**Abstract.** Emission of nitrogen oxide ( $\text{NO}_x = \text{NO} + \text{NO}_2$ ) from the photolysis of nitrate ( $\text{NO}_3^-$ ) in snow affect the oxidising capacity of the lower troposphere especially in remote regions, of high latitudes with little pollution. Current air-snow exchange models are limited by poor understanding of processes and often require unphysical tuning parameters. Here, two physical multi-phase models were developed from first principles to describe the interaction of nitrate between the surface layer of the snowpack and the overlying atmosphere. The first model is similar to previous approaches and assumes that below a threshold temperature,  $T_o$ , the air-snow grain interface is pure ice and above  $T_o$ , a disordered interface (DI) emerges covering the entire grain surface. The second model assumes that air-ice interactions dominate over all temperatures below melting of ice and that any liquid is concentrated in micropockets above the eutectic temperature. The models are used to predict the nitrate in surface snow with available year-round observations of mixing ratios of nitric acid in air at a cold site on the Antarctic Plateau (Dome C, 75°06'S, 123°33'E, 3233 m a.s.l.) and at a relatively warm site on the Antarctic coast (Halley, 75°35'S, 26°39'E, 35 m a.s.l.). The first model agrees reasonably well with observations at Dome C ( $C_v(\text{RMSE}) = 1.34$ ), but performs poorly at Halley ( $C_v(\text{RMSE}) = 89.28$ ) while the second model reproduces with good agreement observations at both sites ( $C_v(\text{RMSE}) = 0.84$  at both sites). It is therefore suggested that in winter air-snow interactions of nitrate are determined by non-equilibrium surface adsorption and co-condensation on ice coupled with solid-state diffusion inside the grain, similar to Bock et al. (2016). In summer, however, the air-snow exchange of nitrate is mainly driven by solvation into liquid micropockets following Henry's law with contributions to total surface snow  $\text{NO}_3^-$  concentrations of 75% and 80% at Dome C and Halley respectively. It is also found that liquid volume of the snow grain and air-

micropocket partitioning of  $\text{HNO}_3$  are sensitive to both the total solute concentration of mineral ions within the snow and pH of the snow. The second model can be used to predict nitrate concentration in the surface snow layer over the entire range of environmental conditions typical for Antarctica 25 and forms a basis for a future full 1D snowpack model as well as parameterisations in regional or global atmospheric chemistry models.

## 1 Introduction

Emissions of nitrogen oxides,  $\text{NO}_x = \text{NO} + \text{NO}_2$ , from snow to the overlying air as a result of photolysis of the nitrate anion,  $\text{NO}_3^-$ , within snow have been observed in polar (Jones et al., 2001; Beine 30 et al., 2002) and midlatitude regions (Honrath et al., 2000). They were found to have a significant impact on the oxidising capacity of the atmospheric boundary layer, especially in remote areas, such as the polar regions, where anthropogenic pollution is small (Grannas et al., 2007). The cycling of NO and  $\text{NO}_2$  in the troposphere alters the concentration of tropospheric ozone,  $\text{O}_3$ , partitioning of hydroxy radicals,  $\text{HO}_x$ , and organic peroxy radicals,  $\text{RO}_x$ . Tropospheric ozone is a pollutant and a 35 greenhouse gas, and changes in the concentration can impact the regional energy balance and therefore climate (Fowler et al., 2008). Conversely,  $\text{HO}_x$  radicals are responsible for removal of many atmospheric pollutants (e.g. Gligorovski et al., 2015), such as the greenhouse gas methane, and  $\text{RO}_x$  radicals play an important role in the oxidation of volatile organic compounds (VOCs). Moreover, the post-depositional nitrate loss from snowpacks in complicated the interpretation of polar ice core 40 nitrate. To extract paleoclimatic information from the ice core, the interactions between the atmosphere and the snowpack need to be understood.

The exchange of nitric acid,  $\text{HNO}_3$ , between the atmosphere or snow interstitial air (SIA) and snow grains is complex, and is controlled by chemical and physical processes. The relative contribution of the chemical and physical processes has been a matter of debate (Röthlisberger et al., 45 2000). Isotopic studies (Frey et al., 2009; Erbland et al., 2013) have shown photolysis of  $\text{NO}_3^-$  is the dominating loss process of  $\text{NO}_3^-$  in snow. Based on a typical photolysis rate coefficient of nitrate,  $J_{\text{NO}_3^-} \approx 1 \times 10^{-7} \text{ s}^{-1}$  (at the surface in Dome C at a solar zenith angle of 52°, France et al. (2011)), the characteristic time for nitrate photolysis is  $\sim 10^7$  s. The characteristic time of nitrate photolysis is much larger compared to other physical processes near the snowpack surface, such as 50 grain surface adsorption and solid-state diffusion (Table 1). The top few mm of snowpack, hereafter called the skin layer and the focus region of snowpack in this paper, the physical uptake of nitrate is much quicker than the chemical loss due to the availability of nitric acid at the snowpack surface. Therefore, it is assumed that the chemical processes are negligible and consider only the physical processes. The skin layer is defined as the top 4 mm of the snowpack, which is the depth of which 55 the surface snow nitrate samples were collected at Dome C (Sect. 4.1).

The physical exchange of nitric acid,  $\text{HNO}_3$ , between the atmosphere or snow interstitial air (SIA) and snow grain are complex. Gaseous  $\text{HNO}_3$  can be taken up by different reservoirs in snow, for example the molecule can 1) adsorb on the ice surface; 2) diffuse into the ice crystal and form solid solution; 3) co-condense to the growing ice or 4) dissolve into the liquid solution located in grain 60 boundaries, grooves at triple junctions or quadruple points. Therefore, the air and snow grain form a complex multiphase interface (Bartels-Rausch et al., 2014).

Air-snow models have been developed to predict the exchange of trace gases between the snowpack and the overlying atmosphere and the greatest challenge faced currently is the model description of the air-snow grain interface. One group of models assume a disordered interface, DI, at the snow 65 grain surface with liquid-like properties (e.g. Boxe and Saiz-Lopez, 2008; Thomas et al., 2011; Toyota et al., 2014; Murray et al., 2015). The DI is defined as a thin layer on the surface of the snow grain and is assumed to have the following characteristics; 1) DI reaction and partition rate constants are similar to those in the aqueous phase, e.g. Henry's Law coefficient are used to describe the partitioning between the two phases; 2) DI thickness ranges from <1 to a few hundreds nm (Bartels-Rausch 70 et al., 2014) but is often set to an arbitrary value, e.g. 10 nm (Thomas et al., 2011) and Murray et al., 2015; 3) These models also assume all (Toyota et al., 2014) or a fraction (Thomas et al., 2011; Murray et al., 2015) of the total solutes are located in the DI.

Another groups of models assume the interface between snow grain and surrounding air to be ice (e.g. Hutterli et al., 2003; Bock et al., 2016). The distribution of hydrogen peroxide,  $\text{H}_2\text{O}_2$ , and 75 formaldehyde,  $\text{HCHO}$ , within the snowpack has been estimated using a physical air-snow and firn transfer model which included a temperature driven 'Air-Ice' uptake and release (Hutterli et al., 2003; McConnell et al., 1998). The air-ice exchange of  $\text{H}_2\text{O}_2$  is defined by solid-state diffusion of  $\text{H}_2\text{O}_2$  whereas the exchange of  $\text{HCHO}$  is described by linear adsorption isotherm of  $\text{H}_2\text{O}_2$  on ice. A physical exchange model has been developed by Bock et al. (2016) to describe the concentration of 80  $\text{NO}_3^-$  in the skin layer at Dome C, East Antarctic Plateau. Bock et al. (2016) proposed the skin layer snow nitrate concentration at Dome C is determined by thermodynamic equilibrium ice solubility on the grain surface (based on a parameterisation by Thibert et al., 1998) followed by solid-state diffusion during winter. During summer the large increase in  $\text{NO}_3^-$  concentration in the skin layer snow is mainly from co-condensation of  $\text{HNO}_3$  and  $\text{H}_2\text{O}$  (a kinetic process). The model of Bock 85 et al. (2016) implies no loss of  $\text{NO}_3^-$  due to sublimation, a process that has been suggested to be important in surface snow dynamic (Röthlisberger et al., 2000). Both types of models require tuning parameters, for example fraction of solute in the DI (Thomas et al., 2011), ion partitioning coefficients (Hutterli and Röthlisberger, 1999), or co-condensation parameter (Bock et al., 2016), to match the model predictions with the field observations and hence are of limited predictive capacity.

90 The aim of this paper is to develop a physical exchange model from first principles to describe the exchange of nitrate between the atmosphere and the skin layer of snow minimising the number of tuning parameters and is a first step towards a full snowpack model that would include deeper

snow and other processes, such as wind pumping, molecular diffusion, and photochemistry. Two temperature dependent, multi-phase models, are developed to evaluate two different concepts to 95 describe the interaction of nitrate between air and snow. Model 1 is based on the hypothesis of the existence of a DI layer covering the entire snow grain above a threshold temperature,  $T_o$  (Sect. 3.1). Below  $T_o$ , the interface between snow grain and air is assumed to be ‘Air-Ice’, and the grain surface concentration of  $\text{NO}_3^-$  is determined by non-equilibrium surface adsorption and co-condensation coupled with solid-state diffusion into the grain. Above  $T_o$ , the interface is assumed to be ‘Air-DI’ of 100 which the  $\text{NO}_3^-$  concentration is defined by non-equilibrium solvation into the DI followed by solid-state diffusion. Model 2 is based on the hypothesis of Domine et al. (2013), that liquid co-exists with ice above eutectic temperature,  $T_e$ . The liquid forms micropockets and locate in grooves at grain boundaries or triple junctions due to limited wettability of ice (Domine et al., 2013). Therefore, at all temperatures below melting the major interface between air and snow grain is assumed to be pure 105 ice. Above  $T_e$ , the partitioning of  $\text{HNO}_3$  to the micropockets is described by Henry’s Law (Sect. 3.2). Both models are validated with data collected at two sites in Antarctica that have very different atmospheric composition, temperatures and humidities; The East Antarctic Plateau at Dome C and secondly coastal Antarctica at Halley, where long-term atmospheric and meteorological observations are monitored at the Clean Air Sector Laboratory (CASLab) (Jones et al., 2008).

## 110 2 Current Understanding of Physical Air-Snow Processes

Below we briefly review the current understanding of physical air-snow processes, which are relevant to nitrate. A more comprehensive discussion can be found in the recent review paper (Bartels-Rausch et al., 2014).

### 2.1 Surface Adsorption at the Air-Ice Interface

115 The probability of a gas molecule being adsorbed on a clean ice surface can be described by the dimensionless surface accommodation coefficient,  $\alpha$  (Crowley et al., 2010). The adsorbed molecule can then be desorbed thermally or it can be dissociated and diffuse into the bulk and form a solid solution (Abbatt, 1997; Huthwelker et al., 2004; Cox et al., 2005). At a low partial pressure of  $\text{HNO}_3$ , the adsorption of  $\text{HNO}_3$  on an ice surface can be expressed as the single-site Langmuir adsorption 120 (Ullerstam et al., 2005b) with:

where  $\text{HNO}_{3,(\text{g})}$  and  $\text{HNO}_{3,(\text{ads})}$  are the gas-phase and surface adsorbed nitric acid.  $[\text{S}]$  is the concentration of surface sites, i.e. number of site available per unit volume of air and has a units of molecule  $\text{m}^{-3}$ . It is defined as follows:

$$125 \quad [\text{S}] = (1 - \theta) N_{\text{max}} \frac{A_{\text{ice}}}{V_{\text{air}}} \quad (1)$$

Here,  $\theta$  is the fraction of available surface sites being occupied,  $N_{max}$  is the maximum number of surface sites with a unit of molecule  $m_{ice}^{-2}$ ,  $A_{ice}$  is the surface area of ice per unit volume of snowpack with a unit of  $m_{ice}^2 m_{snowpack}^{-3}$ , and  $V_{air}$  is the volume of air per unit volume of snowpack with a unit of  $m_{air}^3 m_{snowpack}^{-3}$ . The adsorption coefficient,  $k_{ads}$ , and desorption coefficient,  $k_{des}$ , in R1 are

130 defined as

$$k_{ads} = \frac{\alpha \bar{v}}{4} \frac{1}{N_{max}} \quad (2)$$

$$k_{des} = \frac{k_{ads}}{K_{eq}} \quad (3)$$

Note that  $k_{ads}$  has a unit of  $m^3 \text{molecule}^{-1} \text{s}^{-1}$  while the unit of  $k_{des}$  is  $\text{s}^{-1}$ ,  $\bar{v}$  is the average gas-phase molecular speed and  $K_{eq}$  is the equilibrium constant for Langmuir adsorption on ice with a unit of  $m^3 \text{molecule}^{-1}$ . The value of  $K_{eq}$  for  $\text{HNO}_3$  is inversely correlated with temperature because the scavenging efficiency of  $\text{HNO}_3$  due to adsorption increases as temperature decreases. The parameterisations and values for the above variables used in this study are listed in App. A Table A1. A comparison of different parameterisations of  $\alpha$  and  $K_{eq}$  are shown in App. A Fig. A1 and A2 respectively.

140 **2.2 Solid-State Diffusion**

A solid solution of  $\text{HNO}_3$  can be formed in ice due to its solubility and diffusivity. The solid-state diffusion in natural snow is found to be an important process for understanding the partitioning of highly soluble gases, including  $\text{HNO}_3$ , between atmosphere and snow when interpreting the composition of environmental ice (Bartels-Rausch et al., 2014). Thibert et al. (1998) derived a solid-state 145 diffusion coefficient,  $k_{diff}$ , and a thermodynamic solubility of  $\text{HNO}_3$  in ice from sets of  $\text{HNO}_3$  concentration - diffusion profiles obtained by exposing single ice crystal to diluted  $\text{HNO}_3$  at different temperatures for a period of days to weeks. However, Thibert et al. (1998) did not present the the kinetics of  $\text{HNO}_3$  uptake on ice and a characteristic time for equilibrium between air and ice could not be established. A diffusion-like behaviour has been observed from flow-tube studies for trace 150 gas uptake onto ice (e.g. Abbatt, 1997; Huthwelker et al., 2004; Cox et al., 2005) suggesting the solid-state diffusion of nitrate molecules can occur concurrently with surface adsorption, such that

where  $\text{HNO}_3, \text{(ice)}$  is the nitric acid incorporated into the ice matrix, occurs with R1.

**2.3 Coexistence of Liquid Solution with Ice**

155 Liquid aqueous solution coexists with ice in the presence of soluble impurities, such as sea salt and acids. The liquid exist down to the eutectic temperature defined by the composition and solubility of the impurities in the ice. Cho et al. (2002) parameterised the liquid water fraction,  $\phi_{\text{H}_2\text{O}}(T)$ , as a

function of total ionic concentration of impurities,  $\text{Ion}_{\text{tot}}$ , and temperature as follows:

$$\phi_{\text{H}_2\text{O}}(T) = \frac{\bar{m}_{\text{H}_2\text{O}}RT_f}{1000\Delta H_f^0} \left( \frac{T}{T_f - T} \right) \Phi_{\text{bulk}}^{\text{aq}} [\text{Ion}_{\text{tot, bulk}}] \quad (4)$$

160 where  $\phi_{\text{H}_2\text{O}}(T)$  has a units of  $\text{m}_{\text{liquid}}^3 \text{m}_{\text{ice}}^{-3}$ ,  $\bar{m}_{\text{H}_2\text{O}}$  is the molecular weight of water,  $R$  is the ideal gas constant,  $T_f$  is the freezing temperature of pure water in K,  $\Delta H_f^0$  is the enthalpy of fusion in  $\text{J mol}^{-1}$ ,  $\Phi_{\text{bulk}}^{\text{aq}}$  is the fraction of the total solute in the aqueous phase and  $[\text{Ion}_{\text{tot, bulk}}]$  is the total ionic concentration in the melted sample. There are different hypotheses on the location of the liquid solution. Most studies assume the liquid solution forms a thin layer covering the whole  
165 grain surface (e.g. Kuo et al., 2011) while Domine et al. (2013) suggested the liquid is located in grooves at grain boundaries and triple junctions. The arguments of the latter study were 1) the ionic concentration is low in natural snow that only small amount of liquid can be formed; and 2) the wettability of liquid water on ice is imperfect, preventing the liquid drop from spreading out across the solid surface. The volume of liquid is small relative to the ice grain and if spread uniformly  
170 across the ice grain the thickness would be less than a molecule which is unrealistic.

The partitioning of trace gases between air and the liquid fraction of snow can be described by Henry's law using the effective dimensionless Henry's law coefficient,  $k_{\text{H}}^{\text{eff}}$ , according to Sander (1999)

$$k_{\text{H}}^{\text{eff}} = k_{\text{H}}^{\text{cc}} \frac{K_{\text{a}}}{[\text{H}_{\text{(aq)}}^+]} \quad (5)$$

175 where  $k_{\text{H}}^{\text{cc}}$  is the dimensionless temperature dependent Henry's Law coefficient (See App. A),  $K_{\text{a}}$  is the acid dissociation constant and  $[\text{H}_{\text{(aq)}}^+]$  is the concentration of hydrogen ions. Fig. A4 shows the temperature and pH dependence of  $k_{\text{H}}^{\text{eff}}$ . At a given pH,  $k_{\text{H}}^{\text{eff}}$  varies by a 2 orders of magnitude between  $-40^{\circ}\text{C}$  and  $0^{\circ}\text{C}$ . While at a given temperature,  $k_{\text{H}}^{\text{eff}}$  varies within one order of magnitude (See Fig. A4), for typical pH value of natural surface snow (5 - 6.5, Udisti et al., 2004).

### 180 3 Modelling Approach

The model constraints are the observed atmospheric concentration of  $\text{HNO}_3$ , air temperature, skin layer temperature, atmospheric pressure and humidity. The loss or gain in the atmospheric concentration of  $\text{HNO}_3$  due to the mass exchange between air and snow are included implicitly by constraining the models with the observed atmospheric concentration of  $\text{HNO}_3$ . The aim of this paper  
185 is to focus on the exchange mechanisms of  $\text{HNO}_3$  between air and snow to predict the concentration of nitrate in snow, limited to the skin layer, as a first step towards a full snowpack model. The following assumptions were made, 1) homogenous physical properties across the skin layer, such as snow density and specific surface area (SSA). 2) the concentration of  $\text{HNO}_3$  in SIA is the same as the overlying atmosphere due to a short characteristic time scale of  $\sim 10^0$  s (Table 1).

190 For simplicity, the snow grain is assumed to be a radially symmetrical sphere with a radius,  $R_{\text{eff}}$ , which is estimated from the SSA as the follows:

$$R_{\text{eff}} = \frac{3}{\rho_{\text{ice}} \text{SSA}} \quad (6)$$

where  $\rho_{\text{ice}}$  is the density of ice. In addition, the grain morphology is also assumed to be constant, i.e. snow metamorphism is not taken into account.

195 **3.1 Model 1 - Surface Adsorption/Solvation & Solid Diffusion**

In Model 1, the uptake of  $\text{HNO}_3$  is treated as a two-step process consisting of interfacial mass transport across the air-snow grain boundary and subsequent diffusion into the bulk. Below a threshold temperature,  $T_0$ , (Sect. 3.1.1 & Fig. 1a) the concentration of nitrate at the snow grain boundary is defined by the combination of adsorption and co-condensation. Above  $T_0$ , the snow grain boundary 200 concentration is defined by solvation governed by Henry's law into the disordered interface, DI, (See Sect. 3.1.2 & Fig. 1b). A DI on pure ice has been detected between 238 and 270 K depending on the measurement technique (Domine et al., 2013 and references therein). The threshold temperature,  $T_0$ , for the work described here is set to the lower end of the range (238 K). The difference in concentration of nitrate between the grain boundary and its centre drives the transport of  $\text{NO}_3^-$  within 205 the grain, which can be characterised by the solid-state diffusion of  $\text{NO}_3^-$  (Sect. 3.1.3).

**3.1.1 Ambient Temperature  $\leq 238$  K: Non-Equilibrium Surface Adsorption & Co-condensation**

At a temperature below  $T_0 = 238$  K the interface between air and snow grain is assumed to be pure ice. The concentration of nitrate at the grain boundary,  $[\text{HNO}_3(\text{surf})]$ , is determined by a combination of non-equilibrium kinetic adsorption and co-condensation:

210  $[\text{HNO}_3(\text{surf})] = [\text{HNO}_3(\text{ads})] + [\text{HNO}_3(\text{cc})] \quad \text{if } T \leq 238\text{K} \quad (7)$

where  $[\text{HNO}_3(\text{ads})]$  is the concentration contributed by the sum of surface adsorption and desorption (Eq. 8), and  $[\text{HNO}_3(\text{cc})]$  is the concentration contributed by co-condensation or co-sublimation (Eq. 9).

A non-equilibrium kinetic approach is taken instead of saturation or equilibrium adsorption for 215 two main reasons: Firstly, Ullerstam et al. (2005b) have shown that for partial pressures of  $\text{HNO}_3$  lower than  $10^{-5}$  Pa the ice surface is not entirely covered and therefore undersaturated. The annual average atmospheric partial pressure of  $\text{HNO}_3$  recorded at Dome C is  $\sim 10^{-6}$  Pa (Traversi et al., 2014) and is  $\sim 10^{-7}$  Pa at Halley (Jones et al., 2008), hence, the ice surface is unlikely to be saturated with  $\text{HNO}_3$ . Secondly, natural snowpacks are constantly undergoing sublimation and 220 condensation of  $\text{H}_2\text{O}$ , especially at the skin layer, due to temperature gradient over a range of timescales from a fraction of seconds to days and seasons (Bartels-Rausch et al., 2014). Pinzer et al. (2012) observed up to 60% of the total ice mass redistributed under a constant temperature gradient of 50

K m<sup>-1</sup> over a 12 hour period. Field observations (Frey et al., 2013) and the results from a heat transfer model (Hutterli et al., 2003) at Dome C in summer show absolute temperature gradients of 225 71 K m<sup>-1</sup> across the top 2 cm and 130 K m<sup>-1</sup> across the top 4 mm of the snowpack, respectively. At Halley, the modelled summer absolute temperature gradient in the top cm of snow is about 41 K m<sup>-1</sup>. Therefore, the dynamic H<sub>2</sub>O exchange and redistribution at the snow grain surface prevent the equilibrium of adsorption from being reached and require a kinetic approach. The net rate of adsorption can be described as  $\frac{d[\text{HNO}_3(\text{ads})]}{dt} = k_{\text{ads}}[\text{HNO}_3(\text{g})][\text{S}] - k_{\text{des}}[\text{HNO}_3(\text{ads})]$ . Substituting 230  $k_{\text{des}}$  with Eq. (3), the net adsorption rate is expressed as

$$\frac{d[\text{HNO}_3(\text{ads})]}{dt} = k_{\text{ads}} \left( [\text{HNO}_3(\text{g})][\text{S}] - \frac{[\text{HNO}_3(\text{ads})]}{K_{\text{eq}}} \right) \quad (8)$$

The temperature gradient and relative humidity gradient between the surface of the snowpack and the skin layer create a gradient in water vapour pressure, which drives condensation or sublimation of ice, depending on the sign of the gradient. Uptake of HNO<sub>3</sub> molecules to growing ice is known as co-235 condensation. The surface concentration of NO<sub>3</sub><sup>-</sup> contributed by co-condensation or co-sublimation, [HNO<sub>3(cc)</sub>], is given by

$$[\text{HNO}_3(\text{cc})] = X_{\text{HNO}_3} \frac{\rho_{\text{ice}} N_A}{\bar{m}_{\text{H}_2\text{O}}} \frac{\Delta t}{V_{\text{grain}}} \frac{dV}{dt} \quad (9)$$

where  $X_{\text{HNO}_3}$  is the mole fraction of HNO<sub>3</sub> condensed along with water vapour ( $X_{\text{HNO}_3} = 10^{-3.2} P_{\text{HNO}_3}^{0.56}$ , Ullerstam and Abbatt, 2005a),  $\rho_{\text{ice}}$  is the density of ice (in kg m<sup>-3</sup>),  $N_A$  is Avogadro's constant 240 (6.022 × 10<sup>23</sup> molecule mol<sup>-1</sup>) and  $\Delta t$  is the model time step. The rate of volume change of snow grain,  $\frac{dV}{dt}$ , is specified by the growth law by described (Flanner and Zender, 2006)

$$\frac{dV}{dt} = \frac{4\pi R_{\text{eff}}^2}{\rho_{\text{ice}}} D_v \left( \frac{d\rho_v}{dx} \right)_{x=r} \quad (10)$$

where  $D_v$  is the diffusivity of water vapour in air and  $\frac{d\rho_v}{dx}$  is the local water vapour density gradient, i.e. between air away from the snow grain and the air near the grain surface. However, to the author's 245 knowledge there are no observations reported and the calculation of water vapour density at these microscopic scales is computational costly as it would require 3-D modelling of the metamorphism of the snow grain. For simplicity, the macroscopic (few mm) water vapour gradient across the skin layer was used to estimate the rate of volume change of snow grain due to condensation or sublimation, i.e.  $\left( \frac{d\rho_v}{dx} \right)_{x=r}$  in Eq. 10 is replaced by  $\left( \frac{d\rho_v}{dz} \right)_{z=4\text{mm}}$ . The water vapour density,  $\rho_v$ , can be 250 calculated as follows:

$$\rho_v = \frac{P_{\text{sat}} \text{RH}}{100 R_v T} \quad (11)$$

where  $P_{\text{sat}}$  is the saturated vapour pressure (Pa), RH is the relative humidity (%),  $R_v$  is the gas constant (J kg<sup>-1</sup> K<sup>-1</sup>) and  $T$  is temperature (K). There are no measurements of fine resolution of vertical snow profile of RH and temperature available, therefore, RH within the snowpack was as-255 sumed to be 100% and the temperature of the skin layer is estimated using a heat transfer temperature

model based on the heat diffusion equation (Hutterli et al., 2003):

$$\frac{\partial T}{\partial t} = \frac{\partial}{\partial z} k_w(z) \frac{\partial T}{\partial z} \quad (12)$$

where  $T$  is the temperature,  $t$  is time,  $k_w$  is the thermal conductivity (App. A) of snowpack and  $z$  is the depth.

### 260 3.1.2 Ambient Temperature > 238 K: Non-Equilibrium Solvation

At temperature above  $T_0 = 238$  K the interface between air and snow grain surface is assumed to be a DI. The DI is assumed to be covering the entire grain surface and the partitioning into the DI based on Henry's law. The grain boundary concentration is determined by non-equilibrium solvation into the DI such that

$$265 \quad [\text{HNO}_3(\text{surf})] = [\text{HNO}_3(\text{DI})] \quad \text{if } T > 238\text{K} \quad (13)$$

The DI is also assumed to be out of equilibrium with the surrounding air for similar reasons as discussed above (Sect. 3.1.1). The grain boundary concentration is then defined by the following equation:

$$\frac{d[\text{HNO}_3(\text{DI})]}{dt} = k_{\text{mt}} \left( [\text{HNO}_3(\text{g})] - \frac{[\text{HNO}_3(\text{DI})]}{k_{\text{H}}^{\text{eff}}} \right) \quad (14)$$

270 The mass-transfer coefficient,  $k_{\text{mt}}$ , is defined as  $k_{\text{mt}} = \left( \frac{R_{\text{eff}}^2}{3D_g} + \frac{4R_{\text{eff}}}{3\bar{v}\alpha} \right)^{-1}$ , where  $D_g$  is the gas-phase diffusivity (Sander, 1999). Note that in this model the DI is treated as the boundary between the air and bulk ice. The concentration of the DI is used as the outermost boundary condition for solid-state diffusion within the grain, therefore, the DI has no thickness.

### 3.1.3 Solid-State Diffusion

275 The concentration gradient between the grain boundary and its centre drives solid state diffusion of nitrate within the bulk ice. The concentration at the grain boundary is defined by surface adsorption and co-condensation at temperatures below  $T_0$  or solvation into the DI at temperatures above  $T_0$ , discussed above. The  $\text{NO}_3^-$  concentration profile within the snow grain can be found by solving the following partial differential equation

$$280 \quad \frac{\partial[\text{NO}_3^-](r)}{\partial t} = k_{\text{diff}} \left( \frac{2}{r} \frac{\partial[\text{NO}_3^-](r)}{\partial r} + \frac{\partial^2[\text{NO}_3^-](r)}{\partial r^2} \right) \quad (15)$$

where  $[\text{NO}_3^-](r)$  is the local  $\text{NO}_3^-$  concentration in the  $r^{\text{th}}$  concentric layer of the ice sphere and  $k_{\text{diff}}$  is the solid state diffusion coefficient for ice. The typical length-scale,  $\langle x \rangle$ , a molecule diffuses in a given time,  $t$ , can be described by the root-mean square displacement,  $\langle x \rangle = \sqrt{6t k_{\text{diff}}}$ . The typical length-scale,  $\langle x \rangle$ , is 1.5 and 5.5  $\mu\text{m}$  at Dome C (Sect. 4.1) and Halley (Sect. 4.2), respectively, 285 during a model time step of  $\Delta t = 10$  min. To optimise the performance and computational cost of

the models, 85 evenly spread concentric shells (i.e.  $r = 1, 2, 3, \dots, 85$  with 85<sup>th</sup> being the outermost shell) were used to represent the snow grain, such that the thickness of the concentric shell is less than the average root-mean square displacement.

The diffusion equation is solved with the Crank-Nicolson scheme (Press et al., 1996) and the bulk concentration of  $\text{NO}_3^-$  in the ice grain,  $[\text{NO}_3^-]_{\text{(bulk)}}$ , is the sum of the number of  $\text{NO}_3^-$  molecules in each layer divided by the volume of the whole grain, expressed as

$$[\text{NO}_3^-]_{\text{(bulk)}} = \frac{\sum [\text{NO}_3^-](r) V(r)}{\sum V(r)} \quad (16)$$

where  $V(r)$  is the volume of the  $r^{\text{th}}$  layer and  $\sum V(r)$  is the total volume of the grain,  $V_{\text{grain}}$ , and  $[\text{NO}_3^-](r)$  is the concentration of nitrate in the  $r^{\text{th}}$  layer.

295 **3.2 Model 2 - Non-Equilibrium Kinetic Adsorption & Solid Diffusion and Equilibrium Air -  
Liquid Micropocket**

Model 2 is based on the hypothesis that the major air-snow grain interface is pure ice at all temperatures below the melting,  $T_m$ , and that liquid coexists with ice when the temperature is above the eutectic temperature,  $T_e$  (Fig. 2). The liquid water is assumed to be located in grooves at grain boundaries or triple junctions between grains and in the form of micropockets. This assumption implies the grain surface area being covered by liquid water is negligible. The bulk concentration of  $\text{NO}_3^-$  in Model 2 is defined as follows:

$$[\text{NO}_3^-]_{\text{(bulk)}} = \begin{cases} \frac{\sum [\text{NO}_3^-](r) V(r)}{V_{\text{grain}}} & \text{if } T < T_e. \\ \frac{\sum [\text{NO}_3^-](r) V(r)}{V_{\text{grain}}} + \phi_{\text{H}_2\text{O}} k_{\text{H}}^{\text{eff}} [\text{HNO}_3_{\text{(g)}}] & \text{if } T_e \leq T < T_m. \end{cases} \quad (17)$$

At all temperatures below  $T_m$ ,  $\text{HNO}_3$  can be adsorbed/desorbed and co-condensed/co-sublimated from the surface as in Model 1 (Sect. 3.1.1). The adsorbed and co-condensed molecules on the grain surface then diffuse into or out of the bulk ice depending on the concentration gradient of nitrate as in Model 1 Sect. 3.1.3). Above  $T_e$ , liquid co-exists with ice, and its volume can be calculated from the liquid water fraction,  $\phi_{\text{H}_2\text{O}}$  (Eq. 4). The term ' $\phi_{\text{H}_2\text{O}} k_{\text{H}}^{\text{eff}} [\text{HNO}_3_{\text{(g)}}]$ ' in Eq. 17 is the bulk concentration of nitrate contributed from the solvation of nitric acid in the liquid micropockets. The partitioning between air and liquid micropockets is described by Henry's Law, with the effective Henry's Law coefficient,  $k_{\text{H}}^{\text{eff}}$ , as the partitioning coefficient. An instantaneous equilibrium is assumed because 1) the volume of the liquid solution is small ( $10^{-7} - 10^{-6}\%$  of the total volume of the ice grain, discussed below) 2)  $\text{HNO}_3$  is strongly soluble in water; 3) the characteristic time of the interfacial mass transport across a liquid surface of a droplet with 70  $\mu\text{m}$  diameter is only  $\sim 10^{-7}$  s (Table 1); and 4) the diffusion rate is faster in liquid (at 0°C, diffusion of  $\text{NO}_3^-$  is  $9.78 \times 10^{-10} \text{ m}^2 \text{s}^{-1}$  in liquid, Yuan-Hui and Gregory, 1974) than in ice (at 0°C, diffusion of  $\text{NO}_3^-$  is  $3.8 \times 10^{-14} \text{ m}^2 \text{s}^{-1}$  in ice). The characteristic time of liquid-phase diffusion within a 70  $\mu\text{m}$  diameter water droplet is  $\sim 10^0$  s (Table 1).

Both the values of pH and  $\Phi_{\text{bulk}}^{\text{aq}}$  (in Eq. 4) are updated at each model time step with values from the previous time step. At Dome C, the major anion in melted snow is  $\text{NO}_3^-$  (e.g. Udisti et al., 2004). Therefore, it is assumed that nitrate and hydrogen ions are the only ions present in the skin layer snow, i.e.  $[\text{Ion}_{\text{tot}(\text{bulk})}] = 2 \times [\text{NO}_3^-]$  in Eq. 4, and the eutectic temperature of the  $\text{H}_2\text{O}-\text{HNO}_3$  system of 230.64 K (Beyer et al., 2002) are chosen as the threshold temperature for the existence of micropockets. In contrast, at Halley snowpack ion chemistry is dominated by NaCl (Wolff et al., 2008), contributing  $\sim 85\%$  to the total ion concentration in the 2004-05 Halley data set, due to the proximity of sea ice and open ocean. For simplicity, the only anions included in the calculation of  $\phi_{\text{H}_2\text{O}}$  at Halley are  $\text{NO}_3^-$  and  $\text{Cl}^-$ , such that  $[\text{Ion}_{\text{tot}(\text{bulk})}] = 2 \times ([\text{Cl}^-] + [\text{NO}_3^-])$  in Eq. 4 and the value of  $T_e$  used is that for a  $\text{H}_2\text{O}-\text{NaCl}$  system of 251.95 K (Akinfiev et al., 2001).

## 4 Model Validation

Model calculations are constrained and validated with existing observation of atmospheric nitrate, skin layer snow  $\text{NO}_3^-$  concentration and meteorological data at Dome C and Halley. Below a brief summary of the available data is given.

### 4.1 Observation at Dome C

Dome C is characterised by the following: 1) temperatures are below freezing year round, and no snow melt occurs, with an annual mean of  $-52^\circ\text{C}$  and a maximum of  $-17^\circ\text{C}$  in summer (mid November till end of January) and minimum temperature of  $-80^\circ\text{C}$  in winter (April to mid September) (e.g. Argentini et al., 2014). The diurnal temperature variation is  $\sim 10$  K in summer, spring (mid September until mid November) and autumn (February to March). 2) the air-snow chemistry of reactive nitrogen is relatively simple due to the remoteness of the site. In particular, concentrations of sea salt and other particles that scavenge  $\text{HNO}_3$  in the air are low on the East Antarctica Plateau (Legrand et al., 2016). Hence, the main atmospheric nitrate is gaseous  $\text{HNO}_3$  that dissolves in and/or adsorbs onto snow grains (Traversi et al., 2014). 3) Furthermore, a low snow accumulation rate of  $27 \text{ kg m}^{-2} \text{ yr}^{-1}$  (Röthlisberger et al., 2000) allows post-depositional processing of nitrate before the surface snow is buried by new snowfall (e.g. Röthlisberger et al., 2000; Frey et al., 2009).

Observations of skin layer snow nitrate concentration, atmospheric nitrate concentration, temperature, and pressure during January 2009 to 2010 at Dome C are shown in Fig. 3. The snow samples were collected from the ‘skin layer’ snow, the top  $4 \pm 2$  mm of the snowpack, approximately every 3 days. The skin layer was assumed to be spatially heterogeneous with an uncertainty in thickness about 20% due to the softness of the uppermost layer and sampling by different people. The nitrate concentration in the melted sample was measured by ion chromatography (IC) (Erblad et al., 2013).

The concentration of atmospheric nitrate, i.e. the sum of atmospheric particulate nitrate ( $p-\text{NO}_3^-$ ) and the concentration of gaseous nitric acid ( $\text{HNO}_3$ ), was collected on glass fibre filters by high

volume air sampler (HVAS) as described in Morin et al. (2008). Erbland et al. (2013) stated that the concentration of particulate nitrate shows good agreement with  $\text{HNO}_3$  gas-phase concentration measured by denuder tubes at Dome C over the same time period, therefore we equate the observed atmospheric nitrate with gaseous  $\text{HNO}_3$ . The filter was positioned approximately 1 m above the snow surface and changed weekly. The atmospheric boundary layer is assumed to be well mixed so that the atmospheric nitrate at the snowpack surface would be the same at 1 m. The characteristic transport time of  $\text{HNO}_3$  from the snowpack surface to the skin layer (4 mm) is on the order of  $10^0$  s, which is much shorter than the temporal resolution of the model (10 min, Table 1). Therefore, the concentration of  $\text{HNO}_3$  in the skin layer was assumed to be the same as above the snow. The maximum concentration of atmospheric  $\text{HNO}_3$  of  $167 \text{ ng m}^{-3}$  was observed during the summer period, while the minimum concentration of  $1.2 \text{ ng m}^{-3}$  was recorded during the autumn and early winter period.

Continuous meteorological observation and snow science are carried out at Dome C under the 'Routine Meteorological Observations' of the Concordia Project by the Italian National Antarctic Research Programme, PNRA, and the French Polar Institute, IPEV (<http://www.climantartide.it>). Temperature and humidity were measured at 10 s resolution. Both the temperature and relative humidity were measured at 1.6 m above the snow surface with a platinum resistance thermometer (VAISALA PT100 DTS12) with a precision of  $\pm 0.13^\circ\text{C}$  at  $-15^\circ\text{C}$ , and the humidity sensor (HUMICAP, VAISALA) had a precision of  $\pm 2\%$ . Based on the assumption of a well mixed boundary layer, the RH above the snowpack surface was assumed to be the same as that at 1.6 m. Atmospheric nitrate concentrations and meteorological data used as model input have been linearly interpolated to 10 minute resolution.

#### 375 4.2 Observation at Halley

Halley, in coastal Antarctica, is at a similar latitude as Dome C but at sea level in coastal Antarctica, as opposed to the Antarctic Plateau, with very different geographic features. Halley is on the Brunt Ice Shelf and is close to the Weddell Sea in three directions. Hence the temperature, relative humidity, and concentration of atmospheric aerosol are much larger at Halley than Dome C. The average surface temperature in summer days is around  $-10^\circ\text{C}$  and below  $-20^\circ\text{C}$  in the winter. Occasionally, the temperature can rise above  $0^\circ\text{C}$  (surface melt is possible) or drop to  $-55^\circ\text{C}$  (See Fig. 4). The snow accumulation rate at Halley is much larger than at Dome C, which has an average of  $480 \text{ kg m}^{-2} \text{ yr}^{-1}$  (Wolff et al., 2008), limiting post-depositional processes relative to Dome C.

Meteorological and chemical data were collected at Halley under the CHABLIS (Chemistry of the Antarctic Boundary Layer and the Interface with Snow) campaign at the Clean Air Sector Laboratory (CASLab), (details in Jones et al. (2008, 2011)). Measurement of atmospheric concentration of  $\text{HNO}_3$  were carried out at weekly resolution using annular denuders (URG corporation) mounted 7-8 m above the snow surface with a collection efficiency of 91% (Jones et al., 2008). The atmospheric

boundary layer is assumed to be well-mixed that the nitric acid concentration at the snowpack surface  
390 would be the same as at 7-8 m. Surface snow (the top 10 to 25 mm) was collected on a daily basis and the samples were analysed using ion chromatography (IC). Bulk concentrations of the major anions and cations were measured, including  $\text{Cl}^-$  and  $\text{NO}_3^-$  (Wolff et al., 2008). The concentrations were interpolated to the 10 minutes model resolution.

Other meteorological data included 10 minute averages of air temperature by Aspirated PRT, RH  
395 by Humidity probe (Vaisala Corp) and wind speed and direction by Propeller vane. All sensors were at 1 m above the snow surface (Fig. 4). All values were linearly interpolated to the model time step of 10 min.

#### 4.3 Other Model Inputs

There are no available pH measurements of the snowpack, therefore, the pH of the DI in Model 1  
400 and the initial pH in Model 2 is assumed to be 5.6 (Udisti et al., 2004) at both Dome C and Halley. There are no measurement of SSA recorded during 2009-2010 for skin layer snow. The SSA and effective grain radius in this study are estimated based on observation at Dome C from 2012 to 2015 by Picard et al. (2016), as shown in Fig. A3, solid line. No observations of SSA are available for Halley. Therefore the observations of SSA from Dome C were adjusted taking into account the  
405 shorter cold period, which tends to have a larger SSA (Fig. A3, dashed line).

#### 4.4 Statistical Analysis

Three-day running means are calculated from all model outputs to better match the time resolution of the observations. The performance of the models is assessed by the coefficient of variation of RMSE,  $C_v(\text{RMSE})$ , as a goodness of fit. The  $C_v(\text{RMSE})$  is defined as

$$410 \quad C_v(\text{RMSE}) = \frac{\sqrt{\sum_{t=1}^n (obs(t) - model(t))^2 / n}}{\overline{obs}} \quad (18)$$

where  $obs(t)$  and  $model(t)$  are the observed value and modelled value at time  $t$  respectively,  $n$  is the number of observations, and  $\overline{obs}$  is the observation mean.

### 5 Results

#### 5.1 Dome C

415 The predicted concentration of nitrate in skin layer snow for Model 1 and Model 2 in Dome C (Fig. 5 and Table 2) are discussed by season - Winter to Spring (April - Mid November) and Summer (Mid November - January).

### 5.1.1 Winter to Spring

The average temperature ( $\pm 1\sigma$ ) at Dome C between late autumn to late spring in 2009 is 213.7  
420 ( $\pm 7.9$ ) K (Fig. 3a), which is below the threshold temperature,  $T_0$ , for detection of DI layer (set at 238 K) for Model 1 and below the eutectic temperature,  $T_e$ , for a  $\text{H}_2\text{O}-\text{HNO}_3$  mixture (230 K) for Model 2. Therefore, in winter, the skin layer concentration of nitrate described well by non-equilibrium kinetic surface adsorption and co-condensation coupled to solid-state diffusion within the snow grain in both models. The models combine both processes and agreed very well with the  
425 observations of nitrate (Fig. 5a) with a  $C_v(\text{RMSE}) = 0.73$ . Both models captured the small peak from mid April to early May and another peak from mid to end of August then a steady increase from middle September till the end of October, except for the peak in late February.

Below we compare our ‘Kinetic approach’ (a ‘non-equilibrium surface adsorption followed by solid diffusion’ configuration) with the ‘Equilibrium approach’ suggested by Bock et al. (2016, Configuration 2 - BC1) in estimating skin layer  $[\text{NO}_3^-]$  in the winter period (Fig. 6a). The grain surface concentration,  $[\text{HNO}_3(\text{surf})]$ , for the ‘Equilibrium’ approach is determined by parameterisation from Thibert et al. (1998):

$$[\text{HNO}_3(\text{surf})] = 2.37 \times 10^{-12} \exp\left(\frac{3532.2}{T}\right) P_{\text{HNO}_3}^{1/2.3} \frac{\rho_{\text{ice}} N_A}{M_{\text{H}_2\text{O}}} \quad (19)$$

where  $T$  is the snow temperature (K),  $P_{\text{HNO}_3}$  is the partial pressure of  $\text{HNO}_3$  (Pa) and  $M_{\text{H}_2\text{O}}$  is the  
435 molar mass of  $\text{H}_2\text{O}$ . Note that the co-condensation was excluded in these model runs for a direct comparison between the two different approaches. Both the ‘Equilibrium’ and ‘Kinetic’ approaches resulted in a very similar trend and variation until mid Sept. Despite the ‘Kinetic’ approach yielding a larger  $C_v(\text{RMSE})$  compared to the ‘Equilibrium’ approach ( $C_v(\text{RMSE}) = 0.65$  & 0.52, respectively, Table. 2), the ‘Kinetic’ approach captures the temporal pattern from mid September till early  
440 November, yet, the ‘Equilibrium’ approach does not.

### 5.1.2 Summer

The average temperature ( $\pm 1\sigma$ ) from late spring to early autumn is 240.0 ( $\pm 5.0$ ) K (Fig. 3a) and the dominant process determining the snow nitrate concentration are solvation in DI coupled to solid state diffusion in Model 1 and partitioning of nitrate to the micropockets in Model 2.

445 Model 1 captures some trends observed in early spring and during the summer period, including the decrease in concentration of nitrate from the beginning of February, the rise between mid and late November, and the sharp increase in mid December (Fig. 5a). It also reproduced the steep decrease in concentration at the beginning of 2010 (Fig. 5a) . However, Model 1 (with  $T_0 = 238$  K) did not capture the peak in early February and overestimated the concentration of nitrate by a factor of 1.5-5  
450 in December (Fig. 5a).

The results from Model 2 agreed reasonably well with the observation in these few months with  $C_v(\text{RMSE})$  of 0.67. With the contribution from the partitioning of  $\text{HNO}_3$  in the micropockets, the

features in early February and the peaks between November and mid December were captured (Fig. 5b). The model underestimates the the nitrate concentration from mid December until January 2010  
455 by a factor of 3. During the summer period, the partitioning into the micropockets contributed  $\sim$ 75% of the total  $\text{NO}_3^-$  concentration.

## 5.2 Halley

Model results for Model 1 and Model 2 in Halley (Fig. 7 and Table 3).are presented by the season - Late Autumn to Winter (April - Mid September) and Spring to Early Autumn (Mid September -  
460 February).

### 5.2.1 Late Autumn to Winter

The mean temperature ( $\pm 1\sigma$ ) during this period at Halley is  $244.72(\pm 7.7)$  K (Fig. 4a). During this period, the temperature was mostly above the threshold temperature ( $T_0 = 238$  K) used in Model 1 but below the eutectic temperature for a  $\text{H}_2\text{O-NaCl}$  mixture (251 K) used in at Halley in Model  
465 2. Therefore, the main process controlling the concentration of  $\text{NO}_3^-$  in Model 1 is solvation into the DI whereas in Model 2 the main controlling processes are the combination of non-equilibrium adsorption and co-condensation coupled with solid-state diffusion. Performance of Model 1 was poor ( $C_v(\text{RMSE}) = 27.78$ ), overestimating the concentration of  $\text{NO}_3^-$  by two orders of magnitude (Fig. 7a). However, some of the trends were reproduced during this cold period such as the two small  
470 peaks in mid April and early May, and the rise in mid September (Fig. 7a).

The modelled results from Model 2 ( $C_v(\text{RMSE}) = 1.08$ ) were a much closer match to the observations compared to Model 1. It captured the first peak in mid April and the small peak in beginning of September. However, it did not reproduce the peak in mid August and underestimated the  $\text{NO}_3^-$  concentration for the majority of the time.

475 Similar to the Dome C site, the 'Equilibrium' approach after Bock et al. (2016) was run alongside the 'Kinetic' approach from late autumn until winter, again, no co-condensation processes were included in these 2 runs for a direct comparison. The modelled results from both approaches are very similar in value and temporal variations (Fig. 6b). Both the 'Kinetic' and 'Equilibrium' approach failed to reproduce the peak in mid August.

### 480 5.2.2 Spring to Early Autumn

Similar to the winter months, Model 1 overestimated the bulk  $\text{NO}_3^-$  concentration at Halley by an order of magnitude and failed to capture any of the variability (Fig. 7a). Model 2, however, reproduced some features during the warmer months, such as the peak in late September followed by a steady rise in October, the spikes in mid December, beginning of and mid January and also the  
485 peak and trough in late January (Fig. 7b). The partitioning to the micropockets contributed  $\sim$ 80%

of the total  $\text{NO}_3^-$  concentration during this period. The model results are within the same order of magnitude compared to the observations ( $C_v(\text{RMSE}) = 0.65$ ).

## 6 Discussion

The results from both Model 1 and 2 show that the bulk  $\text{NO}_3^-$  concentration in surface snow can be  
490 reasonably well described by non-equilibrium adsorption and co-condensation coupled with solid-state diffusion during autumn to spring at Dome C and in winter at Halley, i.e. when it is cold and the solar irradiance is small. In the summer months, the combination of warmer temperatures and a larger range of diurnal temperature causes the ‘Air-Ice’ only processes to no longer provide an accurate prediction. The concentration of  $\text{NO}_3^-$  in the surface snow, during the warmer months, is  
495 mainly determined by solvation into DI in Model 1 or partitioning into micropockets in Model 2.

Overall, the results from Model 1 match reasonably well with the year-round observations at Dome C ( $C_v(\text{RMSE}) = 1.34$ ). However, for Halley, Model 1 overestimated the concentration by two order of magnitude ( $C_v(\text{RMSE}) = 89.28$ ). On the other hand, results from Model 2 agree well for both study sites all year-round ( $C_v(\text{RMSE}) = 0.84$  for both Dome C and Halley). The mismatch  
500 between the models and observations can be separated into 2 categories - data limitations and model configurations, and will be discussed below.

The temporal resolution of the concentration of atmospheric nitrate at both study sites was roughly 5 to 10 days, therefore, any substantial changes in the atmospheric input within a short time scale might be missed and consequently the relative changes in concentration of nitrate in snow might  
505 not be observed. Secondly, the vertical snow pit profile of  $\text{NO}_3^-$  at Dome C (and sites with a low accumulation rate) tended to have a maximum concentration of  $\text{NO}_3^-$  at the surface of the snowpack (Röthlisberger et al., 2000), especially during the summer period, and the concentration of  $\text{NO}_3^-$  decreases sharply with the depth inf the snowpack. The skin layer is the most responsive layer of snow to the changes in the concentration of  $\text{HNO}_3$  in the atmosphere above. The snow samples  
510 from Dome C were collected carefully from the top  $4 \pm 2$  mm while the snow samples from Halley were collected from the top 25 mm. It is possible that the snow  $\text{NO}_3^-$  concentrations measured at Halley may be ‘diluted’ from deeper snow, with a smaller nitrate concentration than the surface, layer leading to a positive model bias. Thirdly, atmospheric nitrate can be find in a more stable forms of  $\text{NO}_3^-$ , i.e. associated with  $\text{Na}^+$ ,  $\text{Ca}^{2+}$  or  $\text{Mg}^{2+}$  (Beine et al., 2003). An increase in sea  
515 salt aerosol concentration can shift gaseous  $\text{HNO}_3$  to particle-phase (i.e.  $\text{NaNO}_3$ , Dasgupta et al., 2007), hence, decreases the ratio of gaseous  $\text{HNO}_3$  to the total atmospheric nitrate. At Dome C, the atmospheric sea salt aerosol concentration has a strong seasonal variability. The maximum sea salt aerosol concentration tends to be in the late winter or early spring which can be a factor of 4 larger than the annual mean (Legrand et al., 2016). Therefore, using the total measured atmospheric nitrate

520 as gaseous  $\text{HNO}_3$  for constraining the models might cause the mismatch between the modelled results and observations at Dome C, especially around November.

Lastly, no detailed information on timing and amount of snowfall events for the time periods in question at both study sites. Single snowfall events can increase the nitrate concentration in surface snow by up to a factor of 4 above the background (Wolff et al., 2008). The contribution of snow 525 nitrate from fresh precipitation maybe less important at low accumulation sites, such as Dome C -  $27 \text{ kg m}^{-2} \text{ yr}^{-1}$  (Röthlisberger et al., 2000), compared to sites with large snow accumulation like Halley  $\sim 480 \text{ kg m}^{-2} \text{ yr}^{-1}$  (Arthern et al., 2006). Wolff et al. (2008) reports that the large concentration of  $\text{NO}_3^-$  recorded from mid until end of August was due to new snowfall, which explains why both models failed to reproduce the peak. In the following sections, various processes included in 530 Model 1 and 2 will be discussed.

## 6.1 ‘Kinetic’ Approach vs ‘Equilibrium’ Approach

The ‘Kinetic’ approach defines the snow grain boundary concentration of  $\text{NO}_3^-$  by non-equilibrium, kinetic surface adsorption while the ‘Equilibrium’ approach after Bock et al. (2016) defines the concentration of the outermost layer of the snow grain (outermost layer thickness = 0.5-1.5  $\mu\text{m}$  in 535 this study) by thermodynamic equilibrium ice solubility. Both approaches describe the interaction between air and ice, therefore, only results from the winter period are compared. For both sites, the ‘Kinetic’ and ‘Equilibrium’ approach resulted in very similar trends except the peak in late October at Dome C (Fig. 6), of which the ‘Kinetic’ approach managed to reproduce but not the ‘Equilibrium’ approach.

540 The peak of snow nitrate in late October at Dome C corresponds to an increase in atmospheric  $\text{HNO}_3$  (Fig. 3b). The grain surface concentration of the ‘Equilibrium’ approach is a function of the partial pressure of  $\text{HNO}_3$  with an exponent of 1/2.3 (Eq. 19), while the concentration of the grain boundary defined by the ‘Kinetic Approach’ is linearly related to the concentration of atmospheric nitrate (Eq. 8). Therefore, the ‘Kinetic’ approach is more responsive to changes in the atmospheric 545 nitrate concentration compared to the ‘Equilibrium’ approach. Other advantages of the former approach are, 1) dynamic characteristics of the grain surface due to changing temperature gradients are taken into consideration; 2) applicability even for sites with high accumulation rates where the skin layer is buried by subsequent snowfall before reaching equilibrium.

At Halley, in winter, the concentrations of  $\text{NO}_3^-$  are underestimated by both approaches (Fig. 6 550 and Table 3). There are 2 possible explanations. First, the SSA values used maybe underestimated and lead to an underestimation on adsorption or dissolution in the outermost layer of the snow grain, further field observations are required to verify this. Secondly, due to higher temperatures at Halley compared to Dome C, other processes might be involved in controlling the snow surface concentration of  $\text{NO}_3^-$ , such as snowfall (not included in the models) or partitioning into liquid 555 micropockets in Model 2 (discussed in Sect. 6.4).

## 6.2 Co-Condensation - 'Air-Ice' Interaction

The process of co-condensation/sublimation is considered as part of the 'Air-Ice' interaction in both Models 1 and 2. It is driven by the difference in water vapour density across the skin layer snow and the overlying atmosphere. The water vapour density gradient depends exponentially on the temperature gradient. At Dome C the temperature is extremely low and relatively dry, especially in winter, and therefore it is not surprising that only 2% of the grain surface concentration of  $\text{NO}_3^-$  is from co-condensation during winter and spring (Fig. 6a, difference between the light and dark blue line). In contrast, at Halley, where winter is warmer and it is relatively humid,  $\sim 21\%$  of the grain surface concentration is contributed by co-condensation during winter (Fig. 6b, difference between the light and dark blue line). As shown in Table 3, the  $C_v(\text{RMSE})$  decreased slightly in winter after including co-condensation as part of the 'Air-Ice' interaction. In the summer, the dominant process in Model 1 is solvation in the DI (See Sect. 6.3) while in Model 2 the dominant process is partitioning in the micropockets (See Sect. 6.4), hence the contribution from co-condensation to the skin nitrate concentration is insignificant.

There are a few possible sources of uncertainties in the calculation of co-condensation/sublimation processes. For example, the macro-scale gradients of water vapour pressure (across few mm) were used instead of micro-scale gradients (across few  $\mu\text{m}$ ) and there were no precise measurements of skin layer snow density. Uncertainty in the density would lead to uncertainty in the modelled skin layer snow temperature. Despite the potential errors in the calculation of co-condensation, the large  $\text{NO}_3^-$  concentrations in the skin layer in the summer are unlikely to be driven by co-condensation. An unrealistically large average rate of volume change,  $\frac{dV}{dt}$ , of  $130$  and  $118 \mu\text{m}^{-3} \text{s}^{-1}$ , equivalent to an average grain volume increases of 170% and 135% per day, would be required for Dome C and Halley respectively if the large concentration of  $\text{NO}_3^-$  in summer was contributed by co-condensation. Assuming the RH of skin layer snow to be 100% and RH of the overlying atmosphere is the same as measured at 1 m above snowpack, a macro-temperature gradient as high as  $2.7 \times 10^3 \text{ K m}^{-1}$  would be required across the top 4 mm of the snowpack to match the large concentration of bulk  $\text{NO}_3^-$  in the summer at Dome C and in an average temperature gradient of  $500 \text{ K m}^{-1}$  would be required across the top 10 mm of the snowpack in Halley, which are 1- 2 orders of magnitude higher than observations (Frey et al., 2013) and the modelled temperature gradient (listed in Sect. 3.1.1).

## 6.3 Disordered Interface - Model 1 (Temperature $> 238 \text{ K}$ )

In Model 1, the interfacial layer between air and snow grain is described as 'Air-DI' when the ambient temperatures are above the threshold temperature,  $T_0 = 238 \text{ K}$ . Therefore, at Dome C, the 'Air-DI' regime applies only during summer months due to the extremely cold temperatures in winter, whereas, at Halley most of the time the interface is considered as 'Air-DI'. The model

simulations suggest that an ‘Air-ID’ interface above 238 K (the lower end of the DI detection limit of pure ice (Domine et al., 2013)) leads to an overestimation of nitrate concentration in early December at Dome C and all year round at Halley.

The onset temperature for observation of DI on pure ice varies with different experimental setups, 595 probing techniques and how the samples were prepared (Bartels-Rausch et al., 2014). Conde et al. (2008) also found a small fraction of water molecules beginning to leave the outermost crystalline layer of the ice and becoming mobile at 100 K below the melting point of that particular mixture of  $\text{H}_2\text{O}$  and impurities and the number of mobile molecules increases with increasing temperature. When the temperature is larger than 10 K below the melting point, molecules might even begin to 600 leave the deeper crystalline layer. The existence of DI not only depends on temperature, but also the speciation and quantity of impurities present within the snow grain (McNeill et al., 2012). Different impurities have different impacts on the hydrogen bonding network at the ice surface and hence have a different impact on the characteristics, such as thickness, of the DI (Bartels-Rausch et al., 2014). Therefore, the chosen threshold temperature,  $T_0$ , might be substantially different from what would 605 be found in natural snow or it might not be representative enough to be used as the threshold all year-round (See Sect. 6.5 for the sensitivity analysis regarding to  $T_0$ ).

Moreover, the partitioning coefficient and mass transport coefficient of the DI were assumed to be the same as those in the aqueous phase. These assumptions might not be realistic and could lead to overestimation of solvation of  $\text{HNO}_3$  in the DI. However, the real values for partition and mass 610 transport coefficients are difficult to measure with the current measurement techniques and need to be re-examined in the future.

There are 2 possible explanations for why Model 1 provided a reasonable estimation of skin layer snow  $\text{NO}_3^-$  concentration at Dome C, but not at Halley. Firstly, the chemical composition of surface snow at Dome C is relatively simple, dominated by nitrate anion, which would induce insignificant 615 changes to the hydrogen bonding network at the DI surface compared to a more complicated snow composition (Bartels-Rausch et al., 2014) suggesting the surface properties of snow at Dome C are likely to be comparable to pure ice. Secondly, the temperature at Halley occasionally rises above 0 °C potentially causing melting and significant changes in snow grain morphology at the surface especially.

## 620 6.4 Micro-Liquid Pocket - Model 2 (Temperature > Eutectic Temperature)

Model 2, which includes non-equilibrium surface adsorption and co-condensation coupled with solid diffusion within the grain and partitioning in liquid micropockets, successfully reproduces the concentration of  $\text{NO}_3^-$  of the surface snow without any tuning parameters for both Dome C and Halley all year round. This is a crucial outcome as it indicates that Model 2 can be used for predicting 625 the air-snow exchange of nitrate at the surface for a wide range of meteorological and depositional conditions that typical for the entire Antarctica.

The liquid water fraction is a function of the total ionic concentration (Eq. 4). Hence, neglecting the existence of other ions may lead to underestimation of the micropocket volume. The additional liquid would increase the dissolution capacity of  $\text{HNO}_3$  and hence increase the estimated  $\text{NO}_3^-$  concentration. As shown in Fig. 7b, the estimated bulk  $\text{NO}_3^-$  concentration followed a similar trend as the ‘other ions concentration’ (the observed  $\text{Cl}^-$  concentration). Despite  $\text{NO}_3^-$  being the major anion in the surface snow in Dome C, other anions, such as  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$ , were also detected from the same samples (Udisti et al., 2004). Jones et al. (2008) also measured  $\text{SO}_4^{2-}$  along with  $\text{Cl}^-$  and  $\text{NO}_3^-$  from the surface snow samples from Halley. The mismatch between modelled and observed nitrate concentration in the summer can be explained by assuming nitrate to be the only impurity at Dome C, or nitrate and sea salt as the only impurities at Halley. Nevertheless, the underestimation of the  $\text{NO}_3^-$  concentration due to underestimating the liquid-water content may be compensated or even overwhelmed if atmospheric deposition of other acids such as  $\text{HCl}$  or  $\text{H}_2\text{SO}_4$  increases, which lowers the pH and reduces the solubility of  $\text{HNO}_3$  in the micropocket.

Note that the micropockets only exist above the eutectic temperature. For simplification, the eutectic temperature was based on a system containing  $\text{H}_2\text{O}$  and the most abundant solute within surface snow. However, in reality, the presence of other impurities might have an impact on the eutectic temperature.

## 6.5 Sensitivity Analysis

In order to assess the robustness of the findings presented here they were analysed as a function of model sensitivities to constraints, parameterisations and measurement uncertainties. Parameters were varied one at a time by the given range while keeping all others constraints and parameterisation the same (Table. 4, Col. 1.). The coefficient of variation,  $C_v(\text{RMSE})$ , was calculated from each sensitivity test (Table. 4) and compared with the  $C_v(\text{RMSE})$  of the ‘Control’, which uses the observed values and parameterisation listed in Sect. 4 and Table. A1.

Both Model 1 and 2 are sensitive to the concentration of  $\text{HNO}_3$  in the air and the concentration of  $\text{NO}_3^-$  in snow. Reducing concentration of  $\text{HNO}_3$  in the atmosphere by 20% or increasing the concentration of  $\text{NO}_3^-$  in snow by 20% improves the performance of both models. This supports the suggestion that the atmospheric nitrate observed at Dome C only represents the upper limit of nitric acid and it is likely to lead to an overestimation of the concentration of nitrate in snow (Sect. 6) while at Halley, the skin layer snow might well be ‘diluted’ by snow sample from the deeper layer (Sect. 6).

Both models are sensitive to the value of SSA as a smaller SSA implies a smaller surface area per unit column of snow, and hence, less surface sites available for adsorption per unit column of snow. It has a more notable impact in Model 1 and in the winter, when the grain boundary processes play an important role for the overall snow nitrate concentration due to the cold temperature. A similar explanation applies the value of the maximum number of adsorption site,  $N_{\text{max}}$ . However, varying

the accommodation coefficient,  $\alpha$  by  $\pm 10\%$  does not have a significant impact on the performance of the models (Table 4).

665 Model 1 is very sensitive to the threshold temperature,  $T_0$ . At Dome C, the best match (lowest  $C_v(\text{RMSE})$ ) between modelled and observation is with a threshold temperature 2 K larger than the control  $T_0 = 238$  K. However, increasing  $T_0$  to 242 K worsens the model performance further (Fig. 5A, Green line & Table 4). In general, the grain boundary concentration of nitrate defined by solvation into the DI is much larger than when it is defined by the combination of surface adsorption 670 and co-condensation on ice. A larger temperature is required to assume the interface is 'Air-DI' when a large value of  $T_0$  is used. At Dome C, a larger value of  $T_0$  may have reduced the overestimation in late November due to a larger fraction of time falling below the threshold but compromised the good fit from mid December onward and yield a higher  $C_v(\text{RMSE})$ . At Halley, despite the improvement in  $C_v(\text{RMSE})$  when a higher temperature threshold was used, the modelled  $[\text{NO}_3^-]$  is still an order 675 of magnitude larger than the observation (Fig. 7b).

Model 1 is not sensitive to the pH of the DI layer. Even though the effective Henry's law coefficient increases by an order of magnitude when pH increases from 5 to 6.5 (Fig. A4), the  $C_v(\text{RMSE})$  remains the same. This behaviour can be explained by the combination of the kinetic approach and slow diffusion rate of nitrate in ice that the rate of change in the grain boundary concentration 680 remains small even the boundary concentration increases.

Model 2 is sensitive to the eutectic temperature,  $T_e$ , but not as much as for  $T_0$  in Model 1. Increasing  $T_e$  in Model 2, only improves the performance at Dome C but not Halley. Higher  $T_e$  implies that a larger temperature is required for the co-existence of liquid micropockets. For Dome C, increasing  $T_e$  by 2-4 K reduces the overestimation in November without compromising the results from mid 685 December onwards, as the average temperature during that period was higher than  $T_e = 234$ K.

## 7 Conclusions

Two surface physical models were developed from first principles to estimate the bulk concentration of  $\text{NO}_3^-$  in the skin layer of snow using observed atmospheric nitrate concentration, temperature and humidity as inputs. Model 1 is based on the assumption of a homogeneous disordered interface (DI) 690 as the interface between air and snow grain above 238 K and Model 2 is based on the hypothesis of the majority of the snow crystal surfaces being ice, and above the eutectic temperature a liquid exists in grooves at grain boundaries and triple junction.

The modelled skin layer concentration of  $\text{NO}_3^-$  from Model 1 agreed reasonably well with observations at Dome C but overestimated observations by an order of magnitude at the relatively warmer 695 Halley site. The uncertainties in Model 1 are the temperature threshold,  $T_o$ , that defines the onset of 'Air-DI' interface and the partition coefficient of DI. The poor performance of Model 1 at the warmer site supports the argument in previous studies (Bartels-Rausch et al., 2014; Domine et al.,

2013) that the disordered interface cannot be parameterised as a thin, homogenous water-like layer covering the entire grain surface or that its air-DI partitioning is the same as air-liquid partitioning.

700 Model 2 reproduced the skin layer concentration of  $\text{NO}_3^-$  with good agreement at both Dome C and Halley without any tuning parameters. Thus the major interface between skin layer snow grain and surrounding air can well be described as ‘Air-Ice’ with a liquid formed by impurities present as micropockets as suggested by Domine et al. (2013). In the winter the interaction of nitrate between the air and skin layer snow can be described as a combination of non-equilibrium kinetic 705 ice surface adsorption and co-condensation coupled with solid diffusion within the grain. In summer, the equilibrium solvation into liquid micropockets dominates the exchange of nitrate between air and skin layer snow.

Additional modelling studies, e.g. including uptake of other chemical species or aerosols, backed up by field observations from other locations with various meteorological conditions as well as 710 laboratory studies on the eutectic point of a multi-ions -  $\text{H}_2\text{O}$  system, uptake coefficient at a higher temperature, are needed to confirm the representativeness and improve the performance of Model 2.

Despite the simplified parameterisation of processes in Model 2, such as the impurities content in snow and the behaviour of the liquid micropockets, it is a excellent step towards parameterising the interactions between air and snow. The models presented here are describing the exchange between 715 air and the skin layer of snowpack as the uptake processes are much quicker than the photochemical loss, and therefore, can be modelled by ‘physical-only’ processes.

Atmospheric nitrate can reach deeper than the skin layer via wind pumping and temperature gradient, however, the nitric acid concentration in snow interstitial air (SIA) is expected to be small compared to the overlying atmosphere due to the high uptake of nitrate near the surface of the 720 snowpack. A smaller concentration of  $\text{HNO}_3$  in SIA implies a smaller uptake in deeper snow, and hence the photochemical loss cannot be assumed to be negligible in deeper snow. Therefore, a more complex multi-layer model including both physical and chemical processes is required to reproduce the nitrate concentration in deeper snow and being implement in regional and global atmospheric chemistry model.

## 8 Notation

Symbol	Description	units
$\alpha$	Accommodation coefficient	dimensionless
$A_{\text{ice}}$	Surface area of ice per unit volume of snowpack	$\text{m}^2 \text{m}_{\text{snowpack}}^{-3}$
$C_v(\text{RMSE})$	Coefficient of variation	N/A
DI	Disordered Interface	N/A
$D_v$	Water vapour diffusivity	$\text{m}^2 \text{s}^{-1}$
$D'_s$	Gas-phase diffusivity in snow	$\text{m}^2 \text{s}^{-1}$
$[\text{HNO}_3(\text{ads})]$	Nitric acid concentration contributed by surface adsorption	$\text{molecule m}^{-3}$
$[\text{HNO}_3(\text{cc})]$	Nitric acid concentration contributed by co-condensation	$\text{molecule m}^{-3}$
$[\text{HNO}_3(\text{DI})]$	Nitric acid concentration in the DI	$\text{molecule m}^{-3}$
$[\text{HNO}_3(\text{ice})]$	Nitric acid concentration in solid ice	$\text{molecule m}^{-3}$
$[\text{HNO}_3(\text{surf})]$	Nitric acid concentration on surface of grain	$\text{molecule m}^{-3}$
$k_{\text{ads}}$	Adsorption coefficient on ice	$\text{m}^3 \text{molecule}^{-1} \text{s}^{-1}$
$k_{\text{des}}$	Desorption coefficient on ice	$\text{s}^{-1}$
$k_{\text{Hcc}}$	Henry's Law coefficient	dimensionless
$k_{\text{H}}^{\text{eff}}$	Effective Henry's Law coefficient	dimensionless
$k_{\text{diff}}$	Diffusion coefficient in ice	$\text{m}^2 \text{s}^{-1}$
$k_w$	Thermal conductivity of snowpack	$\text{Wm}^{-1} \text{K}^{-1}$
$K_a$	Acid dissociation constant	$\text{molecule m}^{-3}$
$K_{\text{eq}}$	Equilibrium constant for Langmuir adsorption	$\text{m}^3 \text{molecule}^{-1}$
$N_{\text{max}}$	Maximum number of adsorption sites	$\text{molecule m}^{-2}$
$[\text{NO}_3^-(\text{bulk})]$	Bulk nitrate concentration	$\text{molecule m}^{-3}$
$\phi_{\text{H}_2\text{O}}$	Liquid water fraction	dimensionless
$\Phi_{\text{bulk}}^{\text{aq}}$	Fraction of the total amount of solute in aqueous phase	dimensionless
$R_{\text{eff}}$	Effective radius of snow grain derived from SSA data	m
$\rho_{\text{ice}}$	Density of ice	$\text{kg m}^{-3}$
$\rho_v$	Water vapour density	$\text{kg m}^{-3}$
$[\text{S}]$	Number of available surface sites per unit volume of air	$\text{molecule m}_{\text{air}}^{-3}$
SSA	Specific surface area	$\text{m}^2 \text{kg}^{-1}$
$T_e$	Eutectic temperature	K
$T_f$	Reference temperature	K
$T_o$	Threshold temperature in Model 1	K
$\bar{v}$	Mean molecular speed	$\text{m s}^{-1}$
$V_{\text{air}}$	Volume of air per unit volume of snowpack	$\text{m}_{\text{air}}^3 \text{m}_{\text{snowpack}}^{-3}$
$V_{\text{grain}}$	Volume of a snow grain	$\text{m}^3$

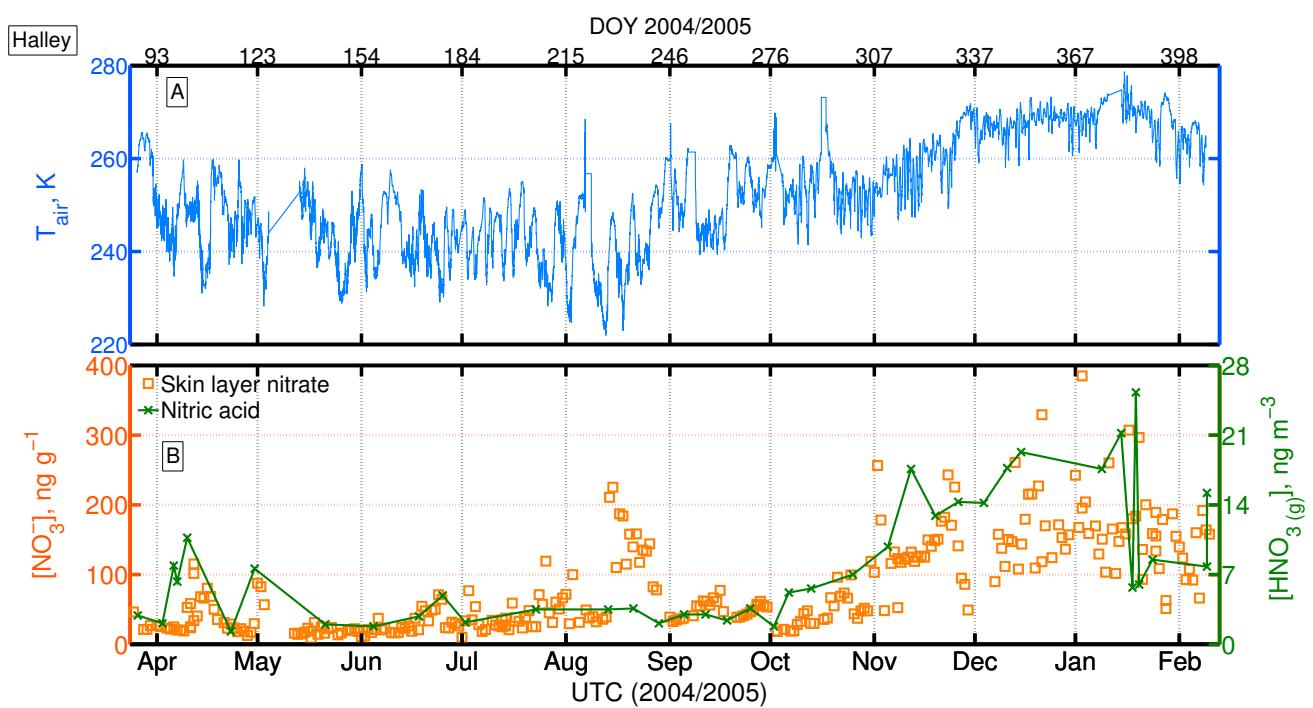

**Figure 1.** Schematic of Model 1. a) At temperatures below 238 K the concentration of  $\text{NO}_3^-$  at the surface of the snow grain is determined by Air-Ice processes, i.e. non-equilibrium adsorption and co-condensation. b) At temperatures above 238 K the concentration of  $\text{NO}_3^-$  at the surface of the snow grain is determined by Air-DI processes, i.e. non-equilibrium solvation.

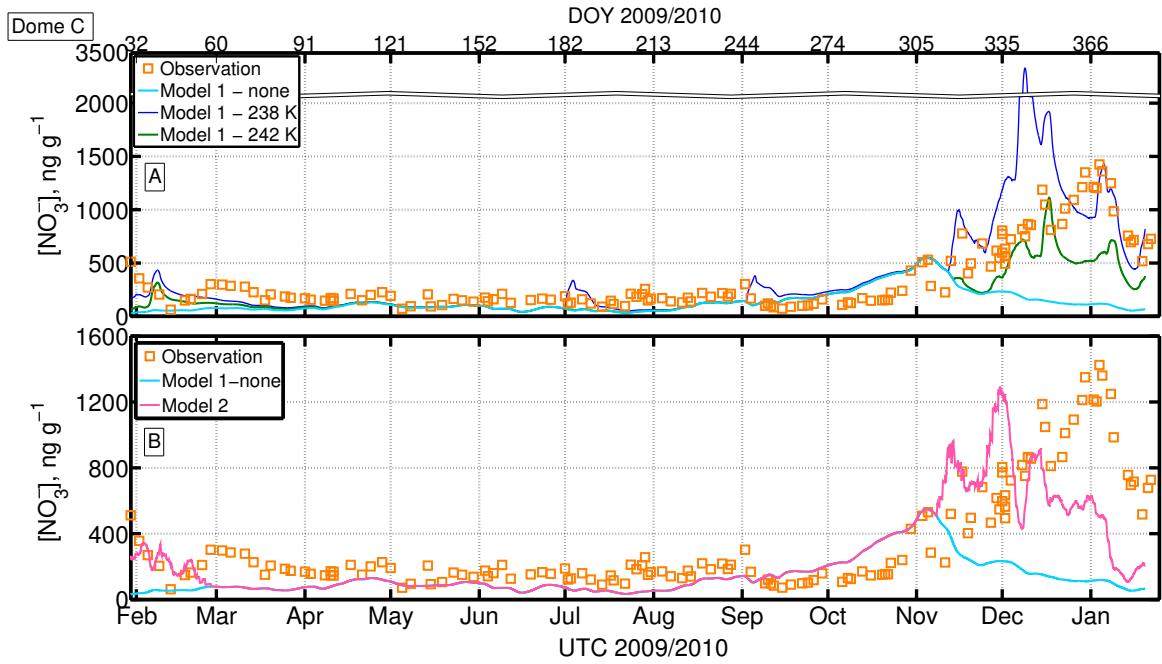

**Figure 2.** Schematic of Model 2. At all temperatures below melting, the concentration of  $\text{NO}_3^-$  at the surface of the snow grain is determined by Air-Ice processes, i.e. non-equilibrium adsorption and co-condensation. At temperatures above the eutectic temperature, liquid is assumed to co-exist with ice and the liquid fraction is in the form of micropockets that are located at grain boundaries and triple junctions (Domine et al., 2013).

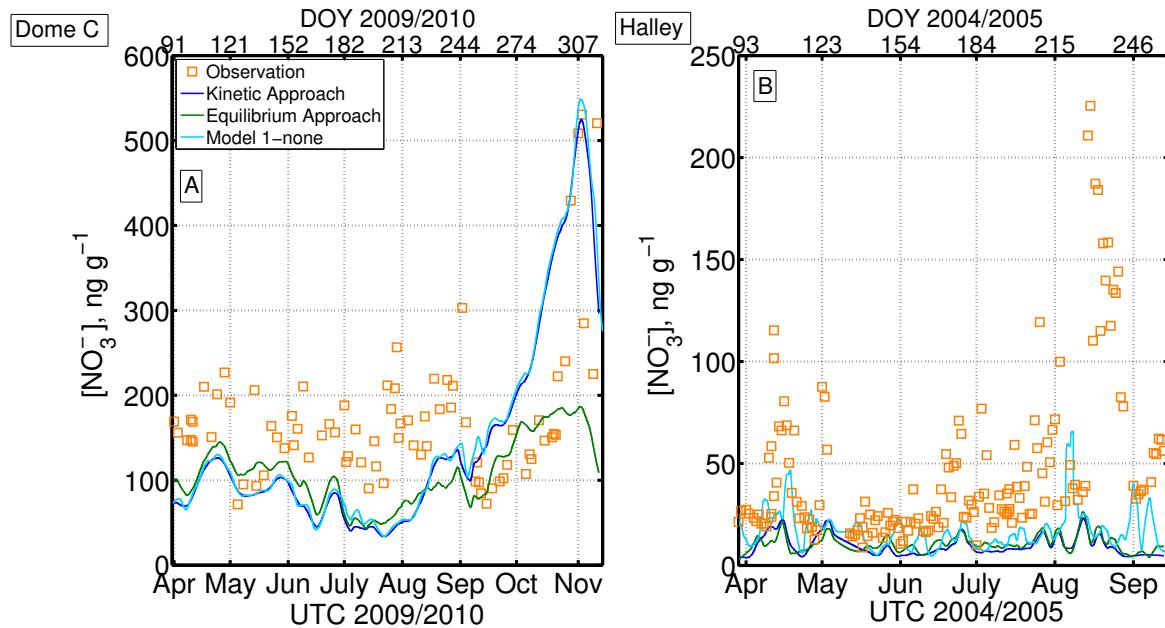

**Figure 3.** Atmospheric and snow observations from Dome C (published previously by Erbland et al., 2013, Fig. 6). (A) Air temperature (blue, left axis) and atmospheric pressure (red, right axis). (B) skin layer snow (i.e. top  $4 \pm 2$  mm) nitrate concentrations (orange square, left axis) and atmospheric nitrate concentrations, sum of the atmospheric particulate nitrate and  $\text{HNO}_3$  (green, right axis).

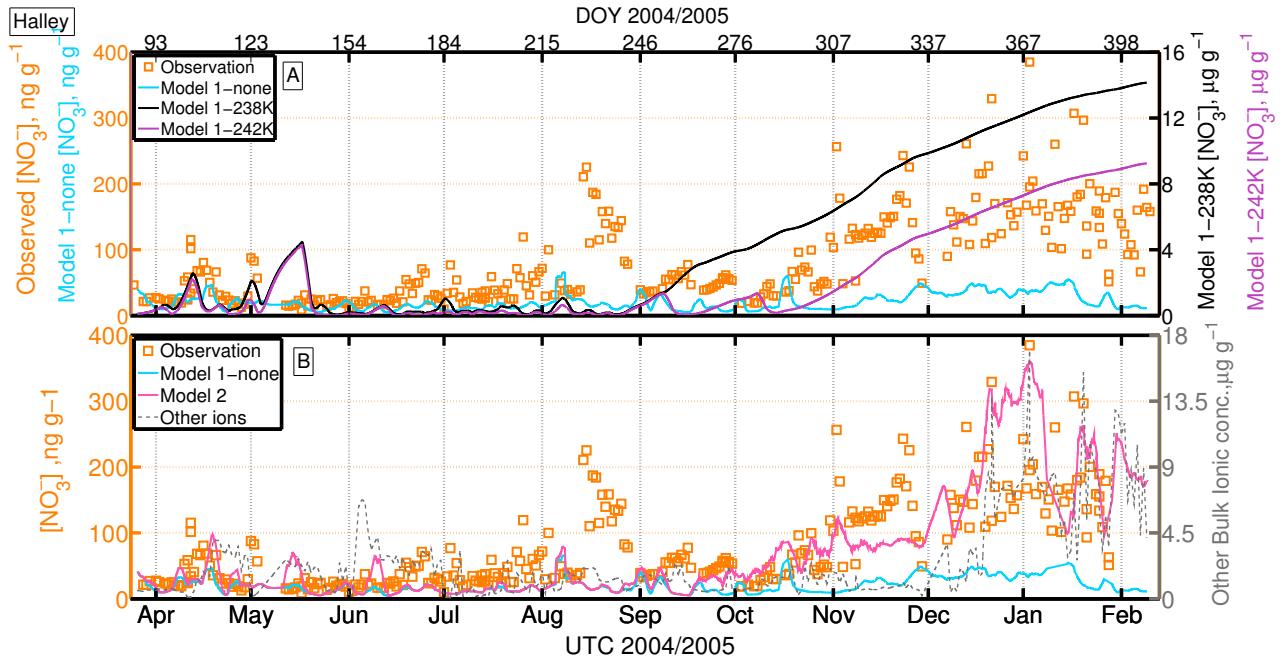

**Figure 4.** Atmospheric and snow observations at Halley between 27<sup>th</sup> March 2004 and 9<sup>th</sup> February 2005 (Jones et al., 2008). (A) Air temperature. (B) surface snow, the top 10  $\pm$  15 mm, nitrate concentrations (orange square, left axis) and gas-phase nitric acid concentrations (green, right axis).

**Figure 5.** (A) Model 1 output of Dome C skin layer snow concentration of  $\text{NO}_3^-$ . At temperatures less than the threshold temperature,  $T_o$ , the interface between air and snow grain is assumed to be ice ('Air-Ice') and the  $\text{NO}_3^-$  concentration is determined by a combination of non-equilibrium adsorption on ice and co-condensation coupled with solid-state diffusion. Above  $T_o$ , the interface between air and snow grain is assumed to be DI ('Air-DI'), i.e. the  $\text{NO}_3^-$  concentration is determined by combination of non-equilibrium solvation in DI coupled with solid-state diffusion. Note that the y-axis is broken between 2000-3500 ng g<sup>-1</sup>. Orange squares: observation. Dark blue: 'Mode 1 - 238 K', Model 1 with  $T_o$  set as 238 K; Green: 'Mode 1 - 242 K', Model 1 with  $T_o$  set as 242 K; Light blue: 'Mode 1 - none', Model 1 with  $T_o$  set above the melting temperature, i.e. air-ice only interaction; (B) Model 2 output of Dome C skin layer snow  $\text{NO}_3^-$  concentration. The major interface between air and snow is assumed to be ice ('Air-Ice') at all temperatures below melting and the  $\text{NO}_3^-$  concentration in ice is determined by a combination of non-equilibrium adsorption and co-condensation coupled with solid-state diffusion. Above eutectic temperature,  $T_e$  (230 K), liquid co-existed with ice in the form of micropocket. The partition between air and micropocket is determined by Henry's law. Orange squares: observation; Light blue: 'Mode 1 - none', Model 1 with  $T_o$  set above the melting temperature, i.e. air-ice only interaction; Pink: 'Model 2' - air-ice interaction plus micro-liquidpockets.

**Figure 6.** Comparison of the ‘Kinetic’ approach (this work, in dark blue) with the ‘Equilibrium’ approach (similar to Bock et al. (2016), in green), and the contribution from the co-condensation process (Results from Model 1- none, in light blue) in winter. The ‘Kinetic’ approach describes the air-snow interaction of nitrate as non-equilibrium kinetic surface adsorption coupled with solid diffusion inside the grain whereas the ‘Equilibrium’ approach describes the interaction as equilibrium solubility coupled with solid diffusion inside the grain. The ‘Model 1-none’ describes the interaction as co-condensation plus non-equilibrium kinetic surface adsorption coupled with solid diffusion within the grain. **(A)** Results at Dome C. **(B)** Results at Halley.

**Figure 7.** (A) Model 1 output of skin layer snow concentration of  $\text{NO}_3^-$  at Halley. At temperatures below the threshold temperature,  $T_o$ , the interface between air and snow grain is assumed to be ice ('Air-Ice') and the  $\text{NO}_3^-$  concentration is determined by a combination of non-equilibrium adsorption on ice and co-condensation coupled with solid-state diffusion. At temperature above  $T_o$ , the interface between air and snow grain is assumed to be DI ('Air-Ice'), where the  $\text{NO}_3^-$  concentration is determined by a combination of non-equilibrium solvation in DI coupled with solid-state diffusion. Orange square (Left axis) - observation; Light blue (Left axis) : 'Mode 1 - none', Model 1 with  $T_o$  set above the melting temperature, i.e. air-ice only interaction; Black (Right axis): 'Model 1-238 K' - Model 1 with  $T_o$  set to 238 K; Purple (Right axis): 'Model 1-242 K' - Model 1 with  $T_o$  set to 242 K. (B) Model 2 output of Halley skin layer snow  $\text{NO}_3^-$  concentration. The major interface between air and snow is assumed to be ice ('Air-Ice') at all temperature below melting and the  $\text{NO}_3^-$  concentration in ice is determined by a combination of non-equilibrium adsorption and co-condensation coupled with solid-state diffusion. Above eutectic temperature,  $T_e$  (252 K), liquid co-exists with ice in the form of micropocket. The partition between air and micropocket is determined by Henry's law. Orange squares: observation; Light Blue: 'Mode 1 - none', Model 1 with  $T_o$  set above the melting temperature, i.e. air-ice only interaction; Pink: 'Model 2' - air-ice interaction plus micro-liquidpockets; Grey (Right axis) - measured bulk concentration of other ions, where other ions refers to the sum of  $[\text{Na}^+]$  and  $[\text{Cl}^-]$ .

## Appendix A: Parameterisation

**Table A1.** Parameterisation for  $\text{HNO}_3$

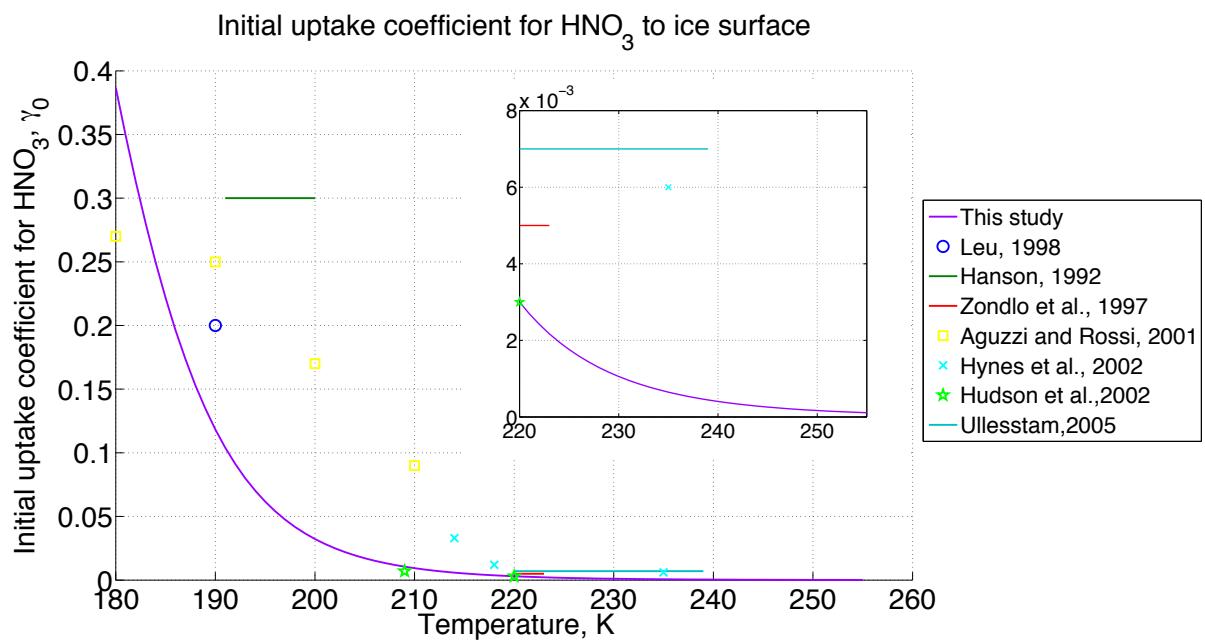

Symbol	Parameter	Value/Parameterisation	units	Reference
$\alpha_0$	Accommodation coefficient at reference temperature	$3 \times 10^{-3}$ <sup>i</sup>	Dimensionless	Hudson et al. (2002)
$k_{\text{diff}}$	Diffusion coefficient of nitrate in ice	$1.37 \times 10^{-2610/T}$	$\text{cm}^2 \text{s}^{-1}$	Thibert et al. (1998)
$k_w$	Thermal conductivity of snow-pack	$k_w = k_{\text{ice}} \left( \frac{\rho}{\rho_{\text{ice}}} \right)^{2-0.5 \frac{\rho}{\rho_{\text{ice}}}}$	$\text{W m}^{-1} \text{K}^{-1}$	Hutterli et al. (2003), therein
$k_{\text{ice}}$	Thermal conductivity of ice	$k_{\text{ice}} = 9.828 \exp(-0.0057T)$	$\text{W m}^{-1} \text{K}^{-1}$	Hutterli et al. (2003), therein
$\Delta_{\text{sol}}H$	Enthalpy of solution at standard temperature	-72.3	$\text{kJ mol}^{-1}$	Brimblecombe and Clegg (1988)
$\Delta_{\text{obs}}H$	Enthalpy of uptake	-44	$\text{kJ mol}^{-1}$	Thomas et al. (2011)
$k_{\text{H}}^0$	Henry constant at 298 K	$1.7 \times 10^5$ <sup>ii</sup>	$\text{M atm}^{-1}$	Brimblecombe and Clegg (1988)
$N_{\text{max}}$	Maximum adsorption site	$2.7 \times 10^{18}$	molecules $\text{m}^{-2}$	Crowley et al. (2010)
$\bar{v}$	Mean molecular speed	$\sqrt{\frac{8RT}{M_m \pi}}$ <sup>iii</sup>	$\text{m s}^{-1}$	Sander (1999)
$X_{\text{HNO}_3}^0$	Molar fraction of $\text{HNO}_3$ in ice	$X_{\text{HNO}_3}^0 = 2.37 \times 10^{-12} \exp\left(\frac{3532.2}{T}\right) P_{\text{HNO}_3}^{1/2.3}$	$\text{mol mol}^{-1}$	Thibert et al. (1998)
$K_{\text{eq}}$	Langmuir adsorption equilibrium constant	$-8.2 \times 10^{-18} T + 2.01 \times 10^{-15}$	$\text{m}^3 \text{molecule}^{-1}$	Burkholder and Wine (2015)
$D_v$	Water vapour diffusivity	$D_v = 2.11 \times 10^{-5} \left( \frac{T}{T_o} \right)^{1.94} \frac{P_o}{P}$	$\text{m}^2 \text{s}^{-1}$	Pruppacher and Klett (1997)

<sup>i</sup> Temperature dependent accommodation coefficient,  $\alpha = \frac{\exp\{\ln(\frac{\alpha_0}{1-\alpha_0})[-\frac{\Delta_{\text{obs}}H}{R}(\frac{1}{T} - \frac{1}{T_f})]\}}{1 - \exp\{\ln(\frac{\alpha_0}{1-\alpha_0})[-\frac{\Delta_{\text{obs}}H}{R}(\frac{1}{T} - \frac{1}{T_f})]\}}$ , where  $R$  is the molar gas constant,  $T$  is the temperature,  $T_f$  is the reference temperature (220 K)

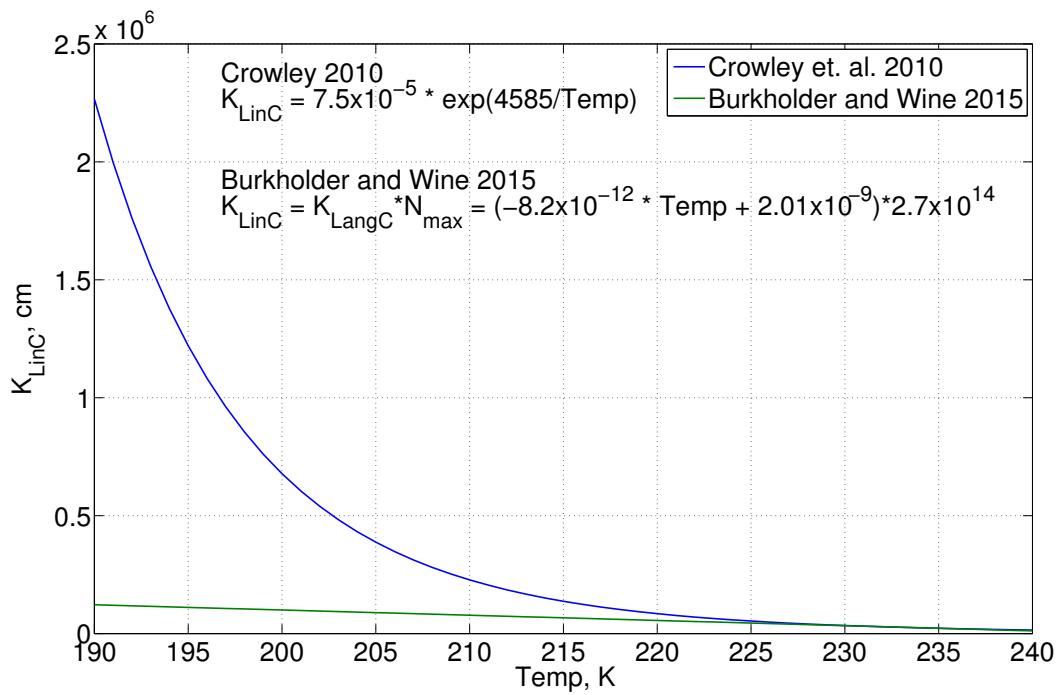

<sup>ii</sup> Temperature dependent dimensionless Henry's Law coefficient,  $k_{\text{H}}^{\text{cc}} = k_{\text{H}}^0 \times RT \times \exp\left(\frac{-\Delta_{\text{sol}}H}{R}\left(\frac{1}{T} - \frac{1}{T^{\oplus}}\right)\right)$ ,

where  $T^{\oplus}$  is the standard temperature (298 K).

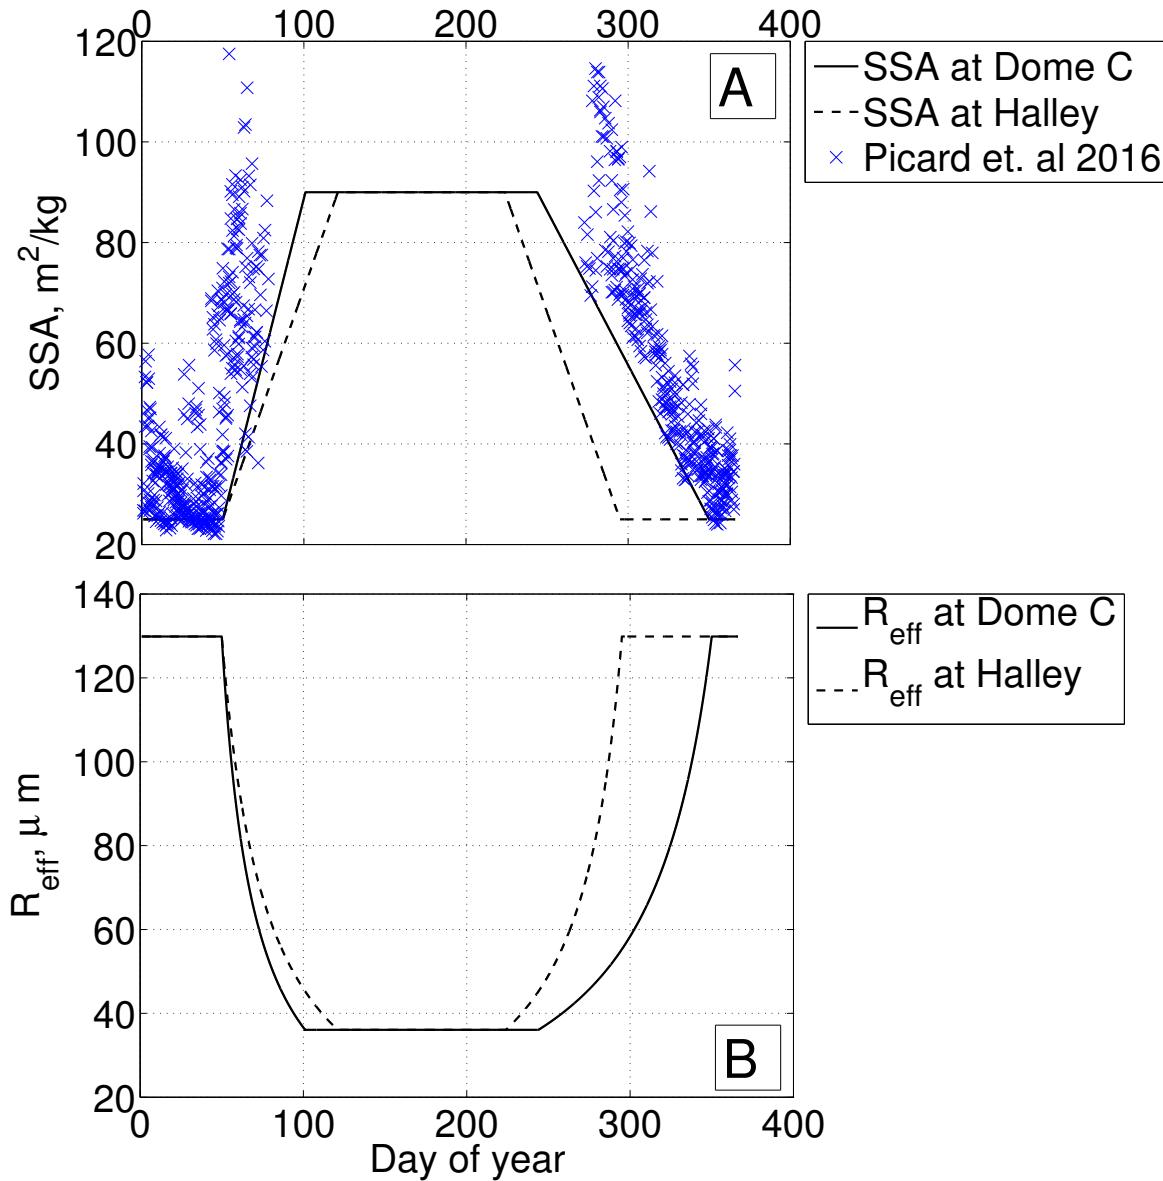

<sup>iii</sup>  $M_m$  is the molar mass of the gas.

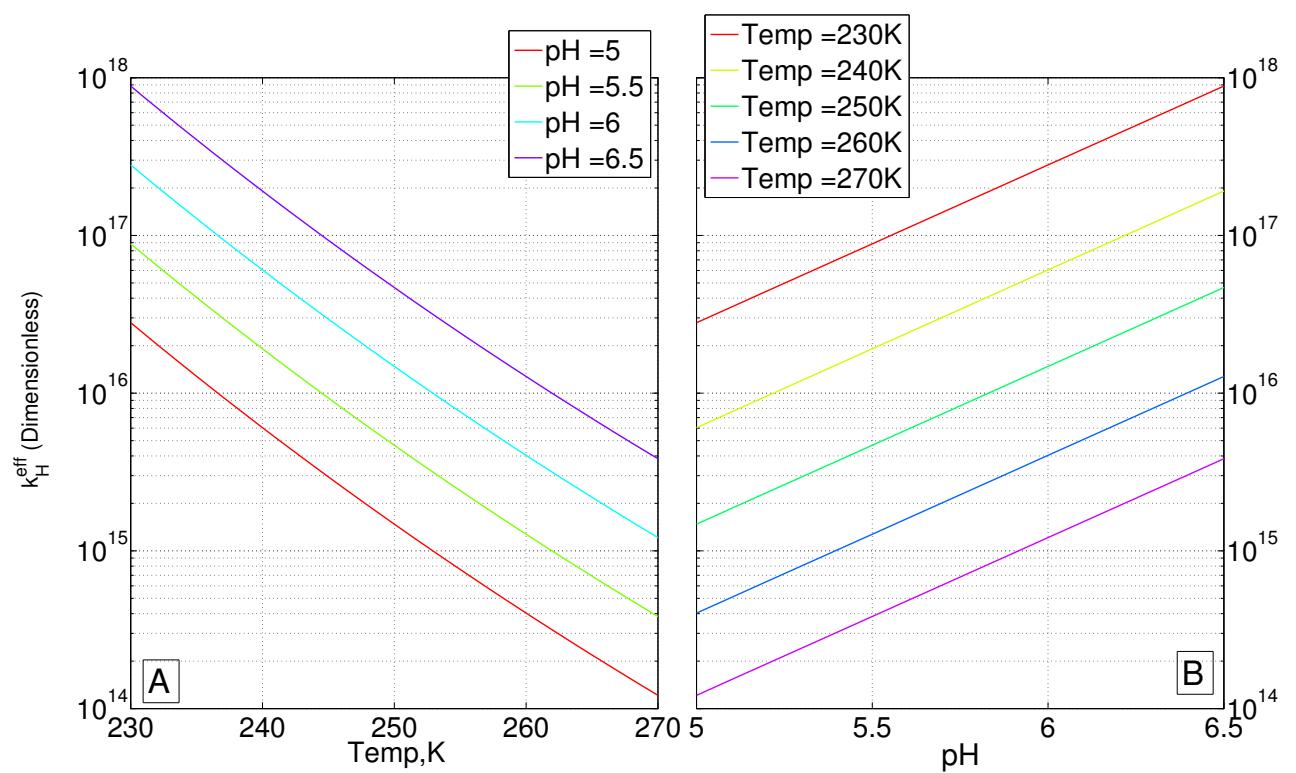

**Figure A1.** Initial uptake coefficient for  $\text{HNO}_3$  as a function of temperature obtained from different studies. The parameterisation used within this study is formulated in Table A1 and is chosen to give the best representation of the dependency on temperature.

**Figure A2.** Langmuir adsorption equilibrium constant,  $K_{\text{LinC}} = K_{\text{eq}} \times N_{\text{max}}$ . The preferred temperature range for both parameterisation is 214-240 K and within this range the two parameterisations provide a comparable value. The Crowley et al. (2010) parameterisation deviate from the Burkholder and Wine (2015) parameterisation as temperature drop below 214 K due to the exponential temperature term. Here, the parameterisation from Burkholder and Wine (2015) was chosen based on the extreme cold temperature found in our validation sites.

**Figure A3.** (A) Year-round estimates of the specific surface area (SSA) of snow at Dome C (—) and Halley (---) were interpolated from observations at Dome C during 2012-2015 by Picard et al. (2016) (×). The SSA estimates for Halley take into account the shorter cold period compare to Dome C, which tends to have larger SSA. (B) Year-round estimates of effective grain radius ( $R_{\text{eff}}$ ) at Dome C (—) and Halley (---) derived from Eq. 6.

**Figure A4.** The dependence of the effective Henry's Law coefficient,  $k_{\text{H}}^{\text{eff}}$ , of  $\text{HNO}_3$  on (A) temperature and (B) pH
