southwest China  
394 also produce a widespread impact on BC over other neighboring regions. The  
395 impacts of BC emitted from the remaining China regions are relatively small both in  
396 local and non-local regions due to weak emissions (Fig. 1b). All the sources in China  
397 have the largest impact in DJF, resulting from the strong BC emissions in winter,  
398 while emissions from outside China have the largest impact on BC over China in  
399 MAM due to the seasonal high emission over Southeast Asia and the strong  
400 springtime southwesterly winds.

401 Averaged over continental China, emissions of BC from North China produce  
402 mean BC concentrations of 0.4–1.3  $\mu\text{g m}^{-3}$ , followed by 0.2–0.5  $\mu\text{g m}^{-3}$  from South  
403 China and 0.1–0.3  $\mu\text{g m}^{-3}$  from Southwest China emissions. For emissions over  
404 Central-West China, Northeast China, Northwest China, and Tibetan Plateau, their  
405 individual impact is less than 0.2  $\mu\text{g m}^{-3}$ . In contrast, emissions from outside China  
406 result in 0.12  $\mu\text{g m}^{-3}$  of BC concentrations in China in MAM and less than 0.06  $\mu\text{g m}^{-3}$   
407 in JJA and son. The simulated source contributions to column burden of BC are  
408 shown in Figure S4. They present a very similar spatial distribution and seasonal  
409 variation to those of near-surface BC concentrations. However, the emissions from  
410 outside China have a larger impact on the average column burden of BC over China  
411 than on surface concentrations, with a magnitude of 0.4  $\text{mg m}^{-2}$  in MAM, which is  
412 similar to that from sources in North China.

413 Figure 6 shows the spatial distribution of simulated relative contributions to  
414 near-surface BC concentrations from sources in the seven regions in continental  
415 China and those outside China by season. (The same plots for BC column burden are  
416 shown in Figure S5.) For regions with higher emissions, their BC concentrations are  
417 dominated by local emissions. In contrast, BC levels, especially column burden of BC,  
418 over central and western China with lower emissions are strongly influenced by  
419 non-local sources. Emissions from outside China can be the largest contributor to BC  
420 over these regions. During DJF, MAM and SON, they contribute more than 70% to  
421 both surface concentrations and column burden of BC in Tibetan Plateau, which is  
422 important to the climate change due to the large climate efficacy of BC in snow (Qian  
423 et al., 2011) and acceleration of snowmelt through elevated BC heat pump  
424 mechanism (Lau et al., 2010). BC emissions from outside China also account for a  
425 quite significant fraction of surface concentrations over Northwest and Southwest  
426 China in MAM, which contribute to poor air quality over these regions.

427 Figure 7 summarizes source attribution for spatially averaged seasonal surface  
428 BC concentrations for the seven receptor regions and continental China combined  
429 (CN). Over North China, the majority of the BC concentrations are attributed to local  
430 emissions in all seasons, with seasonal fractional contributions of 85–94%. Over

431 South China, the seasonal contributions from local emissions are in the range of 58–  
432 88%. Emissions from North China account for 35% of BC concentrations over South  
433 China in DJF, resulting from the wintertime northwesterly winds (Figure S6a), while  
434 emissions from outside China contribute about 10% in MAM due to the strong  
435 springtime biomass burning over southeast Asia and southwesterly winds transporting  
436 BC from southeast Asia to South China (Figure S6b). Southwest China has a similar  
437 level of local influence, with 47–81% of the BC concentration from local emissions,  
438 whereas 19% are due to emissions from outside China transported by westerly winds  
439 in MAM.

440 Non-local emissions from Southwest and North China together contribute 32–44%  
441 of BC concentration in Central-West China. North China emissions play an important  
442 role in BC concentrations over Northeast China, with relative contributions in a range  
443 of 21–30% in MAM, JJA and SON, while only 11% in DJF, which is associated with  
444 northwesterly winds in winter preventing northward transport of BC from North China  
445 to Northeast China. Over Northwest China and Tibetan Plateau, 18–34% and 46–  
446 78%, respectively, of BC originate from emissions outside China due to the low  
447 emissions over the less economically developed western China. For all of continental  
448 China as the receptor, the seasonal BC concentrations are largely attributed to the  
449 emissions from North and South China, with relative contributions ranging from 44–  
450 53% and 18–22%, respectively, followed by contributions from Southwest China (10–  
451 12%) and outside China (5–11%).

452 The source region contributions to column burden of BC in each receptor regions  
453 in China are shown in Figure S7. In general, impacts on the non-local BC column  
454 burden are larger than on surface concentrations because aerosol transport is  
455 relatively easier in free-troposphere than in the boundary layer (e.g., Yang et al.,  
456 2015). Column burdens of BC averaged over continental China mainly originate from  
457 emissions in North China, South China and outside China, with relative contributions  
458 ranging from 35–46%, 14–21% and 12–30%, respectively.

459

## 460 **4.2. Source contributions during polluted days**

461 Knowing the source attribution of BC during polluted days in China is important for  
462 policy makers, which could provide an effective way for the mitigation of poor air  
463 quality. Here, the polluted days are simply identified as days with daily concentrations  
464 of BC higher than 90th percentile of probability density function in each receptor  
465 regions. A total of different 45 days in winter in the 5-year simulation are identified as  
466 polluted days for each region in China.

467 Figure 8 shows the DJF composite differences in near-surface BC concentrations  
468 and winds at 850 hPa between polluted and normal days for each receptor region, and  
469 Figure 9 summarizes the local and non-local source contributions to the differences.  
470 When North China is under the polluted condition, BC concentrations are higher by  
471 more than 70% compared to DJF average over North China, with a maximum increase  
472 exceeding  $5 \mu\text{g m}^{-3}$ . North China local emissions contribute  $5.6 \mu\text{g m}^{-3}$  to the  
473 averaged increase in BC concentrations over North China during North China  
474 polluted days, about 90% of the total increase. In winter, eastern China is dominated  
475 by strong northwesterly winds (Figure S6a). The anomalous southerly winds during  
476 polluted days (relative to DJF average) over North China prevent the high BC  
477 concentrations from being transported to South China, leading to a reduced ventilation  
478 and accumulated aerosols in North China.

479 Over South China, BC concentrations increase by up to  $2\text{--}5 \mu\text{g m}^{-3}$ , in part due to  
480 the transport from North China by anomalous northerly winds in the north part of  
481 South China in South China polluted days. On average, contribution of North China  
482 emissions to mean concentrations over South China increases by  $2.0 \mu\text{g m}^{-3}$  (60% of  
483 total increase) during the South China polluted days.

484 During polluted days in Southwest China, the anomalous northeasterly winds in  
485 the east part of Southwest China bring in BC from the highly polluted eastern China,  
486 resulting in  $2.1 \mu\text{g m}^{-3}$  increase (74% of total increase) in the Southwest China, which  
487 is much larger than the  $0.7 \mu\text{g m}^{-3}$  contribution from the Southwest China local  
488 emissions.

489 The increase in BC concentrations during polluted days over Central-West China  
490 is also largely influenced by the accumulation effect of the anomalous winds over

491 eastern and central China, which also transport BC from Southwest and eastern China  
492 into the receptor region.

493 The polluted days in Northeast China are caused by both the accumulation of local  
494 emissions due to the reduced prevailing northeasterly winds and anomalous transport  
495 of BC from North China.

496 Emissions from outside China could contribute to increases in BC concentrations  
497 over Northwest China and Tibetan Plateau during polluted days. However, during  
498 wintertime regional polluted days in eastern and central China, the contributions of  
499 emissions from outside China do not have a significant influence on the changes in  
500 BC concentrations.

501 These results suggest that the transport of aerosols plays an important role in  
502 increasing BC concentrations during regional polluted days in eastern and central  
503 China. Reductions in local emissions could benefit mitigation of both local and  
504 non-local haze in China. Emissions from outside China are not as important to hazy  
505 pollution in eastern and central China, where haze episodes occur frequently in winter  
506 due to relatively high anthropogenic aerosol emissions and abnormal meteorological  
507 conditions (Sun et al., 2014; R. H. Zhang et al., 2014; Yang et al., 2016). Note that, in  
508 this study, we only focus on the source-receptor relationships related to the wind  
509 anomalies during polluted days. In addition to winds, changes in other meteorological  
510 fields, such as precipitation, temperature, humidity, and planetary boundary layer  
511 height, could also influence the contributions of local aerosols between polluted and  
512 normal days. Although the BC emissions used in the simulation include a seasonal  
513 variability that could cause some variations in simulated concentrations, the monthly  
514 variability in DJF of BC emissions is less than 4% over China, which is negligible  
515 compared to the differences in concentrations between polluted and normal days.

516

#### 517 **4.3. Source contributions to trans-boundary and trans-Pacific transport**

518 Considering the large contributions of emissions from South and Southeast Asia  
519 to MAM BC concentrations in the southwest China (Figure 6) and the large outflow of  
520 aerosols from East Asia in springtime (Yu et al., 2008), it is valuable to examine the

521 inflow and outflow of BC in China. Figures S8a and S8b show the vertical distribution  
522 of source contributions of emissions from outside China to BC concentrations  
523 averaged over 75°–120°E and 25°–35°N, respectively, around the south boundary of  
524 continental China in MAM. High concentrations of BC originating from South and  
525 Southeast Asia are lifted to the free atmosphere in the south slope of Tibetan Plateau.  
526 Then westerly winds transport these BC particles to Southwest China and South  
527 China in both low- and mid-troposphere. Figures S8c and S8d present the  
528 contributions of emissions from China to BC concentrations averaged over 120°–  
529 135°E and 20°–50°N, respectively, around the east boundary of continental China. In  
530 MAM, the northward meridional winds over 25°–35°N and the southward meridional  
531 winds over 40°–50°N lead to the accumulation of BC in the lower atmosphere in  
532 eastern China. Westerly winds then transport these BC out of China mostly under 500  
533 hPa.

534 Figure 10 shows the spatial distribution of column burden and surface  
535 concentrations of BC resulting from emissions in and outside China in MAM. Column  
536 burden is used to represent the outflow in this study following previous studies (Chin et  
537 al., 2007; Hadley et al., 2007). There are strong outflows across the Pacific Ocean  
538 originating from emissions both in and outside China. Emissions from China contribute  
539  $0.20 \text{ mg m}^{-2}$  (or 55%) of MAM mean BC along 150°E averaged over 20°–60°N,  
540 whereas emissions outside China contribute  $0.16 \text{ mg m}^{-2}$  (or 45%). It suggests that  
541 both emissions from China and outside China are important for the outflow from East  
542 Asia. The yearly contribution from emissions from China to outflow from East Asia in  
543 this study is 59%, similar to the contribution of 61% in Matsui et al. (2013) calculated  
544 based on eastward BC mass flux using WRF-CMAQ model with INTEX-B missions.  
545 Averaged over western United States (125°–105°W, 30°–50°N), emissions from  
546 China account for 8% of near-surface BC concentrations and 29% in column burden in  
547 MAM, indicating that emissions from China could have a significant impact on air  
548 quality in western United States. More than half of the China contribution to BC over  
549 western United States originates from eastern China (i.e., the tagged North and South  
550 China).

551

#### 552 **4.4. Source contributions to direct radiative forcing**

553 The high concentrations of BC in China could also have a significant impact on the  
554 climate system through atmospheric heating or direct radiative forcing. As shown in  
555 Figure 11, the annual mean direct radiative forcing (DRF) of BC at TOA is as high as  
556 3–5 W m<sup>-2</sup> at some locations. Similar to the source attributions of BC concentrations  
557 (Figure 5) and burden (Figure S4), regional sources contribute the largest to DRF over  
558 the respective local regions. Among all the source regions in China, emissions from  
559 North, South, and Southwest China contribute the largest to local DRF of BC, with  
560 maximum DRF in a range of 3–5, 2–3, and 3–5 W m<sup>-2</sup>, respectively. Other sources  
561 regions in China have relatively low contributions, with maximum values less than 2 W  
562 m<sup>-2</sup>. Emissions outside China lead to 1–2 W m<sup>-2</sup> of DRF of BC over South, Southwest,  
563 Northwest China and Tibetan Plateau, and 0.2–1 W m<sup>-2</sup> over other parts of China, an  
564 effect that is quite widespread.

565 The total DRF of BC averaged over continental China simulated in this study is  
566 2.20 W m<sup>-2</sup>, larger than 0.64–1.55 W m<sup>-2</sup> in previous studies (Wu et al., 2008; Zhuang  
567 et al., 2011; Li et al., 2016), probably due to the different emissions in the time periods  
568 of study, as shown in Table S5. Emissions outside China have the largest  
569 contributions to DRF of BC in China compared to any of the individual source regions  
570 in China, with an averaged contribution of 0.78 W m<sup>-2</sup> (35%). This fractional  
571 contribution from emissions outside China is larger than 25% in Li et al. (2016),  
572 however we use different emissions, model and meteorology. Emissions from North  
573 China result in 0.55 W m<sup>-2</sup> (25%) of DRF of BC over China, followed by 0.30 W m<sup>-2</sup>  
574 (14%) and 0.28 W m<sup>-2</sup> (13%) from Southwest and South China, respectively.  
575 Emissions from Central-West, Northeast, Northwest China, and Tibetan Plateau taken  
576 together account for 0.29 W m<sup>-2</sup> (13%) of DRF of BC over China.

577 Figure 12a shows the seasonal mean DRF of BC averaged over China as a  
578 function of regional BC emissions. Because of high emissions, DRF of BC emitted  
579 from North China is the largest in all seasons, with values in a range of 0.5–0.8 W m<sup>-2</sup>  
580 averaged over China, followed by 0.2–0.5 W m<sup>-2</sup> from South and Southwest China. BC

581 from the other tagged regions in China contribute less than  $0.2 \text{ W m}^{-2}$  in all seasons. In  
582 general, BC DRF in each season is proportional to its emission rate.

583 Figure 12b presents the seasonal DRF efficiency of BC emitted from the tagged  
584 regions and Table S6 summarizes these efficiencies. The variability of DRF efficiency  
585 for forcing over China is determined by several factors, such as incoming solar  
586 radiation (location of source regions), BC column burden and vertical distribution, and  
587 transport out of the region. The China DRF efficiency is largest in western China (NW  
588 and TP). This spatial pattern was also found by Henze et al. (2012). It can be  
589 explained by the increase of multiple scattering effects and attenuation of the  
590 transmitted radiation for large AOD (García et al., 2012). The Northeast China region  
591 has a low China DRF efficiency due to transport eastward outside of China. The  
592 remaining central and southern China regions have China DRF efficiencies that are  
593 fairly consistent, varying by 20-30% about the average. The annual mean and  
594 regional mean DRF efficiency in China is  $0.88 \text{ W m}^{-2} \text{ Tg}^{-1}$ , within the range of  $0.41$ –  
595  $1.55 \text{ W m}^{-2} \text{ Tg}^{-1}$  from the previous studies (Table S5).

596 DRF efficiencies of BC from most regions have higher values in JJA and lower  
597 values in DJF. This is primarily due to more incoming solar radiation in summer.  
598 Insolation is the largest over Northwest China in JJA, together with less precipitation  
599 than other regions, resulting in large DRF efficiency there. Global BC DRF efficiency,  
600 particularly the annual average, is fairly similar for central, southern, and eastern  
601 China regions (Fig. 12c, d). Global efficiency is still much higher for the western  
602 regions.

603 BC emission reductions may impact mitigation of climate change and improve air  
604 quality. To compare the relative importance of climate and air quality effects of BC  
605 from different regions in China, Fig. 13 shows the near-surface concentration and  
606 column burden efficiency of BC over China and globally and Table S7 summarizes  
607 these efficiencies. For near-surface concentration (Fig. 13a and 13b), the efficiencies  
608 are largest in DJF and lowest in JJA, in contrast to the DRF efficiencies, resulting  
609 from the less precipitation and wet deposition of aerosols in winter. Unlike the DRF  
610 efficiencies, the near-surface concentration efficiencies over eastern China are

611 similar and even larger than those for central and western China. These results  
612 suggest that reduction in BC emissions in eastern China could benefit more on the  
613 regional air quality in China, especially in winter haze season.

614 The relative distributions of column burden efficiencies (Fig. 13c and 13d) are  
615 similar to the DRF efficiencies for the major emitting region in China, indicating that  
616 aerosol lifetime in atmosphere drives DRF that influences regional and global climate.  
617 The western regions (NW and TP), as expected, have a higher forcing per unit  
618 column burden.

619

## 620 **5. Conclusions and discussions**

621 In this study, the Community Earth System Model (CESM) with a source-tagging  
622 technique is used to quantify the contributions of BC emitted from seven regions in  
623 continental China, including North China (NC), South China (SC), Southwest China  
624 (SW), Central-West China (CW), Northeast China (NE), Northwest China (NW), and  
625 Tibetan Plateau (TP), and sources outside China (RW) to concentrations, haze  
626 formation, trans-boundary and trans-Pacific transport, and direct radiative forcing  
627 (DRF) of BC in China. The anthropogenic emissions of BC for years 2010-2014 used  
628 in this study were developed for the Coupled Model Intercomparison Project Phase 6  
629 (CMIP6) from the Community Emissions Data System (CEDS). The annual total  
630 emission of BC from continental China is 2497 Gg C averaged over years 2010–2014.  
631 The model captures well the spatial distribution and seasonal variation in China.  
632 AAOD compares well with measurements, which are largely located in central and  
633 eastern China. Surface BC concentrations are underestimated by 48% compared to  
634 point observations.

635 The individual source regions are the largest contributors to their local BC  
636 concentration levels. Over North China where the air quality is often poor, about 90%  
637 of near-surface BC concentration is contributed by local emissions. However, some  
638 source regions also impact BC in neighboring regions. Due to the seasonal variability  
639 of winds and emission rates, emissions from North China account for 35% of  
640 near-surface BC concentrations over South China in DJF

641 (December-January-February), while emissions from outside China contribute about  
642 10% in MAM (March-April-May). Over Southwest China, 19% of BC in MAM comes  
643 from sources outside China. Southwest and North China emissions contribute largely  
644 to BC in Central-West China. North China emissions have a contribution in a range of  
645 21–30% to BC concentrations in Northeast China. Over Northwest China and Tibetan  
646 Plateau, more than 20% and 40% of BC, respectively, originates from emissions  
647 outside China. These indicate that, for regions with high emissions, their BC  
648 concentrations are dominated by local emissions. In contrast, BC levels over central  
649 and western China with lower emissions are more strongly influenced by non-local  
650 emissions. For all continental China as a whole, seasonal BC concentrations are  
651 largely due to emissions from North and South China, with relative contributions  
652 ranging from 44–53% and 18–22%, respectively, followed by contributions from  
653 Southwest (10–12%) and outside China (5–11%).

654 Emissions from non-local sources together with abnormal winds are one of the  
655 important factors contributing to high winter time pollution events in China. Over  
656 South China, about 60% of the increase in BC concentrations during high pollution  
657 conditions results from North China emissions. The increases in BC concentrations  
658 during polluted days over Southwest, Central-West and Northeast China are strongly  
659 influenced by emissions from eastern China. Emissions from outside China could  
660 contribute significantly to increases in BC concentrations over Northwest China and  
661 Tibetan Plateau during their polluted days. However, emissions from outside China do  
662 not have a significant contribution to haze in eastern and central China, suggesting  
663 that reduction in emissions within China would be needed to mitigate both local and  
664 non-local BC concentrations under high-polluted conditions.

665 Emissions from regions in and outside China both account for about half of BC  
666 outflow from East Asia, suggesting that emissions from China and other regions are  
667 equally important for the BC outflow from East Asia. Through long-range transport,  
668 emissions from China result in 8% of near-surface BC concentration and 29% in  
669 column burden over western United States in MAM, indicating that emissions from  
670 China could have an impact on air quality in western United States.

671 The total DRF of BC averaged over continental China simulated in this study is  
672  $2.20 \text{ W m}^{-2}$ . Among the tagged regions, emissions outside China have the largest  
673 single contribution to DRF of BC in China, with an average contribution of 35%,  
674 followed by 25%, 14%, and 13% due to emissions from North, South and Southwest  
675 China, respectively. DRF efficiencies over eastern China are small compared to  
676 central and western China in all seasons. For near-surface concentration, the  
677 efficiencies are largest in DJF and lowest in JJA, and efficiencies over eastern China  
678 are similar and even larger than central and western China. These suggest that  
679 reduction in BC emissions over eastern China could benefit more on the regional air  
680 quality in China, especially in winter haze season.

681 Note that the model largely underestimates BC concentrations over China,  
682 compared to the observation, which has also been reported in many previous studies  
683 using different models and different emission inventories (e.g., Liu et al., 2012; Fu et  
684 al., 2012; Huang et al., 2013; H. Wang et al., 2013; Q. Wang et al., 2014; R. Wang et  
685 al., 2014; Li et al., 2016). One possible reason is that in situ measurements are point  
686 observations, while the model does not treat the subgrid variability of aerosols and  
687 assumes aerosols are uniformly distributed over the grid cell. R. Wang et al. (2014)  
688 found a reduction of negative bias (from  $-88\%$  to  $-35\%$ ) in the modeled surface BC  
689 concentrations when using high-resolution emissions and modeling at  $0.5^\circ \times 0.7^\circ$   
690 resolution. This result indicates that the siting of observational stations can result in  
691 an artificial bias when comparing with relatively coarse model results. Further  
692 investigation of this siting/resolution bias is warranted, including investigation on  
693 whether this type of bias might extend, presumably to a lesser extent, also to AOD  
694 measurements.

695 Further reasons that could contribute to this bias are emission underestimation or  
696 inaccurate aerosol processes in the model. Given that the differences between  
697 modeled and observed AOD over eastern China are relatively small ( $-6\%$ ), we  
698 conclude that, given current evidence, the total amount of atmospheric BC in these  
699 simulations is reasonable at least in this sub-region.

700 Over eastern China, the BC concentrations are dominated by local emissions in  
701 this study, with local contribution of 58–94%. The underestimation of simulated BC  
702 concentrations over eastern China is more likely due to either underestimation of  
703 local emissions, too much aerosol removal within these regions, or resolution bias  
704 between observations and model grids. Over western China, 18–78% of the BC  
705 originates from emissions outside China. Thus biases of simulated BC concentrations  
706 could also come from underestimation of emissions outside China and or too much  
707 removal of BC during long-range transport. Satellite data are a promising method to  
708 validate modeling and emissions inventories, given that they do not depend on the  
709 location of observing stations, providing more uniform spatial coverage. A  
710 comparison of modeled AAOD and satellite AI provides an indication that the  
711 modeled burden in western China is underestimated, although the role of dust needs  
712 to be better characterized.

713 Uncertainty in China BC emissions has been estimated as –43% to 93% by Lu et  
714 al. (2011), –50% to 164% by Qin and Xie (2012),  $\pm 176\%$  by Kurokawa et al. (2013),  
715 and –28 to 126% by Zhao et al. (2013). The BC emissions estimates used here for  
716 China in 2010 are 40% higher than those of Zhao et al. (2013) and Lu et al. (2011)  
717 and 30% higher than Klimont et al. (2016), in large part due to a higher estimate of  
718 BC emissions from coal coke production. Emissions from coke production are  
719 particularly uncertain given that “there are no measurements for PM<sub>2.5</sub> and BC  
720 emissions” (Huo et al. 2012) available to guide inventory estimates. Total rest of the  
721 world emissions other than China, which appear to be a major contributor to burdens  
722 over western regions, are within 1% of those from Klimont et al. (2016).

723 BC aging in the atmosphere is important for BC concentration and its optical  
724 properties, which transforms BC from hydrophobic aggregates to hydrophilic particles  
725 coated with soluble materials. He et al. (2015, 2016a) found that BC optical properties  
726 varied by a factor of two or more due to different coating structures during BC aging  
727 process based on their theoretical and experimental intercomparison. Oshima et al.  
728 (2009) and He et al. (2016b) pointed out that the use of various microphysical BC  
729 aging schemes could significantly improve simulations of BC concentrations,

730 compared to the simplified aging parameterizations. Liu et al. (2012) also reported that  
731 the wet removal rate of BC simulated in standard CAM5 is 60% higher than AeroCom  
732 multi-model mean due to the rapid or instantaneous aging of BC. H. Wang et al. (2013)  
733 showed that the explicit treatment of BC aging process with slow aging assumptions in  
734 CAM5 could significantly increase BC lifetime and the efficiency of BC long-range  
735 transport. In the three-mode aerosol module (MAM3) of CAM5 used in this study, the  
736 aging process of BC is neglected by assuming the immediate internal mixing of BC  
737 with other aerosol species in the same mode. This assumption could lead to an  
738 overestimation of wet removal of BC and, therefore, an underestimation of BC  
739 concentrations, absorption optical depth (Fig. 3) and direct radiative forcing. In  
740 addition, the internally-mixed optical treatment in CAM5 could also cause bias in BC  
741 absorption calculation. However, H. Wang et al. (2014) examined source-receptor  
742 relationships for BC under the different BC aging assumptions and found that the  
743 quantitative source attributions varied slightly while the qualitative source-receptor  
744 relationships still hold. Therefore, although the magnitude of simulated BC and its  
745 optical properties could be underestimated due to the instantaneous aging of BC and  
746 uncertainty in coating structures, we expect that the aging treatment in MAM3 of  
747 CAM5 should not influence the qualitative source attributions examined in this study.

748 In this study, BC is used as an indicator of pollution (or air quality) in China.  
749 Although BC is often co-emitted with other species, such as primary organic matter,  
750 organic gases and sulfuric gases, source-receptor relationship of BC may not fully  
751 represent that of total aerosols. The contribution of BC to total near-surface  $PM_{2.5}$   
752 concentrations averaged over China is less than 10%. Other aerosols, such as sulfate,  
753 are dominant in China during polluted days. The spatio-temporal variations and  
754 source contributions of these species are largely different from those of BC because  
755 spatial distributions of emissions (e.g.,  $SO_2$ ) and formation processes can be  
756 considerably different. For example, Matsui et al. (2009) showed that primary aerosols  
757 around Beijing were determined by emissions within 100 km around Beijing within the  
758 preceding 24 hours, while emissions as far as 500 km and within the preceding 3 days  
759 were found to affect secondary aerosols in Beijing. Thus, the secondary aerosols

760 could have larger contributions from non-local emissions than BC. BC concentrations  
761 are highest in winter over China due to higher emissions, while sulfate concentrations  
762 reach maximum in summer when the strong sunlight and high temperature favor the  
763 sulfate formation. Therefore, knowing the accurate source attributions of air pollution  
764 in China requires source tagging for more aerosol species, such as sulfate.

1190 **Figure Captions**

1191

1192 **Figure 1.** (a) Spatial distribution of annual mean total emissions (anthropogenic plus  
1193 biomass burning, units:  $\text{g C m}^{-2} \text{ yr}^{-1}$ ) of black carbon (BC) averaged over 2010–2014.  
1194 The geographical BC source regions are selected as North China (NC,  $109^\circ\text{E}$ –east  
1195 boundary,  $30^\circ$ – $41^\circ\text{N}$ ), South China (SC,  $109^\circ\text{E}$ –east boundary, south boundary–  
1196  $30^\circ\text{N}$ ), Southwest China (SW,  $100^\circ$ – $109^\circ\text{N}$ , south boundary– $32^\circ\text{N}$ ), Central-West  
1197 China (CW,  $100^\circ$ – $109^\circ\text{N}$ ,  $32^\circ\text{N}$ –north boundary), Northeast China (NE,  $109^\circ\text{E}$ –east  
1198 boundary,  $41^\circ\text{N}$ –north boundary), Northwest China (NW, west boundary– $100^\circ\text{E}$ ,  
1199  $36^\circ\text{N}$ –north boundary), and Tibetan Plateau (TP, west boundary– $100^\circ\text{E}$ , south  
1200 boundary– $36^\circ\text{N}$ ) in China and regions outside of China (RW, rest of the world). (b)  
1201 Seasonal mean total emissions (units:  $\text{Gg C}$ ,  $\text{Gg} = 10^9\text{g}$ ) of BC from the seven BC  
1202 source regions in China and emissions from rest of East Asia (REA, with China  
1203 excluded), South Asia (SAS), Southeast Asia (SEA), and Russia/Belarus/Ukraine  
1204 (RBU).

1205

1206 **Figure 2.** Simulated seasonal mean near-surface concentrations (left, units:  $\mu\text{g m}^{-3}$ )  
1207 and column burden (right, units:  $\text{mg m}^{-2}$ ) of BC in December-January-February (DJF),  
1208 March-April-May (MAM), June-July-August (JJA), and  
1209 September-October-November (SON).

1210

1211 **Figure 3.** Comparisons of observed and modeled seasonal mean (a) near-surface  
1212 concentrations (units:  $\mu\text{g m}^{-3}$ ) and (b) aerosol absorption optical depth (AAOD) of BC  
1213 in China. Solid lines mark the 1:1 ratios and dashed lines mark the 1:3 and 3:1 ratios.  
1214 Observed BC concentrations were taken between 2006 and 2007 at 14 sites of the  
1215 China Meteorological Administration (CMA) Atmosphere Watch Network (CAWNET)  
1216 (Zhang et al., 2012). Observed AAOD of BC are obtained by removing dust AAOD  
1217 from total AAOD at 10 sites of the Aerosol Robotic Network (AERONET) (Holben et  
1218 al., 2001), following Bond et al. (2013). The observed AAOD are averaged over years  
1219 of 2005–2014 with data available. Correlation coefficient (R) and normalized mean

1220 bias (NMB) between observation and simulation are shown on top left of each panel.  
1221  $NMB = 100\% \times \sum(M_i - O_i) / \sum O_i$ , where  $M_i$  and  $O_i$  are the modeled and observed  
1222 values at site  $i$ , respectively. Site locations are shown in Figure S1a.

1223

1224 **Figure 4.** Spatial distribution of seasonal mean AAOD of total aerosols (left) and  
1225 Aerosol Index (AI) derived from Ozone Monitoring Instrument (OMI) measurements  
1226 over years of 2010–2014 (right).

1227

1228 **Figure 5.** Spatial distribution of seasonal mean near-surface concentrations of BC  
1229 ( $\mu\text{g m}^{-3}$ ) originating from the seven source regions in China (NC, SC, SW, CW, NE,  
1230 NW, and TP), marked with black outlines, and sources outside China (RW).  
1231 Regionally averaged BC in China contributed by individual source regions is shown at  
1232 the bottom right of each panel.

1233

1234 **Figure 6.** Spatial distribution of relative contributions (%) to seasonal mean  
1235 near-surface BC concentrations from each of the tagged source regions.

1236

1237 **Figure 7.** Relative contributions (%) from the tagged source regions (denoted by  
1238 colors) to regional mean surface concentrations of BC over seven receptor regions in  
1239 China (NC, SC, SW, CW, NE, NW, and TP) and China (seven regions combined, CN)  
1240 in different seasons. The receptor regions are marked on the horizontal axis in each  
1241 panel.

1242

1243 **Figure 8.** Composite differences in winds at 850 hPa ( $\text{m s}^{-1}$ ) and near-surface BC  
1244 concentrations ( $\mu\text{g m}^{-3}$ ) between polluted and normal days in DJF.

1245

1246 **Figure 9.** Composite differences in surface BC concentrations ( $\mu\text{g m}^{-3}$ ) averaged  
1247 over receptor regions (marked on the horizontal axis) over eastern and central China  
1248 between polluted and normal days in DJF originating from individual sources regions  
1249 (bars in each column).

1250

1251 **Figure 10.** Spatial distribution of (a, b) column burden ( $\text{mg m}^{-2}$ ) and (c, d)  
1252 near-surface concentrations ( $\mu\text{g m}^{-3}$ ) of BC originating from total emissions inside  
1253 (CN) and outside China (RW), respectively, in March-April-May (MAM). The black  
1254 solid lines over western ( $150^\circ\text{E}$ ,  $20^\circ\text{--}60^\circ\text{N}$ ) Pacific in panel (a) mark the  
1255 cross-sections used to quantify outflow of BC from East Asia. The box over western  
1256 United States ( $125^\circ\text{--}105^\circ\text{W}$ ,  $30^\circ\text{--}50^\circ\text{N}$ ) in panel (c) is used to quantify BC  
1257 concentrations attributed to sources from China.

1258

1259 **Figure 11.** Spatial distribution of annual mean direct radiative forcing of BC ( $\text{W m}^{-2}$ ) at  
1260 the top of the atmosphere originating from the tagged BC source regions in China  
1261 (NC, SC, SW, CW, NE, NW, and TP) and source outside China (RW). Regionally  
1262 averaged forcing in China contributed by individual source regions is shown at the  
1263 bottom right of each panel.

1264

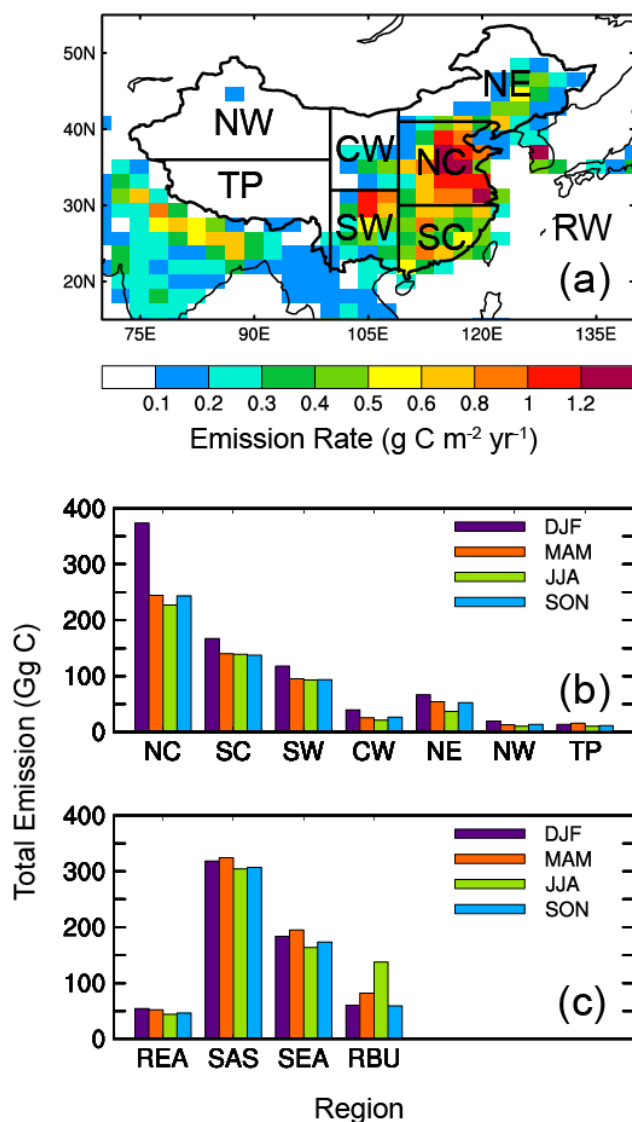

1265 **Figure 12.** (a, c) BC seasonal DRF averaged over China as a function of BC  
1266 emission fraction (the ratio of regional emission to the total emission over China and  
1267 global, respectively, unit: %) for each of the tagged regions. (b, d) Seasonal DRF  
1268 efficiency of BC ( $\text{W m}^{-2} \text{Tg}^{-1}$ ) for each of the tagged source regions over China and  
1269 globally, respectively. The efficiency is defined as the DRF divided by the  
1270 corresponding scaled annual emission (seasonal emission multiplied by 4). Error bars  
1271 indicate  $1\text{-}\sigma$  of mean values during years 2010–2014.

1272

1273 **Figure 13.** Seasonal (a, b) near-surface concentration ( $\mu\text{g m}^{-3} \text{Tg}^{-1}$ ) and (c, d) column  
1274 burden ( $\text{mg m}^{-2} \text{Tg}^{-1}$ ) efficiency of BC for each of the tagged source regions over  
1275 China and globally, respectively.

1276

1277

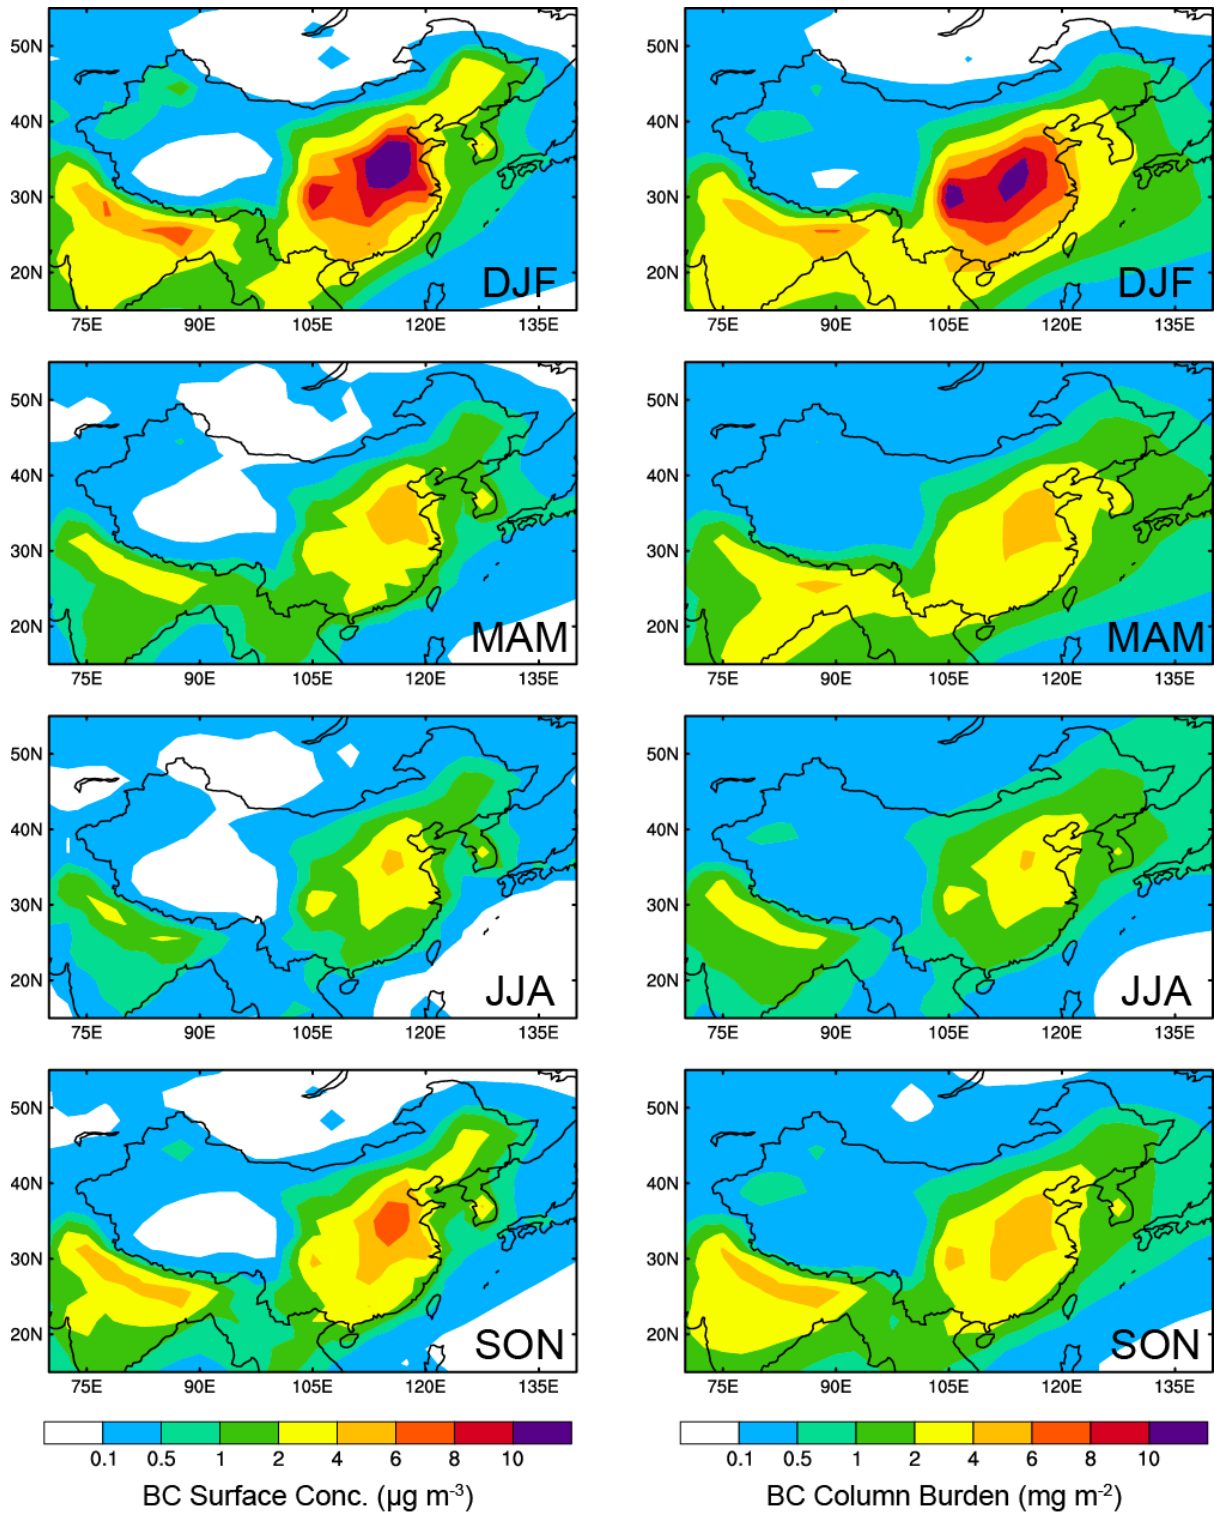

1278

1279

1280 **Figure 1.** (a) Spatial distribution of annual mean total emissions (anthropogenic plus  
 1281 biomass burning, units:  $\text{g C m}^{-2} \text{ yr}^{-1}$ ) of black carbon (BC) averaged over 2010–2014.  
 1282 The geographical BC source regions are selected as North China (NC,  $109^\circ\text{E}$ –east  
 1283 boundary,  $30^\circ$ – $41^\circ\text{N}$ ), South China (SC,  $109^\circ\text{E}$ –east boundary, south boundary–  
 1284  $30^\circ\text{N}$ ), Southwest China (SW,  $100^\circ$ – $109^\circ\text{E}$ , south boundary– $32^\circ\text{N}$ ), Central-West  
 1285 China (CW,  $100^\circ$ – $109^\circ\text{E}$ ,  $32^\circ\text{N}$ –north boundary), Northeast China (NE,  $109^\circ\text{E}$ –east  
 1286 boundary,  $41^\circ\text{N}$ –north boundary), Northwest China (NW, west boundary– $100^\circ\text{E}$ ,  
 1287  $36^\circ\text{N}$ –north boundary), and Tibetan Plateau (TP, west boundary– $100^\circ\text{E}$ , south  
 1288 boundary– $36^\circ\text{N}$ ) in China and regions outside of China (RW, rest of the world). (b)  
 1289 Seasonal mean total emissions (units:  $\text{Gg C}$ ,  $\text{Gg} = 10^9\text{g}$ ) of BC from the seven BC

1290 source regions in China and (c) emissions from rest of East Asia (REA, with China  
1291 excluded), South Asia (SAS), Southeast Asia (SEA), and Russia/Belarus/Ukraine  
1292 (RBU).

1299  
1300

1301 **Figure 3.** Comparisons of observed and modeled seasonal mean (a) near-surface  
1302 concentrations (units:  $\mu\text{g m}^{-3}$ ) and (b) aerosol absorption optical depth (AAOD) of BC  
1303 in China. Solid lines mark the 1:1 ratios and dashed lines mark the 1:3 and 3:1 ratios.  
1304 Observed BC concentrations were taken between 2006 and 2007 at 14 sites of the  
1305 China Meteorological Administration (CMA) Atmosphere Watch Network (CAWNET)  
1306 (Zhang et al., 2012). Observed AAOD of BC are obtained by removing dust AAOD  
1307 from total AAOD at 10 sites of the Aerosol Robotic Network (AERONET) (Holben et  
1308 al., 2001), following Bond et al. (2013). The observed AAOD are averaged over years  
1309 of 2010–2014 over 7 sites and 2005–2010 over 3 sites with data available.  
1310 Correlation coefficient (R) and normalized mean bias (NMB) between observation  
1311 and simulation are shown on top left of each panel.  $\text{NMB} = 100\% \times \sum(M_i - O_i) / \sum O_i$ ,  
1312 where  $M_i$  and  $O_i$  are the modeled and observed values at site  $i$ , respectively. Site  
1313 locations are shown in Figure S1a.

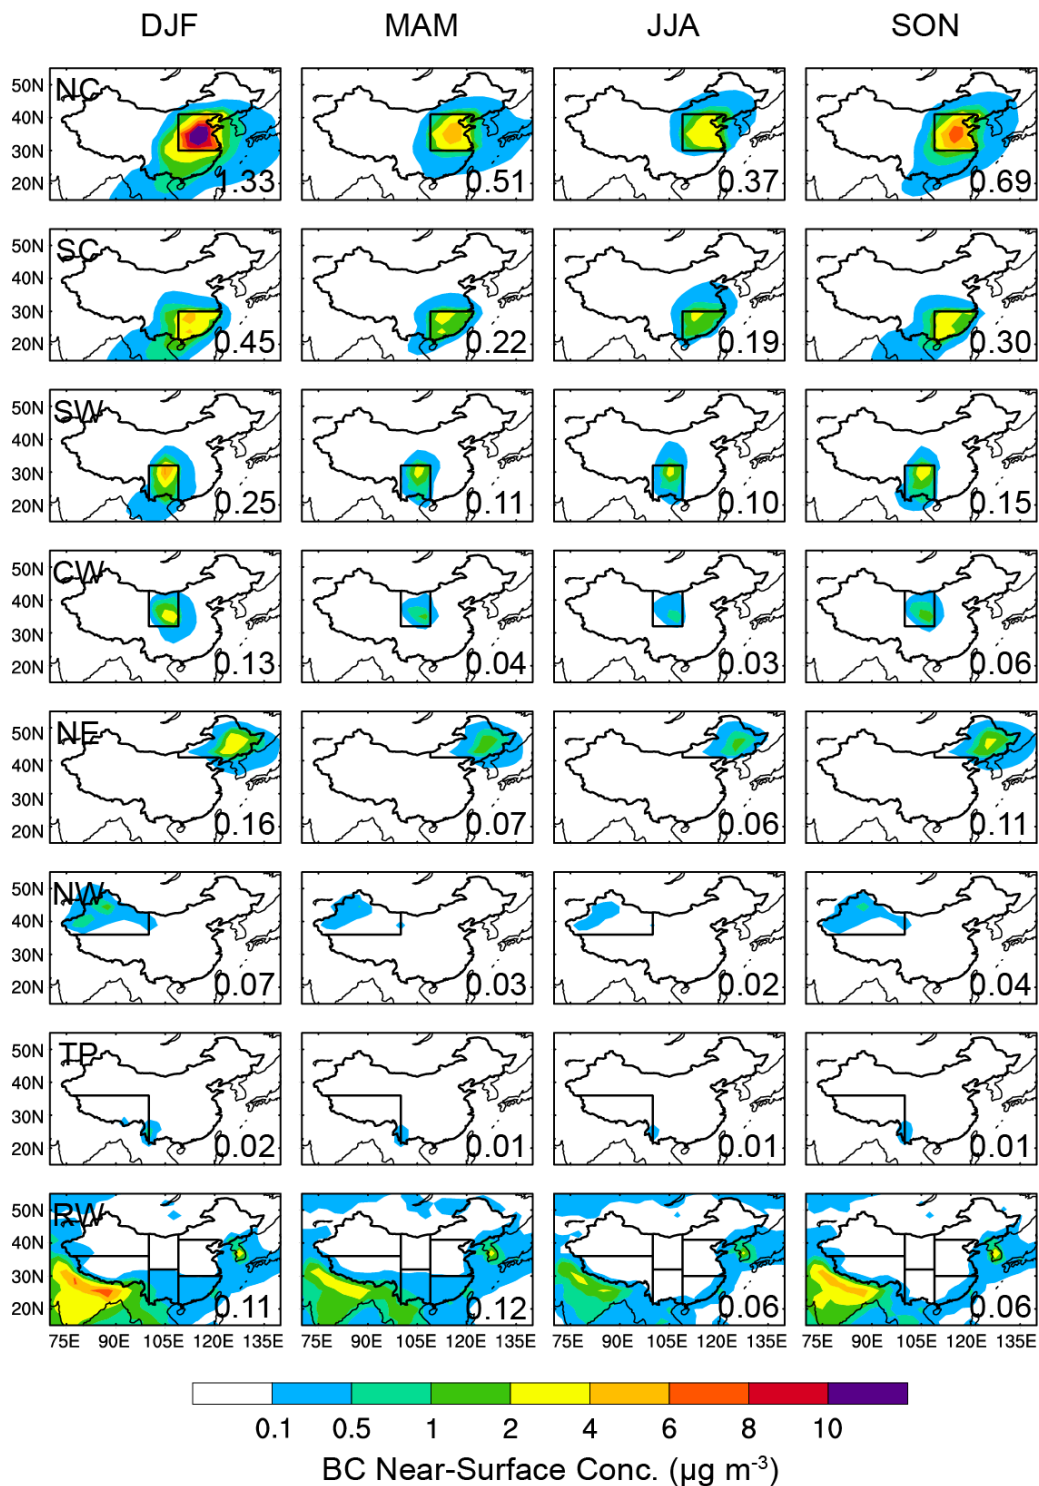

1314
