10  
11 **Abstract.** Biomass burning aerosol has important impact on the global radiative  
12 budget. A better understanding of the correlations between the mixing states of  
13 biomass burning particles and their optical properties is the goal of a number of  
14 current studies. In this work, effective density, chemical composition, and optical  
15 properties of rice straw burning particles in the size range of 50-400 nm were  
16 measured using a suite of online methods. We found that the major components of  
17 rice straw burning particles included black carbon (BC), organic carbon (OC) and  
18 potassium salts, but the mixing states of particles were strongly size-dependent.  
19 Particles of 50 nm had the smallest effective density ( $1.16 \text{ g/cm}^3$ ), due to a relatively  
20 large proportion of aggregate BC. The average effective densities of 100-400 nm  
21 particles ranged from  $1.35\text{-}1.51 \text{ g/cm}^3$  with OC and inorganic salts as dominant  
22 components. Both density distribution and single-particle mass spectrometry showed  
23 more complex mixing states in larger particles. Upon heating, the separation of the  
24 effective density distribution modes testified the external mixing state of less volatile  
25 BC or soot and potassium salts. Size-resolved optical properties of biomass burning  
26 particles were investigated at two wavelengths ( $\lambda=450$  &  $530 \text{ nm}$ ). The single  
27 scattering albedo (SSA) showed the lowest value for 50 nm particles ( $0.741 \pm 0.007$  &  
28  $0.889 \pm 0.006$ ) because of the larger proportion of BC content. Brown carbon played  
29 an important role for the SSA of 100-400 nm particles. The Ångström absorption  
30 exponent (AAE) values for all particles were above 1.6, indicating the significant  
31 presence of brown carbon in all sizes. Concurrent measurements in our work provide  
32 a basis for discussing the physicochemical properties of biomass burning aerosol and  
33 its effects on global climate and atmospheric environment.

## 34 1 Introduction

35 Biomass burning is a significant source of trace gases and aerosol particles (Andreae  
36 and Merlet, 2001). Biomass burning particles affect climate by both absorbing and  
37 scattering solar radiation (Chand et al., 2009) and serve as cloud condensation nuclei  
38 which would modify cloud microphysical properties (Petters et al., 2009). In addition,  
39 biomass burning particles have considerable impacts on air quality, regional visibility,  
40 and human health (Naeher et al., 2007; Park et al., 2006). Global annual emissions of  
41 black carbon (BC) and organic carbon (OC) aerosols are estimated to be ~8 and 33.9

42 Tg yr<sup>-1</sup> while open burning contributes approximately 42% for BC and 74% for OC  
43 (Bond et al., 2004). Along with rapid economic development and increase in  
44 agricultural activities, emissions from agricultural residue combustion in China have  
45 drawn extensive attention. The total amount of straws from open burning in China is  
46 estimated to be ~140 Tg yr<sup>-1</sup> (Cao et al., 2008).

47 Mixing state, composition, and morphology of particles can influence their  
48 radiative properties. BC, which is predominantly produced from the combustion  
49 related sources, absorbs solar radiation across the visible spectrum, resulting in a  
50 warming effect (Bond et al., 2013). The co-emission of BC and OC can lead to  
51 internally mixed particles, in which the OC coating can enhance particle absorption  
52 through lensing effects (Bond and Bergtrom, 2006; Schnaiter et al., 2005). Some  
53 organic matter containing specific functional groups (e.g. nitrated/polycyclic  
54 aromatics, phenols) can itself absorb radiation in the short wavelength visible and UV  
55 wavelengths (Hoffer et al., 2006; Jacobson, 1999) and is referred to as brown carbon  
56 (BrC). As biomass burning is a significant source of BrC, the optical properties of  
57 biomass burning particles need to be further understood. Field works have been  
58 conducted to measure the light absorption enhancement by particle coatings in  
59 different areas (Chan et al., 2011; Nakayama et al., 2014). The degree to which  
60 particles absorb light depends on their composition, shape, and mixing state.  
61 Researches on chemical composition and mixing state of biomass burning particles  
62 have been done by our group members previously (Huo et al., 2016; Zhai et al., 2015).  
63 However, it remains unclear how mixing states and chemical composition of biomass  
64 burning particles influence their morphology and optical properties.

65 Particles emitted from biomass burning are generally composed of a mixture of  
66 spherical and non-spherical particles and chain aggregates (Martins et al., 1998).  
67 Scanning electron microscopy (SEM) as well as transmission electron microscopy  
68 (TEM) are common techniques widely used to investigate the morphology of biomass  
69 burning particles (China et al., 2013; Giordano et al., 2015; Hopkins et al., 2007).  
70 However, these methods are unable to provide continuous “on-line” information and  
71 suffer from limitations arising from primary particle overlap, screening effects, and  
72 cluster anisotropy (Wentzel et al., 2003). Effective density is a good predictor for the  
73 complex properties of biomass burning particles (Pitz et al., 2008) and is often used to  
74 convert particle size distributions into mass loading (Schmid et al., 2007). Variations  
75 in particle effective density can be used to follow compositional transformations  
76 during chemical reactions (Katrib et al., 2005). Online measurements which provide  
77 real-time monitoring of particle effective density variation have been developed.  
78 Kelly and McMurry (1992) developed a density measurement technique based on the  
79 selection of a monodisperse aerosol with a Differential Mobility Analyzer (DMA)  
80 followed by classification according to aerodynamic diameter with an impactor.  
81 McMurry et al. (2002) reported a technique to determine size-resolved effective  
82 density based on using an Aerosol Particle Mass analyzer (APM) to measure the mass  
83 of particles that had been classified according to electrical mobility by a DMA. The  
84 DMA-APM method has been applied extensively in field studies as well as laboratory  
85 experiments (Hu et al., 2012; Barone et al., 2011). However, few measurements of the

86 effective density of biomass burning particles have been done due to the lack of  
87 accompanying on-line chemical information.

88 Mixing state of individual particle can be very different caused by the chemical  
89 composition, aging degree, etc., which greatly influence the morphology and optical  
90 property of particles. Thus, distinctions among particles might be omitted by bulk  
91 measurements. Single particle mass spectrometry techniques have been utilized to  
92 measure the chemical composition, size, density, and shape of individual particles.  
93 Spencer et al. (2007) utilized a DMA-ultrafine aerosol time-of-flight mass  
94 spectrometer (UF-ATOFMS) system to detect the effective density and chemical  
95 composition simultaneously of ambient aerosol at single-particle level. The  
96 comprehensive information about single particles could help to elucidate the  
97 morphology, mixing state, and sphericity of biomass burning particles.

98 The chemical composition, morphology, and optical properties of particles are  
99 usually interrelated. Biomass burning particle is a complex mixture of organic and  
100 inorganic species, including strongly light-absorbing BC and BrC. Size-resolved or  
101 even single particle level information on the morphology, chemical composition, and  
102 optical properties of biomass burning particles are necessary to have a better  
103 understanding of the correlations among these physicochemical properties. In this  
104 study, laboratory experiments were conducted on rice straw combustion, a main  
105 source of biomass burning particles in Southern China. The size-resolved effective  
106 density of biomass burning particles was measured by two different methods. One  
107 was based on a DMA-APM-Condensation Particle Counter (CPC) system. For the  
108 other method, the mobility size-selected particles by a DMA were transported into a  
109 Single Particle Aerosol Mass Spectrometer (SPAMS), where the vacuum  
110 aerodynamic diameter and chemical composition of individual particles were  
111 measured. Size-resolved optical properties of biomass burning particles were also  
112 measured by Cavity Attenuated Phase Shift spectroscopy (CAPS). A thermodenuder  
113 (TD) was used to help analyze the mixing state of particles by removing the volatile  
114 compounds and leaving behind the less volatile species based on the vaporization  
115 temperature of materials. The purpose of our study was to add physicochemical  
116 knowledge regarding biomass burning particles which is an important aerosol source  
117 globally.

## 118 **2 Experiments**

### 119 **2.1 Laboratory-made biomass burning particles**

120 Rice straw, a typical type of crop residue in Southern China, was taken as the  
121 representative biomass burning material in our experiment. The self-designed  
122 combustion setup was introduced in previous work (Huo et al., 2016). Briefly, the rice  
123 straws collected in rural residential area in Shanghai were dehydrated for 24 h at  
124 100°C in an oven prior to combustion. Five replicate tests of straw-burning were  
125 conducted for each experiment. For each test, ~ 50g of dried rice straws were burned  
126 in a combustion stove at a flaming condition. The emitted smoke was introduced into  
127 a 4.5 m<sup>3</sup> (in volume) chamber with a flowrate of 50 L/min. Ambient air was  
128 introduced through a high efficiency particulate air filters to maintain the ambient

129 pressure. The particles in chamber were then introduced into the measurement system  
130 through a silica gel type diffusion drier (shown in Figure 1).

## 131 **2.2 Single particle mass spectrometry**

132 A Single Particle Aerosol Mass Spectrometer (SPAMS) (Hexin Analytical Instrument  
133 Co., Ltd) was deployed to examine the aerosol chemical composition and  
134 aerodynamic diameter at single-particle level. Detailed information on the SPAMS  
135 has been described elsewhere (Li et al., 2011). Briefly, particles in the size range of  
136 0.2-2.0  $\mu\text{m}$  are first drawn into the vacuum through an Aerodynamic Focusing Lens.  
137 Each particle is accelerated to a size-dependent aerodynamic velocity which is  
138 calculated based on two orthogonally oriented continuous lasers (Nd: YAG, 532 nm).  
139 The two lasers are fixed at a 6 cm distance and the delay of the scatter light is  
140 collected by two photomultiplier tubes (PMT). When a particle arrives at the ion  
141 source region, a pulsed desorption/ionization laser (Qswitched Nd: YAG, 266 nm) is  
142 triggered. Ions are recorded by a bipolar time-of-flight spectrometer, which records  
143 both positive and negative mass spectra for each single particle. In this work, the  
144 power of desorption /ionization laser was set to  $\sim 0.6$  mJ per pulse. The aerodynamic  
145 diameter measurement is calibrated with curves generated by monodisperse  
146 polystyrene latex spheres (Nanosphere Size Standards, Duke Scientific Corp.) with  
147 known diameters (0.2-2.0  $\mu\text{m}$ ).

148 All single particle mass spectra acquired were converted to a list of peaks at each  
149  $m/z$  by setting a minimum signal threshold of 30 arbitrary units above the baseline  
150 with TSI MS-Analyze software. The resulting peak lists together with other SPAMS  
151 data were imported into YAADA (version 2.11, [www.yaada.org](http://www.yaada.org)), a software toolkit  
152 for single-particle data analysis written in Matlab (version R2011b). In this work, a  
153 total of 10220 biomass burning particles were chemically analyzed according to their  
154 positive and negative ion spectra, accounting for about 48 % of all sized particles.  
155 According to the similarities of the mass-to-charge ratio and peak intensity, the  
156 biomass burning particles were classified using an adaptive resonance theory-based  
157 clustering method (ART-2a) (Song et al., 1999). Base on previous work (Huang et al.,  
158 2013; Spencer et al., 2007), parameters for ART-2a used in this work such as  
159 vigilance factor, learning rate, and iterations were 0.85, 0.05, and 20, respectively.  
160 The particle clusters resulting from ART-2a were then grouped into 6 particle types  
161 based on the mass spectral patterns and chemical similarities. The name of a particle  
162 type reflects the dominant chemical species.

## 163 **2.3 Effective density measurements**

### 164 **2.3.1 Theoretical calculation and methods**

165 Particle density ( $\rho_p$ ) is referenced to the volume equivalent diameter ( $d_{ve}$ ) which is  
166 defined as the diameter of a spherical particle with the same volume as the particle  
167 under consideration. Particle density can be derived as follows, where  $m_p$  is the  
168 particle mass:

$$169 \quad \rho_p = \frac{m_p}{\frac{\pi}{6}d_{ve}^3} \quad (1)$$

170 When particles are not spherical, the “effective density”, not necessarily a true  
171 measurement of particle density is derived. Various definitions of effective density are  
172 provided in the literature, and a review of these definitions is given by DeCarlo et al.  
173 (2004). Different definitions may aim to present different values for a given particle.  
174 It is important to understand the derivation, calculation, and measurement for one  
175 method of particle effective density.

#### 176 (1) DMA-APM-CPC system

177 The effective density of a particle can be calculated by combining mobility and  
178 mass measurements under the assumption that the particle is spherical, thus its  
179 physical diameter equals to the electrical mobility diameter ( $d_m$ ) measured by a DMA.

180 The effective density ( $\rho_{eff}^I$ ) can be calculated by the following equation:

$$181 \quad \rho_{eff}^I = \frac{m_p}{\frac{\pi}{6}d_m^3} \quad (2)$$

182 where  $m_p$  stands for particle mass obtained by an APM. In our work, we selected  
183 biomass burning particles with mobility diameters of 50 nm, 100 nm, 200 nm, and  
184 400 nm and determined their effective density using the DMA-APM-CPC system.

#### 185 (2) DMA-SPAMS system

186 Another approach of deriving effective density is through a combination of  
187 mobility and aerodynamic measurements. Simultaneously measuring the particle  
188 electrical mobility diameter ( $d_m$ ) by DMA and the vacuum aerodynamic diameter ( $d_{va}$ )  
189 by SPAMS allows for the determination of particle effective density ( $\rho_{eff}^{II}$ ) by the  
190 following equation:

$$191 \quad \rho_{eff}^{II} = \frac{d_{va}}{d_m} \rho_0 \quad (3)$$

192 where  $\rho_0$  is the standard density (1.0 g/cm<sup>3</sup>). In this study, since particles smaller  
193 than 200 nm may not scatter sufficient light to be detected by SPAMS and the number  
194 concentration of biomass burning particles above 400 nm was low (shown in Figure  
195 S1), we selected 200 nm and 400 nm particles by DMA and then introduced them into  
196 SPAMS.

#### 197 (3) Shape factor calculation

198 The shape of particles can influence the optical properties and can reflect the  
199 mixing state of particles to some degree. It is possible to extract the shape information  
200 based on the measurements above.

201 The relationship between the volume equivalent diameter ( $d_{ve}$ ) and mobility  
202 diameter ( $d_m$ ) is shown in the following equation:

$$203 \quad \frac{d_m}{C_c(d_m)} = \frac{d_{ve}\chi}{C_c(d_{ve})} \quad (4)$$

204 where  $\chi$  is the shape factor, the ratio of the resistance force on the nonspherical  
205 particle to the resistance force on its volume equivalent sphere (Hinds, 1999). The  $\chi$

206 value equals 1 for spherical particles and is greater than 1 for nonspherical/irregular  
207 particles.

208  $C_c$  is the Cunningham Slip Correction Factor parameterized as:

$$209 \quad C_c(d) = 1 + \frac{2\lambda}{d} [\alpha + \beta \exp(-\gamma \frac{d}{2\lambda})] \quad (5)$$

210 where  $d$  is the particle diameter ( $d_m$  or  $d_{ve}$ ) and  $\lambda$  is the mean free path of gas  
211 molecules. The empirical constants  $\alpha$ ,  $\beta$ , and  $\gamma$  are 1.142, 0.558, and 0.999  
212 respectively (Allen and Raabe, 1985).

213 The vacuum aerodynamic diameter ( $d_{va}$ ) is related to the volume equivalent  
214 diameter ( $d_{ve}$ ) by:

$$215 \quad d_{va} = \frac{\rho_p d_{ve}}{\rho_0 \chi} \quad (6)$$

216 As the measurements of mobility and aerodynamic diameters are readily  
217 available, we assumed the error was in the particle mass measurement if the measured

218  $\rho_{eff}^{II}$  is used to replace  $\rho_{eff}^I$  in Equation (2) (Decarlo et al., 2004). With assumed  
219 particle density ( $\rho_p$ ) and known particle mass ( $m_p$ ) measured by an APM, a calculated  
220  $d_{ve}$  could be obtained using Equation (1). Though  $\rho_p$  was unknown, it would be  
221 canceled out later. Using the same  $d_{ve}$  and for any shape factor ( $\chi$ ), a calculated  $d_m$  and

222  $d_{va}$  was obtained by Equation (4) and (6), respectively. Thus,  $\rho_{eff}^{II}$  could be obtained

223 by the calculated  $d_m$  and  $d_{va}$  and an estimated  $m_p$  was calculated by replacing  $\rho_{eff}^I$  by

224  $\rho_{eff}^{II}$  in Equation (2). We then calculated the ratio of the estimated  $m_p$  to the exact  $m_p$   
225 as a function of  $d_m$  and  $\chi$  (shown in Figure S4, discussed in Section 3.1.5).

### 226 **2.3.2 Instrumentation for effective density measurements**

227 The size distribution of biomass burning particles was detected by a Scanning  
228 Mobility Particle Sizer (SMPS) consisting of a Differential Mobility Analyzer (DMA,  
229 Model 3080, TSI Inc.) and a Condensation Particle Counter (CPC, Model 3775, TSI  
230 Inc.). An Aerosol Particle Mass analyzer (APM, Model 3601, Kanomax Inc.) was  
231 used to classify aerosol particles according to their mass-to-charge ratio. The detailed  
232 information of the APM classification principle was previously reviewed by Tajima et  
233 al. (2011). Briefly, particles were size-selected by DMA after being charged with a  
234 Kr-85 neutralizer. Particles with a known size were then introduced into APM. When  
235 the radial electrical and centrifugal forces were in balance, particles passed through  
236 the rotating cylinders to CPC. Mass distribution was obtained by voltage scanning and  
237 particle counting.

### 238 **2.4 Optical measurements**

239 Cavity Attenuated Phase Shift (CAPS) spectroscopy (Shoreline Science Research Inc.)  
240 was used to determine the particle extinction and scattering coefficient. Detailed  
241 information on the CAPS is available in Onasch et al. (2015). Briefly, a square-wave

242 modulated light-emitting diode (LED) is transmitted through an optical cavity cell. A  
243 sample cell incorporating two high reflectivity mirrors ( $R \sim 0.9999$ ) with a vacuum  
244 photodiode detector (Hamamatsu R645) centers at the wavelength of the LED. The  
245 particle extinction coefficient [ $b_{ext}(\lambda)$ ] can be obtained from the changes in the phase  
246 shift of the distorted waveform of the LED. An integrating nephelometer using a 10  
247 cm diameter integrating sphere is operated to measure the scattering coefficient [ $b_{scat}$   
248 ( $\lambda$ )]. Particles are illuminated by the collimated light beam which has measured the  
249 extinction. The scattered light of particles is collected at all angles by the integrating  
250 sphere. A PMT (H7828-01, Hamamatsu) with a high voltage power supply and an  
251 amplifier records the scattered light. In this work, we used two CAPSs with the LED  
252 light sources at wavelength of 450 nm and 530 nm to detect the optical properties of  
253 biomass burning particles, respectively.

## 254 **2.5 Thermodenuder**

255 A thermodenuder (TD, Model 3065, TSI Inc.) was utilized to separate volatile and  
256 less volatile species of biomass burning particles at specific temperatures. The TD  
257 consists of a 40 cm long desorber section and a 70 cm long adsorption tube. The  
258 sample can be heated up to 400 °C in the desorber section while we selected 150 °C  
259 and 300 °C in this work. The adsorption tube is surrounded by an annular bed of  
260 activated carbon which adsorbs the evaporated gas-phase compounds, leaving behind  
261 the less volatile fractions. With a flowrate of 0.6 L/min, the residence time of particles  
262 in the TD heating section was approximately 9 s in this work.

263 The particle number fractions after heating do not necessarily represent the  
264 actual number fractions before heating as some of the particles can evaporate  
265 completely. Besides, particle loss could be produced both in the TD heating and  
266 adsorption section due to thermophoretic forces and diffusion, respectively (Philippin  
267 et al., 2004). On account of the quantitative measurements of optical properties,  
268 particle loss could lead to the underestimate of  $b_{ext}$  and  $b_{scat}$ .

269 Sodium chloride (NaCl) aerosol produced by a single-jet atomizer (Model 9302,  
270 TSI Inc.) was used to determine the transport efficiency ( $\eta$ ) in TD. The transport  
271 efficiencies of NaCl of different electric mobility diameters selected by DMA ( $d_m$ : 50,  
272 100, 200, and 400 nm) at a range of temperatures ( $T_i$ : 20, 150, and 300 °C) are shown  
273 in Figure S2. In TD,  $\eta$  decreased with increasing  $T_i$  and decreasing  $d_m$ , which is  
274 consistent with the result in Philippin et al. (2004). The measured  $\eta$  were used to  
275 correct the particle number concentration in the calculation of all the measurements  
276 related to the thermal-denuded process.

## 277 **3 Result and discussion**

### 278 **3.1 Size-resolved effective density**

#### 279 **3.1.1 Effective density from DMA-APM-CPC measurements ( $\rho_{eff}^I$ )**

280 The effective density of particles, measured using the DMA-APM-CPC system ( $\rho_{eff}^I$ ),

281 provided useful information on the mixing state of particles. A Gaussian model was  
282 applied to determine the effective densities of the biomass burning particles selected  
283 by DMA (shown in Figure 2). The density distribution of 50 nm ( $d_m$ ) particles showed  
284 a single peak profile with a peak value of 1.17 g/cm<sup>3</sup> (Table S1). Two possible factors  
285 could be inferred from this feature: a nearly-monodisperse aerosol effective density  
286 distribution or a juncture of two modes with very close peak values. Biomass burning  
287 particles contain highly agglomerated structures like soot (Martins et al., 1998).  
288 Although the material density of black carbon (BC) is ~1.8 g/cm<sup>3</sup> (Bond and  
289 Bergstrom, 2006), fresh BC particles with an aggregate structure can have an effective  
290 density less than 1.0 g/cm<sup>3</sup> (Rissler et al., 2014). The density of organic matter varies  
291 in the range of 1.2-2.0 g/cm<sup>3</sup> depending on sources (Hand et al., 2010; Turpin and Lim,  
292 2001). Since particles of 50 nm have the possibility of containing organic matter  
293 rather than BC alone, the apparent single-peak density distribution of these particles  
294 was more likely due to the combination of two modes representing BC and organic  
295 particles respectively (as the dash lines shown in Figure 2). The thermal desorption  
296 method can help to explain the mixing state of 50 nm particles which will be  
297 discussed in Section 3.1.3.

298 The density distribution of 100 nm particles exhibited a peak at 1.45 g/cm<sup>3</sup> at  
299 room temperature, which suggests that these particles were dominated by organic  
300 matter. However, less-massive composition with effective density of 0.9-1.1 g/cm<sup>3</sup>  
301 was also obtained for 100 nm particles. This range is identical with the density of  
302 fresh BC with aggregate structure. The bi-modal distribution of the density profile of  
303 100 nm particles suggests that BC was partly externally mixed with other components  
304 in ultrafine particles from biomass burning emissions. Similar result has been found  
305 by Lack et al. (2012) and Adachi et al. (2011). The external mixing of BC and organic  
306 particulate matter was evident in the density distribution of 200 nm particles as well  
307 (Figure 2). For 400 nm particles, besides a dominant density mode at 1.34 g/cm<sup>3</sup>, a  
308 relative weak mode with effective density of 1.92 g/cm<sup>3</sup> was observed. Previous  
309 studies have shown that potassium chloride crystals, which have a material density of  
310 ~ 1.99 g/cm<sup>3</sup> (Lide, 2008), were observed in the TEM of fresh biomass burning  
311 particles (Li et al., 2015). Evidence of external mixing sodium and potassium salts in  
312 ambient environment was also observed by single particle mass spectrometry in  
313 previous work (Zauscher et al., 2013; Bi et al., 2011). A recent work performed by  
314 Lee et al. (2016) reported that K<sup>+</sup> was not uniformly mixed in biomass burning  
315 particles with less than 20% particles containing high K<sup>+</sup> content. Thus, we estimate  
316 that the mode at 1.92 g/cm<sup>3</sup> was associated with KCl, and possibly KSO<sub>4</sub> and KNO<sub>3</sub>,  
317 and that these crystalline species were more likely externally mixed with organic  
318 matter in biomass burning particles. The similar results of the externally mixed  
319 aerosol population was observed by Moffet et al. (2008) with a wide range of  
320 densities (1.1-3.4 g/cm<sup>3</sup>).

321 Though freshly emitted, biomass burning particles can be coated by secondary  
322 species, such as ammonium nitrate and ammonium sulfate, pronouncedly in a very  
323 short period (Leskinen et al., 2007). The bulk densities of ammonium nitrate and  
324 ammonium sulfate are ~1.75 g/cm<sup>3</sup>. The differences in the peak values of the

325 dominant mode observed for 50-400 nm particles are associated with the composition  
326 and morphology of particles. Different proportions of the same material can lead to  
327 differences in particle effective density. The dominant modes for biomass burning  
328 particles in the size range of 50-400 nm (Figure 2) could be a mixture of similar  
329 composition (BC, OC, potassium salts and secondary inorganic species) but different  
330 proportions. Detailed information and discussion about the particle composition can  
331 be found in Section 3.2.

### 332 **3.1.2 Effective density from DMA-SPAMS measurements ( $\rho_{eff}^{II}$ )**

333 The vacuum aerodynamic size distributions of 200 nm and 400 nm electrical mobility  
334 selected biomass burning particles are shown in Figure 3. The dominant mode for the  
335 200 nm mobility selected particles was 280 nm in vacuum aerodynamic diameter with  
336 an effective density ( $\rho_{eff}^{II}$ ) of 1.40 g/cm<sup>3</sup> and a second mode at 360 nm ( $d_{va}$ ) with an  
337 effective density of 1.80 g/cm<sup>3</sup>. This is quite consistent with the result from the  
338 DMA-APM-CPC method. The less intense mode at 520 nm ( $d_{va}$ ) should be due to  
339 doubly charged particles (Spencer et al., 2007). For 400 nm mobility selected particles,  
340 the dominant mode in aerodynamic diameter was 540 nm with an effective density of  
341 1.35 g/cm<sup>3</sup>. Since the less massive modes at 660 nm and 840 nm were not in the range  
342 of doubly charged particles, these two modes were singly charged particles with  
343 effective density of 1.65 and 2.10 g/cm<sup>3</sup>, respectively. The single-particle level  
344 chemical composition of biomass burning particles will be discussed below.

345 Figure S3 summarizes that the average effective densities ( $\rho_{eff}^I$  &  $\rho_{eff}^{II}$ ) of  
346 biomass burning particles that were size-selected at 6 different mobility diameters.  
347 Note that the density distributions of the 300 nm and 350 nm ( $d_m$ ) particles are not  
348 contained in Figure 2 since they were similar to those of the 200 nm and 400 nm ( $d_m$ )  
349 particles. The 50 nm biomass burning particles had the lowest effective density of  
350  $1.15 \pm 0.23$  g/cm<sup>3</sup> which could be due to the aggregate structure of black carbon.  
351 Compared with 50 nm ( $d_m$ ) particles, the effective density of 100 nm particles was  
352 higher ( $1.45 \pm 0.15$  g/cm<sup>3</sup>). Since the sampling limitation of SPAMS was 200 nm,  
353  $\rho_{eff}^{II}$  was derived only for particles in the size range of 200-400 nm ( $d_m$ ). Overall, these  
354 two methods had consistent results. The differences between the average values from the two  
355 methods were less than 8% for all particle sizes. We noticed that  $\rho_{eff}^{II}$  were generally smaller  
356 than  $\rho_{eff}^I$ , which could be due to the systematic error from different measurements.

### 357 **3.1.3 Thermal-denuded particle effective density**

358 The average density distributions of 50-400 nm ( $d_m$ ) biomass burning particles after  
359 heating at 150°C and 300 °C, respectively, are shown in Figure 2. It is worth noting  
360 that the thermal-denuded particle density distribution here was not from the particles

361 with the same original dried-particle diameter. However, our observations are still  
362 meaningful since the evolution trends of density distribution after heating were  
363 similar despite of the particle size.

364 After heating by TD, the bi-modal density distributions of biomass burning  
365 particles became more pronounced. At 150 °C, the effective density mode with peak at  
366 ~1.0 g/cm<sup>3</sup> protruded for the whole size range of 50-400 nm particles. The separation  
367 of the peaks after heating suggested that the some less volatile BC or soot with  
368 effective density of ~1.0 g/cm<sup>3</sup> was possibly externally mixed with other  
369 compositions. The dominant density peak values for 50, 100, 200, and 400 nm  
370 particles at 150 °C were 1.64-1.80 g/cm<sup>3</sup>. Li et al. (2016) reported that the density of  
371 organic matter vaporized at 150 °C was 0.61-0.90 g/cm<sup>3</sup>. The increase of the dominant  
372 density peak value (1.34-1.45 g/cm<sup>3</sup> for unheated vs. 1.64-1.80 g/cm<sup>3</sup> for 150 °C  
373 heated) could be due to the volatilization of organics with low effective density. The  
374 dominant density peak values of 50-400 nm particles at 300 °C were 1.75-2.04 g/cm<sup>3</sup>.  
375 The volatilization temperatures of ammonium nitrate and ammonium sulfate are  
376 reported to be ~48-89 °C and ~178-205 °C, respectively (Johnson et al., 2004a;  
377 Johnson et al., 2004b). Thus, the fractions of ammonium nitrate and ammonium  
378 sulfate should be small at 300 °C. The increase of dominant density peak value for  
379 50-400 nm biomass burning particles upon heating could be due to the vaporization of  
380 volatile organics with low effective density and secondary inorganic species such as  
381 NH<sub>4</sub>NO<sub>3</sub> and (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> with density of ~1.75 g/cm<sup>3</sup>. Besides, Bond and Bergstrom  
382 (2006) reported that the density of light-absorbing carbon should be 1.7-2.1 g/cm<sup>3</sup>  
383 which is quite high compared with the density of the volatile organics (0.61-0.90  
384 g/cm<sup>3</sup>). Saleh et al. (2014) had shown that the light-absorbing organics in biomass  
385 burning particles were extremely low volatility organic compounds. Thus, we assume  
386 these extremely low volatility organics should play an important role in the dominant  
387 effective density mode at 300 °C.

388 Upon heating, the density mode of KCl and partly K<sub>2</sub>SO<sub>4</sub> at ~2.0 g/cm<sup>3</sup> was  
389 ambiguous as the dominant mode shifted right and overlapped with the KCl mode  
390 (dash lines shown in Figure 2). However, at 300 °C, the dominant mode of 400 nm  
391 particles was at 2.05 g/cm<sup>3</sup> which fitted the density of potassium salts, indicating the  
392 main material of 400 nm heated (~800 nm unheated, detected by a tandem DMAs)  
393 biomass burning particles should be potassium salts with vaporization temperatures  
394 above 700 °C (Knudsen et al., 2004).

395 With heating by TD, the aerodynamic size distributions of 200 nm and 400 nm  
396 electrical mobility size-selected biomass burning particles at 300 °C are shown in  
397 Figure 3. The increase of  $\rho_{eff}^{II}$  upon heating was consistent with that of  $\rho_{eff}^I$ .

### 398 3.1.4 Shape factor

399 The shape of particles has been suggested to play an important role in their  
400 optical properties (Zhang et al., 2008) and mixing state (China et al., 2013). Shape  
401 factor was introduced to account for the ratio of the drag forces on a particle due to  
402 nonspherical/irregular shape. Shape factor, which can be extracted based on the

403 measurement of particle density and mass has been introduced in Section 2.3.1.

404 We calculated the ratio of the estimated  $m_p$  to the exact  $m_p$  as a function of  $d_m$   
405 and  $\chi$  (shown in Figure S4). For nonspherical particles ( $\chi > 1$ ), the estimated mass was  
406 larger than the actual mass. We calculated the estimated mass using the exact  $\rho_{eff}^{II}$   
407 measured by the DMA-SPAMS to replace the  $\rho_{eff}^I$  in Equation (2) as well. The ratios  
408 of the estimated mass by this mean to the exact mass for 200, 300, 350, and 400 nm  
409 mobility selected particles were 1.4, 1.3, 1.3, and 1.2 respectively (red dots in Figure  
410 S4). Thus, we could estimate the  $\chi$  of the particle measured using the DMA-SPAMS  
411 in the size range of 200-400 nm. Totally, the  $\chi$  of 200-400 nm biomass burning  
412 particle in this work exceeded 1.2 (~1.2-2.2). The  $\chi$  decreased with the increase of  $d_m$   
413 while the effective density showed the same trend. The more regular shape and lower  
414 effective density of 400 nm particles compared with that of 200 nm particles could be  
415 due to the particle chemical composition and particle voids (discussed in Section 3.2).

### 416 3.2 Size-resolved chemical composition

417 The mass spectra of individual biomass burning particles have been studied in  
418 previous work (Silva et al., 1999; Zauscher et al., 2013). Based on the mass spectra of  
419 single particles, the biomass burning particles were classified into 6 particle types: 1)  
420 BB-CN: biomass burning (BB) particles with a strong CN<sup>-</sup> ( $m/z$  -26 [CN<sup>-</sup>]) peak; 2)  
421 BB-EC: BB particles with strong elemental carbon clusters (C<sub>n</sub><sup>+/-</sup>); 3) BB-Nitrate: BB  
422 particles with strong nitrate ( $m/z$  -46[NO<sub>2</sub><sup>-</sup>], -62[NO<sub>3</sub><sup>-</sup>]) signals; 4) BB-Sulfate: BB  
423 particles with strong sulfate ( $m/z$  -97[HSO<sub>4</sub><sup>-</sup>]) signals; 5) BB-KCl: BB particles with  
424 strong potassium chloride ( $m/z$  113[K<sub>2</sub>Cl<sup>+</sup>]) signals; and 6) BB-OC: BB particles with  
425 strong organic carbon peaks (e.g.,  $m/z$  27[C<sub>2</sub>H<sub>3</sub><sup>+</sup>], 37[C<sub>3</sub>H<sup>+</sup>], 43[C<sub>3</sub>H<sub>7</sub><sup>+</sup>], 51[C<sub>4</sub>H<sub>3</sub><sup>+</sup>], et  
426 al.). The naming of the chemical classes is based on some of the dominant chemical  
427 species in an attempt to keep the names short. The mass spectra for each particle type  
428 are presented in Figure S5. The percentages of 6 particle types in different modes of  
429 aerodynamic size distribution for 200 nm and 400 nm mobility selected particles are  
430 shown in Figure 3. For 200 nm mobility selected particles, the dominant particle types  
431 were BB-EC and BB-CN. The percentages of particle types within the two  
432 aerodynamic modes differ slightly. Compared with the first mode, the second mode  
433 contains more BB-CN (24.4% vs. 29.6%), more BB-KCl (1.0% vs. 4.3%) and less  
434 BB-EC (32.2% vs. 22.9%). We supposed that the density of each particle type largely  
435 depended on the dominant species. The exact effective density of each particle type  
436 could not be obtained directly while the relative value compared with other particle  
437 types could be inferred from the material density of dominant species. For example,  
438 the BB-KCl type might have higher effective density compared with others since the  
439 dominant composition KCl has a material density of ~1.99 g/cm<sup>3</sup> (Lide, 2008). The  
440 increased BB-KCl type and the decrease of BB-EC (~1.0 g/cm<sup>3</sup>) resulted in a higher  
441 effective density in the second mode than the first mode.

442 The fractional distributions of the 6 particle types for 200 nm and 400 nm  
443 mobility selected particles were apparently different (Figure 3). For 400 nm mobility

444 selected particles, the proportions of BB-Nitrate, BB-Sulfate and BB-KCl types were  
445 larger than those of 200 nm mobility selected particles. The dominant chemical  
446 species for BB-Nitrate and BB-Sulfate particle types could be  $\text{NH}_4\text{NO}_3$  and  
447  $(\text{NH}_4)_2\text{SO}_4$  with material density of  $\sim 1.75 \text{ g/cm}^3$  (Lide, 2008). Compared with other  
448 types, BB-Nitrate, BB-Sulfate and BB-KCl were particle types with higher density.  
449 However, the effective density for 400 nm mobility selected particles was lower than  
450 that of 200 nm. In addition to the compositional differences, particle morphology  
451 could be another reason responsible for the observed differences in the effective  
452 densities between these two sizes. Indeed, it has been found that the morphology like  
453 void ratio, particle shape factor, and fractal dimension of particles all greatly affect  
454 particle effective density (DeCarlo et al., 2004). Though the shape factor discussed in  
455 Section 3.1 had shown that the 400 nm ( $d_m$ ) particles had a more spherical  
456 morphology, their lower average effective density compared to smaller particles could  
457 be due to the voids in particles. Amorphous species such as  $\text{NH}_4\text{NO}_3$  (Audebrand et  
458 al., 1997) could lead to the low effective density of particles. Thus, we supposed the  
459 lower effective density of 400 nm particles compared with 200 nm particles was  
460 caused by the large proportion of  $\text{NH}_4\text{NO}_3$  and  $(\text{NH}_4)_2\text{SO}_4$  with fluffy material  
461 properties.

462 For 400 nm mobility selected particles, the pie charts of particle type were  
463 almost identical for the first and second modes (as shown in Fig. 3b, 20 °C). Thus, we  
464 assume these two modes were derived from one effective density mode. The  
465 proportion of BB-KCl in the third mode at 840 nm with effective density of  $2.10$   
466  $\text{g/cm}^3$  greatly increased compared with the first two modes (8.8%, 9.2% vs. 32.7%).  
467 The increased BB-KCl indicated that the KCl crystals were external mixed and tended  
468 to be mixed with larger size particles which were consistent with the  
469 DMA-APM-CPC result.

470 Upon heating by TD, the proportions of BB-CN and BB-KCl increased,  
471 indicating that these types of particles were composed of less volatile species (shown  
472 in Figure 3) (Zhai et al., 2015). At 300°C, the fractions of BB-Nitrate and BB-Sulfate  
473 decreased, consistent with the volatilization temperature ranges of ammonium nitrate  
474 ( $\sim 48\text{-}89^\circ\text{C}$ ) and ammonium sulfate ( $\sim 178\text{-}205^\circ\text{C}$ ) (Johnson et al., 2004a; Johnson et  
475 al., 2004b). The high effective density ( $>2.0$ ) of biomass burning particles at 300°C  
476 could be due to the vaporization of volatile organics with low density since the  
477 BB-OC type decreased drastically after thermal treatment. Besides, the increasing  
478 proportion of BB-KCl upon heating could be another important reason for the higher  
479 effective density at 300 °C.

### 480 3.3 Size-resolved optical properties

#### 481 3.3.1 Single scattering albedo (SSA)

482 The single scattering albedo (SSA), was calculated using the following equation:

$$483 \text{SSA}(\lambda) = b_{\text{scat}}(\lambda) / [b_{\text{abs}}(\lambda) + b_{\text{sca}}(\lambda)]$$

484 where  $b_{\text{scat}}$  is the particle light scattering coefficient,  $b_{\text{abs}}$  is the light absorption  
485 coefficient, and  $\lambda$  is wavelength. The light scattering and extinction coefficients ( $b_{\text{ext}}$ ,  
486  $= b_{\text{abs}} + b_{\text{sca}}$ ) for biomass burning particles in this work were measured at 530 nm and

487 450 nm wavelengths using CAPSs.

488 The size-resolved SSAs for biomass burning particles are shown in Figure 4.  
489 Totally, the SSAs for biomass burning particles in the mobility size range of 50-400  
490 nm varied narrowly. It's worth noting that the optical measurement was based on bulk  
491 measurement by CAPSs, which is not sensitive to the diversity of particle mixing  
492 state.

493 The SSA (530 nm) for 50 nm particles was the lowest ( $0.889 \pm 0.006$ ) as the  
494 percentage of strong light-absorbing black carbon for particles in this size range was  
495 larger (shown in Figure 3, discussed in Section 3.2). For 100-400 nm biomass burning  
496 particles, the SSAs were relatively steady ( $0.897 \pm 0.006$  -  $0.900 \pm 0.006$ ).

497 The size-resolved SSAs at 450 nm ( $\lambda$ ) for biomass burning particles were  
498 generally lower than those at 530 nm ( $\lambda$ ). Previous studies have shown that biomass  
499 burning was an important source of brown carbon (BrC) which is light-absorbing in  
500 the UV-vis range (Lack and Cappa, 2010). For 50 nm ( $d_m$ ) particles, the SSA ( $\lambda=450$   
501 nm) was also the lowest, due to the dominance of the strong light-absorbing BC in  
502 these particles. However, unlike the trend of size-resolved SSAs ( $\lambda=530$  nm), the SSA  
503 ( $\lambda=450$  nm) of 100-400 nm particles increased as the size increased. It has been  
504 shown that brown carbon arising from biomass burning is primarily composed of  
505 extremely low volatility organic compounds (Saleh et al., 2014). The CN<sup>-</sup> in biomass  
506 burning particles is representative for some extremely low volatility  
507 nitrogen-containing organics (Zhai et al., 2015). As shown in Figure 3, compared with  
508 400 nm particles, the proportion of organic matter (BB-CN, BB-OC) was larger for  
509 200 nm particles. The nitrogen-containing species might indicate the existence of  
510 light-absorbing organics. The lower SSA ( $\lambda=450$  nm) for 200 nm particles might  
511 indicate a larger proportion of BrC. We assumed the lower SSA ( $\lambda=450$  nm) for 100  
512 nm performed in a similar way with a larger proportion of BrC.

### 513 3.3.2 Ångström absorption exponent (AAE)

514 To investigate the wavelength dependence of the absorption coefficients, we  
515 determined the Ångström absorption exponent (AAE) based on absorption  
516 measurements at two different wavelengths ( $\lambda_1$  &  $\lambda_2$ ) using the following equation:

$$517 \text{AAE}(\lambda_1 / \lambda_2) = - \ln[ b_{abs}(\lambda_1) / b_{abs}(\lambda_2) ] / \ln(\lambda_1 / \lambda_2)$$

518 The AAE in this work was calculated from the light absorption coefficients at  
519 wavelengths of 450 nm and 530 nm measured by the CAPSs. The uncertainties in the  
520 calculated AAE values can be caused by the uncertainties in the calibration factors of  
521 CAPSs. The size-resolved AAEs for biomass burning particles are shown in Figure 4.  
522 Black carbon is highly absorbing in the visible spectrum with little variation with  
523 wavelength and shows an AAE of  $\sim 1.0$  (Bergstrom et al., 2002). As brown carbon  
524 species absorb light in the UV-vis range, BrC-containing particles usually exhibit an  
525 AAE above 1 (Martinsson et al., 2015). Lack and Cappa (2010) used modeling to  
526 calculate AAE values and suggested that particles with AAE exceeding 1.6 should be  
527 classified as BrC. In our study, the AAE values of particles in the size range of 50-400  
528 nm were higher than 1.6, indicating that they were BrC-containing particles from  
529 biomass burning. Among all sizes, the AAE of 50 nm biomass burning particles was

530 the lowest (~5.8) while that of 100 nm particles was the highest (~6.3). The main  
531 light-absorbing functional groups in the UV-vis range is conjugated double bond  
532 (Laskin et al., 2015). BB-CN and BB-OC particle types identified by mass spectra in  
533 our work tended to contain more large molecules of BrC with light-absorbing  
534 functional groups. We noticed that the proportion of BB-OC type species was larger in  
535 200 nm particles (Figure 3) and with higher AAE value, compared with 400 nm  
536 particles. Thus, we suppose the highest AAE value observed for 100 nm particles  
537 might be the result of the largest BrC proportion.

538 The SSA and AAE values of total biomass burning particles are shown in Table  
539 S2. The decrease of SSA values upon heating was due to the vaporization of  
540 secondary inorganic species like  $\text{NH}_4\text{NO}_3$  and less absorbing organics. The AAE  
541 values for all particles at 150 °C and 300 °C were ~19% and ~64%, lower than those  
542 at room temperature (20 °C). The significant decrease of AAE at 300 °C could be due  
543 to the vaporization of light-absorbing organics in the temperature range of 150-300 °C.  
544 However, the AAE value at 300 °C was still above 1.6, indicating the presence of  
545 extremely low volatility light-absorbing organics in biomass burning particles.  
546 McMeeking et al. (2014) found that the strongly light-absorbing biomass burning  
547 particles tended to have a weak wavelength dependent absorption while the weakly  
548 light-absorbing particles tended to have a strong wavelength dependent absorption,  
549 which is consistent with our results. In this work, the high values of AAE (~ 6.23) and  
550 SSA (~0.89, at 530 nm) suggested the light absorbing of rice straw burning particles  
551 were relatively weak compared to the particles emitted from other types of biofuels.

## 552 **4 Conclusions**

553 As a major primary source of aerosols, biomass burning emissions significantly  
554 impact the global radiative budget. It is important to understand the physical and  
555 chemical properties of biomass burning particles, as well as their links to optical  
556 properties. In this work, rice straw was combusted as a representative material of  
557 biomass burning in Southern China. A series of comprehensive methods was used to  
558 detect the size-resolved chemical composition, effective density, and optical  
559 properties of the particles emitted from the burns.

560 Two methods were utilized to measure the effective density of the biomass  
561 burning particles. The DMA-APM-CPC system, which has been widely used in  
562 chamber and field work, offered size-resolved information on the particle effective  
563 density. The DMA-SPAMS system provided physical property and chemical  
564 composition at single-particle level. The 50 nm ( $d_m$ ) biomass burning particles had the  
565 lowest effective density of  $1.15 \pm 0.23 \text{ g/cm}^3$ , which was due to the large proportion  
566 of fractal black carbon. The apparent single-peak density distribution of 50 nm  
567 particles was due to the combination of two modes (BC and organic matter,  
568 respectively). The independent modes at 0.9-1.1  $\text{g/cm}^3$  shown in the density  
569 distribution of 100 nm and 200 nm particles and ~1.92  $\text{g/cm}^3$  mode shown in that of  
570 400 nm particles indicated that BC and crystalline species such as KCl in fresh  
571 biomass burning particles tended to be externally mixed with organic carbon. With  
572 heating by TD, the separation of the effective density distribution modes testified the

573 presence of BC, potassium salts and less volatile OC in the biomass burning particles.

574 The effective density measured by DMA-SPAMS system was consistent with the  
575 result by DMA-APM-CPC method. The dominant modes in the effective density  
576 distributions of 200 nm and 400 nm mobility selected particles were  $1.40 \text{ g/cm}^3$  and  
577  $1.35 \text{ g/cm}^3$ , respectively. The crystalline KCl with an effective density of  $2.10 \text{ g/cm}^3$   
578 (with BB-KCl type accounting for 32.7%) was observed in the density distribution for  
579 400 nm particles measured by DMA-SPAMS. The proportions of BB-Nitrate,  
580 BB-Sulfate, and BB-KCl types in 400 nm mobility selected particles were larger than  
581 those in 200 nm mobility selected particles. Compared with 200 nm particles, 400 nm  
582 particles showed more spherical morphology but lower effective density, which could  
583 be due to the larger proportion of low density organics and amorphous  $\text{NH}_4\text{NO}_3$ .

584 The size-resolved extinction and scattering coefficients were measured by  
585 CAPSs at wavelengths of 450 nm and 530 nm. The SSA ( $\lambda=530 \text{ nm}$ ) for 50 nm  
586 particles was the lowest ( $0.889 \pm 0.006$ ) because of the presence of a larger percentage  
587 of the strongly light-absorbing black carbon particles in this size mode. The  
588 size-resolved SSAs ( $\lambda=450 \text{ nm}$ ) for biomass burning particles were generally lower  
589 than the SSAs ( $\lambda=530 \text{ nm}$ ). The AAE values in the size range of 50-400 nm particles  
590 were all above 1.6, indicating the significant presence of brown carbon in all sizes.  
591 The AAE value was the lowest for 50 nm particles ( $\sim 5.8$ ) while was the highest for  
592 100 nm particles ( $\sim 6.3$ ). Compared with 400 nm particles, the proportions of BB-OC  
593 and BB-CN, the extremely low volatility organic compounds, were larger for 200 nm  
594 particles which might indicate a higher possibility for the existence of light-absorbing  
595 organics. Our work emphasizes on the complex mixing states of aerosols from  
596 primary source. Further research on how particle morphology affects the optical  
597 properties of biomass burning particles is needed.

837 Figure 1. Schematic of the instrumental setup. The CAPS, DMA, CPC, APM and  
838 SPAMS represent Cavity Attenuated Phase Shift spectroscopy, Differential Mobility  
839 Analyzer, Condensation Particle Counter, Aerosol Particle Mass analyzer and Single  
840 Particle Aerosol Mass Spectrometer, respectively.

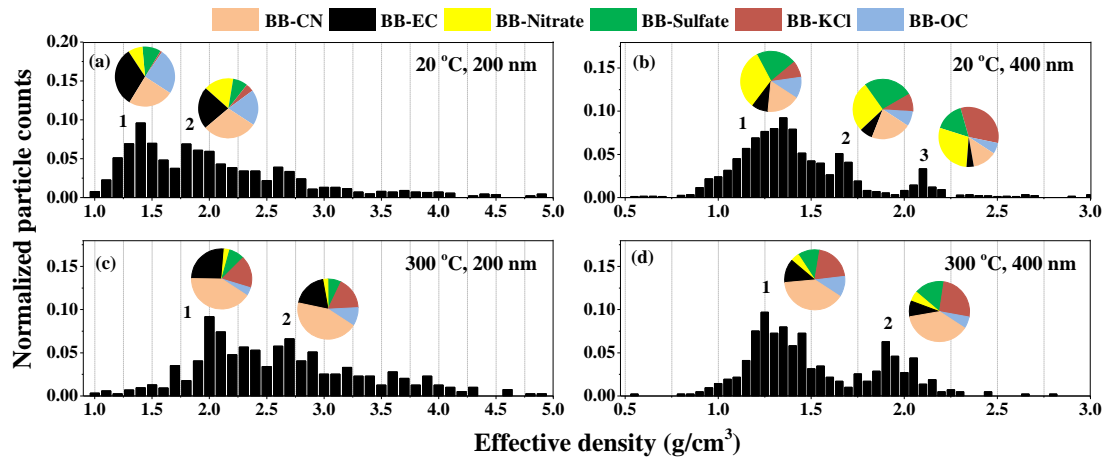

841

842

843 Figure 2. Average density distributions of 50, 100, 200, and 400 nm particles selected  
 844 by DMA at 20 °C (room temperature), 150 °C, and 300 °C. Gaussian model was  
 845 applied in fitting each density scan (red and green lines). Black dashes were the  
 846 assumption Gaussian models application.

847

848

849 Figure 3. Vacuum aerodynamic size distributions detected by the SPAMS of 200 nm  
 850 and 400 nm electrical mobility size-selected biomass burning particles and pie charts  
 851 for the particle types in different aerodynamic modes at 20 °C (room temperature) and  
 852 300 °C.

853

854

855 Figure 4. (a)-(b): Size-resolved single scattering albedo (SSA) at wavelengths of 530  
 856 nm and 450 nm. (c): Ångström absorption exponent (AAE) of biomass burning  
 857 particles at room temperature (20°C).
