

27 **Abstract.** A series of strict emission control measures were implemented in Beijing and
28 the surrounding seven provinces to ensure good air quality during the 2015 China
29 Victory Day parade, rendering a unique opportunity to investigate anthropogenic
30 impact of aerosol properties. Submicron aerosol hygroscopicity and volatility were
31 measured during and after the control period using a hygroscopic and volatile tandem
32 differential mobility analyzer (H/V-TDMA) system. Three periods, namely, the control
33 clean period (Clean1), the non-control clean period (Clean2), and the non-control
34 pollution period (Pollution), were selected to study the effect of the emission control
35 measures on aerosol hygroscopicity and volatility. Aerosol particles became more
36 hydrophobic and volatile due to the emission control measures. The hygroscopicity
37 parameter (κ) of 40–200 nm particles decreased by 32.0 %–8.5 % during the Clean1
38 period relative to the Clean2 period, while the volatile shrink factor (SF) of 40–300 nm
39 particles decreased by 7.5 %–10.5 %. The emission controls also changed the diurnal
40 variation patterns of both the probability density function of κ (κ -PDF) and the
41 probability density function of SF (SF-PDF). During Clean1 the κ -PDF showed one
42 nearly-hydrophobic (NH) mode for particles in the nucleation mode, which was likely
43 due to the dramatic reduction in industrial emissions of inorganic trace gases. Compared
44 to the Pollution period, particles observed during the Clean1 and Clean2 periods
45 exhibited a more significant non-volatile (NV) mode throughout the day, suggesting a
46 more externally-mixed state particularly for the 150 nm particles. Aerosol
47 hygroscopicities increased as particle sizes increased, with the greatest increases seen
48 during the Pollution period. Accordingly, the aerosol volatility became weaker (i.e., SF

49 increased) as particle sizes increased during the Clean1 and Clean2 periods, but no
50 apparent trend was observed during the Pollution period. Based on a correlation
51 analysis of the number fractions of NH and NV particles, we found that a higher number
52 fraction of hydrophobic and volatile particles during the emission control period.

53 **1. Introduction**

54 China, as the world's second largest economy, is facing severe air pollution
55 problems due to its rapid economic growth. This has led to highly elevated aerosol
56 concentrations, especially in urban regions such as Beijing, Shanghai, and Guangzhou
57 (Hsu et al., 2012; Huang et al., 2014). Every year, high levels of fine particulate matter
58 (PM) have caused many severe haze days in these regions, that may pose a great health
59 hazard and changes in the regional climate because of aerosol direct and indirect climate
60 effects (Z. Li et al., 2016; G. X. Wu et al., 2016). However, the pollution formation
61 mechanism and the climate effects of aerosols remain highly uncertain due to the highly
62 variable physical and chemical properties of aerosols, as well as complex mechanisms
63 that govern aerosol-climate interactions (Tao et al., 2012; Wang et al., 2014).

64 Aerosol hygroscopicity and volatility are two important physical properties
65 describing the process of haze formation and its effects on climate. Aerosol
66 hygroscopicity describes the interaction of aerosols and water vapor under sub- and
67 supersaturation conditions, and is a vital parameter to the aerosol life cycle, aerosol
68 activation ability, and aerosol direct and indirect climate effects (Swietlicki et al., 2008;
69 Tao et al., 2012; Bian et al., 2014). Aerosol volatility is a physical parameter correlated

70 with carbonaceous aerosols, commonly used to study the aerosol mixing state and aging
71 level (Wehner et al., 2009; S. L. Zhang et al., 2016). To date, there are many ways to
72 measure aerosol hygroscopicity and volatility, but the most popular one is the
73 Hygroscopic and Volatile Tandem Differential Mobility Analyzer (H/V-TDMA)
74 system because it can measure these properties in great detail (Swietlicki et al., 2008).

75 The Chinese government took many drastic measures to reduce the emissions of
76 air pollutants from industry, road traffic, and construction sites, especially during some
77 great events such as the 2008 Summer Olympic Games, the 2014 Asia-Pacific
78 Economic Cooperation. Swift and drastic improvement in air quality (Huang et al.,
79 2015; Shi et al., 2016) provide unique opportunities to investigate the effects of
80 emissions on air quality. To our knowledge, previous studies have usually focused on
81 aerosol chemistry, sources, and transport (Wang et al., 2010; Gao et al., 2011; Sun et
82 al., 2016b), but not on the effects of emission controls on aerosol hygroscopicity and
83 volatility. Due to the importance of the two factors on describing the process of haze
84 formation as well as the effect on climate, it is necessary to investigate the changes in
85 aerosol hygroscopicity and volatility when emission control measures are in place.

86 To guarantee good air quality in Beijing during the 2015 China Victory Day parade,
87 the Chinese government implemented much stricter emission control measures than
88 normally done in Beijing and the surrounding seven provinces from 20 August to 3
89 September. The control measures consisted of a ban on driving vehicles every other day,
90 shutting down or limiting factory production, stopping construction activities, and so
91 on. These emission control measures successfully ensured a continuous stretch of 15

92 days of blue sky, vividly named “Parade Blue” (H. Li et al., 2016). During and after the
93 parade emission control period, we conducted in situ measurements of submicron
94 aerosol chemical and physical properties in Beijing. Size-resolved chemical
95 compositions were also obtained (Zhao et al., 2017). The average PM less than 1 μm in
96 diameter (PM_{10}) concentration was $19.3 \mu\text{g m}^{-3}$ during the parade emission control
97 period, 57 % lower than that after the control period. All chemical species decreased
98 during the control period, but their decreasing percentages were different.

99 This study period is unique for investigating aerosol properties during low PM level
100 periods. This paper will further evaluate the impact of emission controls on the
101 hygroscopicity and volatility of submicron aerosols, which may bring some insight into
102 how to reduce pollution in the future. Furthermore, investigating aerosol hygroscopicity
103 and volatility with and without emission controls will help in understanding
104 environmental and climate changes in general. This paper is structured as follows.
105 Section 2 describes the instrumentation and data used, and section 3 introduces the
106 methods to data analysis. Aerosol hygroscopicity and volatility during different periods
107 were compared and discussed in section 4. Conclusions and summary are given in
108 section 5.

109 **2. Experimental methods**

110 **2.1. Sampling site and meteorology**

111 The submicron aerosol hygroscopicity and volatility were measured in situ from
112 26 August to 7 October 2015 using the H/VTDMA system located at the Institute of

113 Atmospheric Physics (IAP), Chinese Academy of Sciences (39.97°N, 116.37°E), which
114 is located between the north 3rd and 4th ring road in northern Beijing. The sampling
115 instruments were put into a white container at ground level and an air conditioner was
116 used to maintain the temperature at 20–25° C inside the container. Meteorological
117 variables, including temperature (T), relative humidity (RH), wind speed (WS), and
118 wind direction (WD), were measured at different heights of a 325 m meteorological
119 tower, the tower located ~20 m west of the container. To eliminate the influence of
120 buildings on wind, we selected the 280-m wind direction and 8-m wind speed as
121 references in this study. Simultaneously, particle number concentrations (10–600 nm)
122 were also measured by a scanning mobility particle sizer (SMPS) located at the 260-m
123 level of the tower. The SMPS is equipped with a long differential mobility analyzer
124 (DMA, Model 3081A, TSI Inc.) and a condensation particle counter (CPC, Model 3775,
125 TSI Inc.). In addition, the measurement of aerosol chemical composition using a High-
126 Resolution Aerosol Mass Spectrometer (HR-AMS) and an Aerosol Chemical
127 Speciation Monitor (ACSM) were deployed at ground level and at the 260-m level of
128 the tower, respectively. The HR-AMS was situated in a sampling room located on the
129 rooftop of a two-story building (~8 m), ~25 m north from the container. An analysis of
130 the aerosol chemical composition has been done (Zhao et al., 2017).

131 **2.2. Instrumentation and operation**

132 The H/V-TDMA system developed by the Guangzhou Institute of Tropical and
133 Marine Meteorology (ITMM) was used to measure the submicron aerosol

134 hygroscopicity and volatility. The H-TDMA system (H-mode) shown in Figure 1
135 consists of four main parts: (1) a nafion dryer (Model PD-70T-24ss, Perma Pure Inc.,
136 USA) and a bipolar neutralizer (Kr85, TSI Inc.). The nafion dryer ensured that the RH
137 of the sample flow was below 20 % over the entire measurement period, and the bipolar
138 neutralizer was used to equilibrate the charge of particles (Wiedensohler, 1988); (2) the
139 first differential mobility analyzer (DMA₁, Model 3081L, TSI Inc.): The DMA₁ was
140 used to select quasi-monodisperse particles of a certain diameter through a fixed electric
141 voltage. The diameters selected were 40, 80, 110, 150, and 200 nm; (3) a nafion
142 humidifier (Model PD-70T-24ss, Perma Pure Inc., USA). The nafion humidifier was
143 used to humidify the aerosol flow from the DMA₁ to a defined RH. In the study, we set
144 RH to 90 %; (4) the second DMA (DMA₂, same model as the DMA₁) and a
145 condensation particle counter (CPC, Model 3772, TSI Inc.). The DMA₂ and the CPC
146 were used together to measure the number size distribution of the humidified particles.
147 An automated valve located between the DMA₁ and the nafion humidifier directly
148 connects the DMA₁ with the CPC. This can be used to measure the 10–400 nm particle
149 number size distribution (PNSD) by varying the electric voltage of the DMA₁. Details
150 about the design of the HTDMA system and its applications are given by Tan et al.
151 (2013a).

152 The design of the V-TDMA system (V-mode) is similar to that of the H-TDMA
153 system, except that the nafion humidifier in the V-TDMA system was replaced by a
154 heating tube that induces the evaporation of volatile materials. The heating tube was an
155 80-cm long stainless steel tube with an inner diameter of 8 mm. With a sample flow

156 rate of 1.0 L min^{-1} , its residence time ($\sim 2.4 \text{ s}$) in the heated section is sufficient for the
157 volatile materials to be effectively vaporized (Cheung et al., 2016). In this study, the
158 heating temperature was set to 300°C . The residual particles of volatile compounds at
159 this temperature, such as sulfates, nitrates, and most organics, are mainly refractory
160 non-volatile organic carbon (such as polymer-type organics), and sea salts (Philippin et
161 al., 2004; Wehner et al., 2009; Cheung et al., 2016; Ma et al., 2016). Particle were
162 measured at the diameters of 40, 80, 110, 150, 200 and 300 nm. The H/V-TDMA system
163 has been successfully used in previous studies (Tan et al., 2013b; Cheung et al., 2016;
164 Tan et al., 2016).

165 The hygroscopic growth factor (GF) at a given RH and the volatile shrink factor
166 (SF) at a certain temperature are defined as the ratio of the conditional diameter to the
167 dry diameter, with respect to RH and T, respectively:

$$168 \quad \text{GF} = D_p(\text{RH})/D_{0\text{dry}} , \quad (1)$$

$$169 \quad \text{SF} = D_p(\text{T})/D_{0\text{dry}} . \quad (2)$$

170 Here, $D_p(\text{RH})$ refers to the particle diameter measured at $\text{RH} = 90 \%$, $D_p(\text{T})$ refers to
171 the particle diameter measured at $\text{T} = 300^\circ \text{C}$, and $D_{0\text{dry}}$ refers to the dry diameter set by
172 the DMA_1 . The measured distribution function (MDF) versus GF or SF can be
173 calculated with the number concentration from CPC data downstream from the DMA_1
174 and the DMA_2 . However, the MDF is a skewed and smoothed integral transformation
175 of the particles' actual growth/shrink factor probability density function (GF-PDF or
176 SF-PDF) due to the effect of the DMA diffusion transfer function (Swietlicki et al.,
177 2008; Gysel et al., 2009). In this study, the TDMAfit algorithm (Stolzenburg et al., 1988,

178 2008) was used to retrieve the GF-PDF and the SF-PDF. The TDMAfit algorithm
179 assumes that groups in the PDF following one or more lognormal distribution functions
180 (Gaussian shape), thus allowing for the possibility that particles of a given type are not
181 all identical.

182 3. Data analysis

183 3.1. Hygroscopicity parameter

184 According to the Köhler theory (Petters et al., 2007), the hygroscopicity parameter
185 κ can be used to depict the hygroscopicity of particles at different RHs. Using H-TDMA
186 data, κ is calculated as:

$$187 \quad \kappa(\text{GF}, D_d) = (\text{GF}^3 - 1) \cdot \left[\frac{1}{\text{RH}} \exp\left(\frac{4\sigma_{s/a}M_w}{RT\rho_w D_d \text{GF}}\right) - 1 \right] \quad , \quad (3)$$

188 where RH is the default value of the H-TDMA, $\sigma_{s/a}$ is the surface tension of the
189 solution/air interface, M_w is the molecular weight of water, R is the universal gas
190 constant, T is the temperature, ρ_w is the density of water, D_d is the diameter of the
191 dry particles (equivalent to $D_{0\text{dry}}$ as mentioned above), and GF from equation (1). In this
192 study, T used in the κ calculation is 23° C (the average temperature of the inner
193 container) and $\sigma_{s/a}$ is assumed to be the same as the surface tension of the pure
194 water/air interface (about 0.0723 N m⁻¹ at 23° C).

195 3.2. Statistics of κ -PDF and SF-PDF

196 The probability distribution function of κ (κ -PDF, $c(\kappa, D_d)$) derived from the GF-
197 PDF was normalized as $\int c(\kappa, D_d) d\kappa = 1$. The ensemble mean hygroscopicity

198 parameter is then defined as the number-weighted mean GF of κ -PDF over the whole κ
199 range:

$$200 \quad \kappa_{\text{mean}} = \int_0^{\infty} \kappa c(\kappa, D_d) d\kappa \quad . \quad (4)$$

201 The standard deviation of κ -PDF is:

$$202 \quad \sigma_{\kappa\text{-PDF}} = \left(\int_0^{\infty} (\kappa - \kappa_{\text{mean}})^2 c(\kappa, D_d) d\kappa \right)^{\frac{1}{2}} \quad . \quad (5)$$

203 The calculated statistical parameters of SF-PDF ($c(\text{SF}, D_d)$) are similar to those of κ -
204 PDF, so SF can be used instead of κ and $c(\text{SF}, D_d)$ instead of $c(\kappa, D_d)$ in these
205 equations.

206 **3.3. Classification of different hygroscopic and volatile groups**

207 The mixing state of ambient aerosol particles is complex due to different sources,
208 different aging processes, and so on. Different hygroscopic and volatile groups had been
209 used around the Beijing region using H-TDMAs and V-TDMAs (Massling et al., 2009;
210 Liu et al., 2011; S. L. Zhang et al., 2016). Based on previous studies and our
211 measurements (Fig. S1), ambient aerosol particles were classified into three
212 hygroscopic groups and three volatile groups, where κ and SF are used here to define
213 the boundaries for each group:

214 Nearly-Hydrophobic, NH: $\kappa < 0.1$;

215 Less-Hygroscopic, LH: $0.1 \leq \kappa < 0.2$;

216 More-Hygroscopic, MH: $0.2 \leq \kappa$;

217 Non-Volatile, NV: $\text{SF} \geq 0.88$;

218 Slight-Volatile, SV: $0.88 > \text{SF} \geq 0.55$;

219 Very-Volatile, VV: $SF < 0.55$.

220 The number fraction (NF) for each hygroscopic group with the boundary of [a, b]
221 is defined as:

$$222 \quad NF = \int_a^b c(\kappa, D_p) d\kappa \quad . \quad (6)$$

223 The number fraction of each volatile group also can be calculated using a similar
224 equation.

225 **4. Results and discussion**

226 **4.1. Overview of measurements**

227 **4.1.1. Meteorological conditions during the sampling period**

228 Air quality has a strong correlation with local wind direction in Beijing. Previous
229 studies have shown that high PM concentrations usually correspond to southerly winds,
230 while low PM concentration are generally related to northerly winds, because there
231 were more high concentration air pollutants from source locations south of the Beijing
232 area (Wehner et al., 2008; Wang et al., 2010; Gao et al., 2011). Figure 2 displays time
233 series of WD at 280 m, WS at 8 m, ambient T, and RH. During the emission control
234 period, the prevailing winds were northerly, except for the period from 29 August to 30
235 August due to the influence of accumulated precipitation. During the non-control period,
236 the prevailing winds changed due to the influence of weather systems. Two cold fronts
237 passed on two different days, i.e., on the night of 9 September and in the early morning
238 of 30 September. During these frontal passages, the prevailing winds were northerly,
239 but on other days, the prevailing winds were southerly and the meteorological

240 parameters showed obvious diurnal cycle patterns. Over the measurement period, the
241 average ambient T and RH were 21.9°C and 62.4 %, respectively.

242 **4.1.2. Time series of κ -PDF and SF-PDF, and the division of clean and pollution** 243 **periods**

244 Figure 3 shows the time series of 10–400 nm particle mass concentrations (PM_{10-400}
245 nm) derived from PNSD measurements and the time series of κ -PDF and SF-PDF
246 with 40 nm and 150 nm particles as examples. Particles with D_p equal to 40 nm
247 represent local-impacted particles and particles with D_p equal to 150 nm represent
248 regional-transport particles. Several haze events during the non-control period can be
249 seen from the time series of PM_{10-400} nm, which shows the rapid accumulation of particle
250 mass concentration. Based on mass concentrations and weather conditions, we selected
251 several clean and pollution periods to study the differences in aerosol hygroscopicity
252 and volatility for two different cases (Fig. 3). To further study the effect of emission
253 controls, we divided the clean period into two periods: Clean1 (control clean period)
254 and Clean2 (non-control clean period). During the Clean1, Clean2, and Pollution
255 periods, the average PM_{10-400} nm was 6.9 ± 2.8 , 6.0 ± 4.2 , and 51.0 ± 25.6 $\mu\text{g m}^{-3}$,
256 respectively. There was no significant precipitation during the three selected periods.
257 The time series of κ -PDF and SF-PDF (Fig. 3b–e) showed evident changes and
258 fluctuations in the measurements. The prominent differences in κ -PDF and SF-PDF
259 during the three periods will be discussed in the following sections.

260 A wind rose diagram (Fig. S2) was used to compare winds during the different
261 periods. During the Clean1 and Clean2 periods, wind directions were similar, mainly

262 from the north and northwest. During the Pollution period, the wind direction had the
263 characteristics of mountain-valley breezes where the wind direction changed routinely
264 at midnight and changed the wind direction from southerly to northerly (Fig. 2). The
265 change in wind direction at night would reduce pollution in the short term (Sun et al.,
266 2016b). Even so, the prevailing wind direction was southerly during the Pollution
267 period (Fig. S2), which was favorable for the transport of pollutants from the more
268 populated and more industrialized south and southeast to Beijing. The mean WS and
269 RH were similar during all periods, but the mean temperature during the Clean2 period
270 was lower than during the other periods due to the influence of cold fronts (Table S1).
271 In summary, the meteorological parameters of the Clean1 and Clean2 cases were similar
272 expect for the ambient T. This provided the opportunity to compare the differences in
273 aerosol properties between control and non-control periods. The high level of PM
274 during the Pollution case can also provide a good opportunity to compare differences
275 between clean and polluted environments.

276 **4.2. Diurnal variation**

277 **4.2.1. Diurnal variation in the aerosol size distribution**

278 Figure 4a shows the diurnal variation in total number concentration of 10–400 nm
279 particles ($N_{10-400\text{ nm}}$). In general, $N_{10-400\text{ nm}}$ is higher at night and lower during the day
280 due to the influence of changes in the planetary boundary layer (PBL). However, a
281 significant peak in $N_{10-400\text{ nm}}$ is also seen at noontime because of new particle formation
282 (NPF) events (Fig. S3). NPF started at about 0900 local time (LT) during the Clean1

283 and Clean2 periods. During the Clean1 period, the $N_{10-400\text{ nm}}$ peak was lower than that
284 observed during the Clean2 period, and the peak in the Clean1 case appeared two hours
285 earlier than that in the Clean2 case (1200 LT during Clean1 and 1400 LT during Clean2).
286 This illustrates that the strength of the NPF was weaker during the Clean1 period than
287 during the Clean2 period, and that it was likely related to the decrease in precursors
288 during the Clean1 period. H. Li et al. (2016) have reported that during the parade control
289 period, the precursors SO_2 , NO_x , and volatile organic compounds (VOCs) decreased by
290 36.5 %, 49.9 %, and 32.4 %, respectively. The relatively higher ambient temperature
291 during the Clean1 period was also unfavorable for NPF (Kulmala et al., 2004).

292 Figure 4b compares diurnal variations in total mass concentration of 10–400 nm
293 particles ($\text{PM}_{10-400\text{ nm}}$) during the three periods. No clear increase in $\text{PM}_{10-400\text{ nm}}$ is seen
294 while $N_{10-400\text{ nm}}$ sharply increases during the Clean1 and Clean2 daytime periods. This
295 is because the D_p for most particles was less than 100 nm, which contributed little to
296 $\text{PM}_{10-400\text{ nm}}$. During the Clean1 and Clean2 periods, $\text{PM}_{10-400\text{ nm}}$ had an obvious diurnal
297 variation, which could be attributed to the evolution of the PBL. As is known, the lower
298 PBL at night aids in the accumulation of pollutants (Achtert et al., 2009). However, this
299 effect was weak in the pollution case because of the change in wind direction from
300 southerly to northerly at midnight, which could partly offset the influence of the PBL.

301 **4.2.2. Diurnal variation in aerosol hygroscopicity**

302 Figure 5a shows the diurnal variation in size-resolved κ_{mean} during the three periods.
303 κ_{mean} shows a peak during daytime, and is always higher than that observed during

304 nighttime. This is because more highly aged particles due to photochemical reactions
305 cause the increase in κ_{mean} during daytime. In the evening, thermal inversion would cap
306 the ground level and a number of low hygroscopic primary particles (like black carbon,
307 BC) emitted from local diesel trucks and heavy-duty vehicles results in the decrease in
308 κ_{mean} during nighttime (Liu et al., 2011; S. L. Zhang et al., 2016). During the Clean2
309 period, there is another obvious peak at about 0300 LT in the early morning, likely
310 related to the increase in nitrate. Because there was a large amount of NO_x emitted from
311 traffic sources in the evening during the non-control period, with the PBL height
312 reduction and ambient temperature decrease, NO_x could be transformed into
313 hydrophilic nitrate rapidly through NO_3 and N_2O_5 (Dall'Osto et al., 2009). This was
314 also verified from comparisons of the nitrate diurnal cycle with and without emission
315 controls (Zhao et al., 2017).

316 Figure 5b shows the diurnal variation in κ -PDF for particles with D_p equal to 40
317 nm (i.e., local-impacted particles) during the three periods. During the Clean1 period,
318 the κ -PDF has a quasi-unimodal shape (only in the hydrophobic mode). During NPF
319 events, κ_{mean} increases slightly, indicating that 40-nm particles from local sources were
320 always hydrophobic and a very small amount of hygroscopic particles were produced
321 through the nucleation and growth from gaseous precursors. This is likely because the
322 secondary formation of hydrophilic sulfate and nitrate was suppressed due to low
323 concentrations of SO_2 and NO_x during the parade control period (H. Li et al., 2016).
324 Most of the new particles should consist of less hygroscopic organics that are formed
325 by oxidation and condensation of VOCs. By contrast, during the Clean2 period, the κ -

326 PDF with D_p of 40 nm shows either a bimodal or quasi-trimodal distribution and
327 exhibits a large diurnal variation during the day. Interestingly, when the NPF event
328 occurred at about 0900 LT, the number fraction of the hydrophobic mode quickly
329 decreased and the hydrophilic mode increased (Fig. 5b), suggesting the conversion of
330 externally mixed particles to internally mixed particles due to the species condensation
331 (sulfate, nitrate and organics) from the photochemical reaction of SO_2 , NO_x and VOCs.
332 A similar phenomenon was also observed by Z.J. Wu et al. (2016). For the Clean1 case,
333 much less of these gases were in the atmosphere due to the emission control. Around
334 1700 LT, the fraction of hydrophobic mode particles increased again, mainly due to
335 substantial traffic emissions at rush hour. However, during the Pollution period, the κ -
336 PDF shows a bimodal shape during the day. The hydrophilic mode becomes stronger in
337 the early morning and in the afternoon, which is attributed to the NO_x heterogeneous
338 reactions at night, and the aging and growth of pre-existing particles during the day.

339 In summary, the diurnal variations in κ -PDF for 40-nm particles were significantly
340 different during the three periods and the emission control appeared to change the
341 diurnal pattern of κ -PDF, mainly due to the decrease in gas precursors, like SO_2 and
342 NO_x , the reduction of which will suppress the formation of hydrophilic matter.

343 However, the κ -PDF for 150-nm D_p particles (i.e., regional-transport particles) had
344 a similar diurnal variation pattern during the three periods (Fig. 5c) and showed NH
345 and MH modes. The number fraction of the MH mode increased significantly during
346 daytime. There are different reasons for the diurnal variations. One reason is that during
347 daytime, strong photochemistry can produce a large number of condensable vapors,

348 such as sulfuric acid and secondary organic species, which can condense onto pre-
349 existing particles and enhance their water absorbing capacity (Z. J. Wu et al., 2016).
350 Another reason is that when the sun rises, the PBL height increases and older particles
351 are well-mixed, making them more hydrophilic (S. L. Zhang et al., 2016). However, the
352 MH mode is much more evident for the Pollution case and may be related to the higher
353 mass fractions of inorganic salts and more internal-mixed particles during the Pollution
354 period.

355 **4.2.3. Diurnal variation in aerosol volatility**

356 Figure 6a shows the diurnal variation in SF_{mean} , which shows similar trends for all
357 three cases, with the lowest SF_{mean} in the afternoon (1200–1500 LT) and the highest
358 SF_{mean} in the morning (0700–0900 LT) for all particles with D_p ranging from 40-300
359 nm. The diurnal variations illustrate that particles had a higher volatility during the day
360 than at night. This feature is more obvious for those small particles observed during the
361 Clean1 period. During the Clean1 period, particle volatility increased dramatically (i.e.,
362 SF_{mean} decreased) along with the occurrence of NPF events, suggesting that the earliest
363 newly-formed matter (before ~1200 LT) were always volatile at 300° C. As stated
364 previously, during the Clean1 period VOCs has a weaker decrease than SO_2 and NO_x ,
365 this would lead to more VOC-formed organic particles formed, which are normally
366 highly volatile. Therefore, the highest volatility was observed during the Clean1 period.
367 Wehner et al. (2009) also showed that ~97 % of newly-formed particles are volatile
368 because they are dominated by sulfate and organics. With the processes of particle aging,

369 collision, and growth, they then decrease in volatility (i.e., SF_{mean} increases). This is
370 because these processes can enhance the oxidative level of organics and there are more
371 refractory organics (like polymer-type organics) produced.

372 For 40-nm particles, the lowest SF_{mean} appeared two hours later during the Clean2
373 period (~1500 LT) than during the Clean1 period (~1300 LT). This is probably because
374 NPF lasted longer during the Clean2 period. For larger particles, the coating effect of
375 condensable vapors onto pre-existing particles was the major reason behind the
376 intensification of their volatility during NPF events (Wehner et al., 2009; Cheung et al.,
377 2016). The SF_{mean} decreased little compared to that for 40-nm particles. By comparison,
378 the diurnal variation in SF_{mean} for 40-nm particles during the Pollution period changed
379 more smoothly, likely because under a polluted environment, the mass fractions of all
380 chemical species were relatively stable (Sun et al., 2016a) and the particles were well-
381 mixed with highly aging levels.

382 Figure 6b and 6c show the diurnal variation in SF-PDF for 40 nm and 150 nm
383 particles. The SF-PDF normally has an NV mode and a SV or VV mode. The NV mode
384 consists of non-volatile particles, like BC particles, which do not shrink when aerosols
385 are heated. SV and VV modes suggest a mixture of volatile (e.g., organics) and non-
386 volatile matter that shrink when aerosols are heated (Kuhn et al., 2005). The two SF-
387 PDF modes suggest that the particles during the observed periods were mostly
388 externally-mixed. The 40-nm and 150-nm SF-PDF show similar diurnal patterns.
389 During daytime, active aging processes facilitated the mixing of primary particles with
390 secondary species, leading to the transformation of externally-mixed particles to

391 internally-mixed particles, and weakening the NV mode. In particular, this effect was
392 stronger during the Clean1 period than during the other periods. This may be due to the
393 reduction in emissions of soot particles during the control period. In the evening and
394 the early morning, the number fraction of NV-mode particles increased again because
395 a large amount of refractory particles (like BC) were emitted from traffic sources or
396 cooking, and then the slower particle aging and weaker vertical mixing made the
397 external-mixing BC accumulated (S. L. Zhang et al., 2016). The number fraction of
398 NV-mode 150-nm particles in the Clean1 case had a stronger increase than that of 40-
399 nm particles in the evening and early morning. This is because freshly emitted
400 refractory particles (like BC) are primarily within the 150 nm to 240 nm diameter range
401 (Levy et al., 2013). Furthermore, compared with the Pollution case, the number fraction
402 of NV-mode 150-nm particles are much higher during the Clean1 and Clean2 cases.
403 This may reflect the fact that soot particles in a polluted environment can be coated and
404 aged quickly through the heterogeneous reactions of VOCs and other precursor gases
405 (like SO₂, NO_x), which are usually present in extremely high concentrations during
406 polluted days in urban Beijing (Guo et al., 2014; Sun et al., 2016a).

407 Overall, the diurnal variation in aerosol volatility is different between clean and
408 polluted periods. NPF can enhance volatility through the formation of volatile matter
409 and the coating effect of condensation vapors. Particles observed during the control
410 period showed two significant NV and VV modes during the day, suggesting a more
411 externally-mixed state, particularly for the larger particles.

412 4.3. Size-resolved particle hygroscopic and volatile properties

413 Table 1 summarizes the size-resolved mean κ , the growth spread factor ($\sigma_{\kappa\text{-PDF}}$) of
414 $\kappa\text{-PDF}$, size-resolved SF during different periods, and the change in percentages of κ
415 and SF due to the emission control policy. The $\sigma_{\kappa\text{-PDF}}$, defined as the standard deviation
416 of $\kappa\text{-PDF}$, is an indication of the mixing state of aerosol particles. A higher $\sigma_{\kappa\text{-PDF}}$
417 generally suggests a higher degree of external mixing (Sjogren et al., 2008; Liu et al.,
418 2011; Jiang et al., 2016). Liu et al. (2011) chose $\sigma_{\kappa\text{-PDF}} = 0.08$ as the cut-off point for
419 high external mixing and quasi-internal mixing. In this study, $\sigma_{\kappa\text{-PDF}}$ always exceeds
420 0.08 but the 40-nm particles during the Clean1 period, indicating that the particle
421 population was more externally mixed in urban Beijing. The mean $\sigma_{\kappa\text{-PDF}}$ of 40-nm
422 particles during the Clean1 period is equal to 0.08, suggesting that during the control
423 period, 40-nm particles had a low degree of external mixing. This is also seen in the
424 quasi-unimodal distribution of 40-nm $\kappa\text{-PDF}$ (Fig. 5b).

425 During the selected three periods, aerosol particles were more hygroscopic (i.e., κ
426 increased) with increase in particle size (Fig. 7a). The most significant trend is seen in
427 the Pollution case where κ increases from 0.16 to 0.42 when D_p changes from 40 nm to
428 200 nm, but only increases from 0.10 to 0.25 for the Clean1 case and from 0.14 to 0.28
429 for the Clean2 case. This is because particles with a larger size are usually composed
430 of more inorganic salts or oxidized organics, especially in a polluted environment
431 (Swietlicki et al., 2008; Achtert et al., 2009; Fors et al., 2011; Sun et al., 2016a).
432 Meanwhile, the increase in $\sigma_{\kappa\text{-PDF}}$ with the increase in particle size illustrates that there
433 were more external mixing particles with larger sizes (Table 1). Accordingly, aerosol

434 volatility became weaker (SF increased) as particle size increased during the Clean1
435 and Clean2 periods, but no apparent trend was observed for the Pollution period (Fig.
436 7b). This finding is consistent with that reported by Wehner et al. (2009).

437 Figure 6 also shows that all particles were less hygroscopic and more volatile
438 during the control Clean1 period than during the non-control Clean2 period, which can
439 also be seen from the variation in chemical composition. Based on HR-AMS
440 measurements, secondary inorganic aerosols (SIA) had larger decreases than organic
441 aerosols (OA) during the parade control period. The positive matrix factorization of OA
442 further illustrates that primary OA (POA) had similar decreases as secondary OA
443 (SOA). However, more-oxidized SOA had larger decreases than less-oxidized SOA
444 (Zhao et al., 2017). SIA is always more hydrophilic than OA and more-oxidized SOA
445 is also more hydrophilic than less-oxidized SOA (Jimenez et al., 2009; Chang et al.,
446 2010; Rickards et al., 2013; Zhang et al., 2014; F. Zhang et al., 2016). Therefore, the
447 increased fraction of POA emissions, but weakened age processing due to a sharp
448 reduction in SO₂ and NO_x, lead to particles being less hygroscopic during the control
449 period. Meanwhile, particles become relatively more volatile due to the high number of
450 POA particles because OA volatility is generally inversely correlated with the O:C ratio
451 (an indicator of oxidation state) (Jimenez et al., 2009).

452 To quantify the effects of emission control on aerosol hygroscopicity and volatility,
453 Table 1 also gives the change in percentages of κ and SF during the control Clean1
454 period compared with that during the non-control Clean2 period. Results show that κ
455 decreased by 32.0–8.5 % from 40 nm to 200 nm during the control period, with a more

456 significant reduction for small particles, while SF reduced by 7.5–10.5 % from 40 nm
457 to 300 nm. The significant decrease in aerosol hygroscopicity is favorable for
458 decreasing the aerosol water content, thus suppressing the evolution of regional air
459 pollution (like liquid-phase chemical reaction processes in the atmosphere) (Arellanes
460 et al., 2006; Ye et al., 2011; Bian et al., 2014), and eventually improving atmospheric
461 visibility.

462 In addition, because of the reduced hygroscopicity, fewer particles would be
463 activated as cloud condensation nuclei, which is a critical parameter in evaluating the
464 aerosol indirect effect. Thus, our study is important for investigating environmental and
465 climate changes, and should inspire both scientists and policy makers to think more
466 deeply about the issue of heavy air pollution in China.

467 **4.4. Relationship between nearly-hydrophobic and non-volatile particles**

468 For submicron particles, non-volatile (NV) part particles at 300° C were normally
469 the major nearly-hydrophobic (NH) part particles because both their main components
470 are soot particles (Massling et al., 2009; Wehner et al., 2009). S. L. Zhang et al. (2016)
471 compared the relationship between the number fraction of measured non-volatile
472 particles (NF_{NV}) and nearly hydrophobic (NF_{NH}) particles and found those two groups
473 are very likely to be dominated by the same component. In this study, we also analyze
474 the relationship of NF_{NH} and NF_{NV} particles as shown Fig. 8.

475 The results show that Aitken mode particles (40 nm and 80 nm) have a very weak
476 linear relationship between NF_{NH} and NF_{NV} , likely because Aitken mode particles are

477 not as aged. There are a large number of hydrophobic, but volatile, particles such as
478 POA and less-oxidized SOA. Accumulation mode particles (> 100 nm) show a
479 relatively better linear correlation between $N_{F_{NH}}$ and $N_{F_{NV}}$, i.e., correlation
480 coefficients (R^2) are 0.26, 0.55, and 0.62 for 110, 150, and 200 nm particles,
481 respectively. The higher R^2 for the larger particles may arise because larger particles
482 are highly aged particles from cloud processes. Also, freshly emitted refractory and
483 hydrophobic matter is mostly in the accumulation mode (Levy et al., 2013). The best-
484 fit regression line for the accumulation mode particles is always lower than the 1:1 line.
485 This can be attributed not only to externally mixed SIA and volatile organics
486 (completely volatile), which are not taken into account for calculation, but also to that
487 some medium/high volatile organics are nearly-hydrophobic.

488 There were obvious differences in $N_{F_{NH}}$ and $N_{F_{NV}}$ during the three selected
489 periods. For the Clean1 and Clean2 cases, $N_{F_{NH}}$ and $N_{F_{NV}}$ were larger than those
490 obtained for the Pollution case, but more scatter was seen. This is likely related to the
491 influence of NPF events, during which secondary aerosol material had more complex
492 chemical compositions due to the different sources of precursors. A higher $N_{F_{NH}}/N_{F_{NV}}$
493 ratio was seen during the Clean1 period than during the other two periods, illustrating
494 that a higher number fraction of hydrophobic and volatile particles during the control
495 period.

496

497 5. Conclusions and Summary

498 In this study, a H/V-TDMA system was used to measure submicron aerosol
499 hygroscopic and volatile properties in Beijing during and after the parade emission
500 control period. Three periods, namely, the control clean period (Clean1), the non-
501 control clean period (Clean2), and the non-control pollution period (Pollution), were
502 selected to study the effect of emission control on aerosol hygroscopicity and volatility.

503 When emission control measures were in place, particles became more
504 hydrophobic and volatile compared to particles in the non-control period. The κ of 40–
505 200 nm particles decreased by 32.0–8.5 % during the Clean1 period relative to the
506 Clean2 period, while SF of 40–300 nm particles decreased by 7.5–10.5 %. The diurnal
507 variations of κ -PDF were significantly different during the three selected periods,
508 especially for small particles. During the Clean1 period, the κ -PDF of 40-nm particles
509 always showed a quasi-unimodal distribution and had a weaker diurnal variation than
510 that observed during the Clean2 period. This demonstrates that emission control
511 measures can change the diurnal variation pattern of κ -PDF due to the reduction in gas
512 precursors like SO₂ and NO_x, which suppresses the formation of hydrophilic matter.
513 The diurnal variation in aerosol volatility was different between clean and polluted
514 periods. NPF appears to enhance aerosol volatility through the formation of volatile
515 matter and the coating effect of condensable vapors. The particles observed during the
516 control period showed two significant modes during the day, i.e., NV and VV modes,
517 and a more externally-mixed state particularly for larger particles.

518 Aerosol particles became more hygroscopic (i.e., κ increases) as the particle size

519 increased during the three periods. The trend was greatest for the Pollution case where
520 κ increased from 0.16 to 0.42 when D_p changed from 40 nm to 200 nm, but only
521 increased from 0.10 to 0.25 for the Clean1 case and from 0.14 to 0.28 for the Clean2
522 case. Meanwhile, the increase in $\sigma_{\kappa\text{-PDF}}$ (i.e., the standard deviation of κ -PDF) with the
523 increase in particle size also illustrates that there were more external mixing particles
524 with larger sizes. Accordingly, aerosol volatility became weaker (SF increased) as
525 particle size increased during the Clean1 and Clean2 periods, but no apparent trend was
526 observed for the Pollution period.

527 Our results suggest that emission control measures weaken submicron aerosol
528 hygroscopicity, and that aerosol particles are more hygroscopic in a polluted
529 environment. The significant decrease in aerosol hygroscopicity is favorable for
530 suppressing the evolution of regional air pollution. In addition, because of the reduced
531 hygroscopicity, fewer particles would be activated as cloud condensation nuclei, which
532 is a critical parameter in evaluating the aerosol indirect effect. Thus, our study is
533 important for investigating environmental and climate changes, and should inspire both
534 scientists and policy makers to think more deeply about the issue of heavy air pollution
535 in China from a broader perspective.

698 **Figure 1.** A schematic diagram of the hygroscopic and volatile tandem differential
699 mobility analyzer (H/V-TDMA).

700

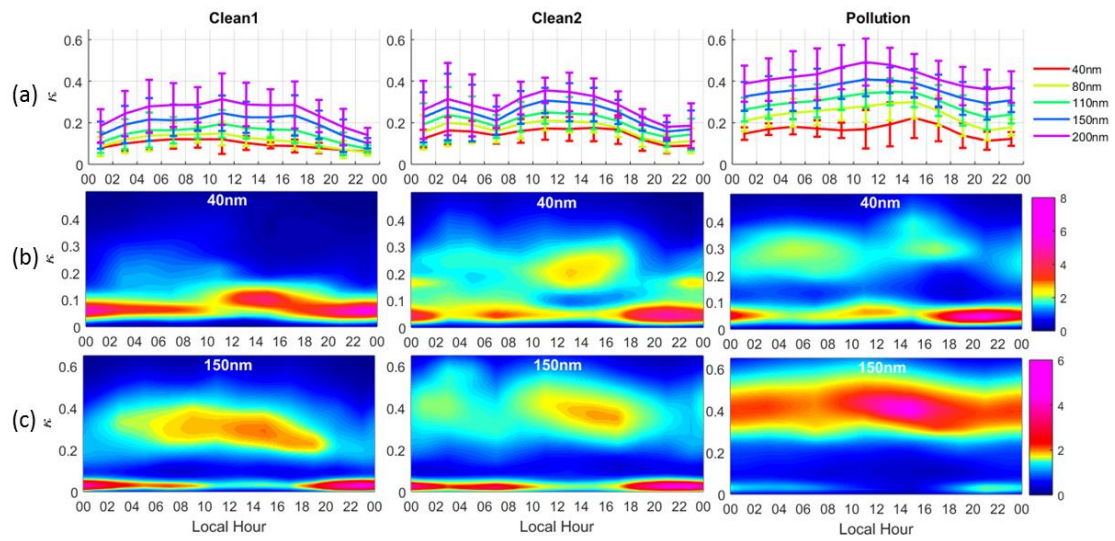

701

702 **Figure 2.** Time series of (a) wind direction at 280 m (in blue) and wind speed at 8 m

703 (in red), and (b) ambient temperature at 8 m (in blue) and relative humidity at 8 m (in

704 red) during the control and non-control periods.

714 red), Clean2 (in green), and Pollution (in blue) cases.

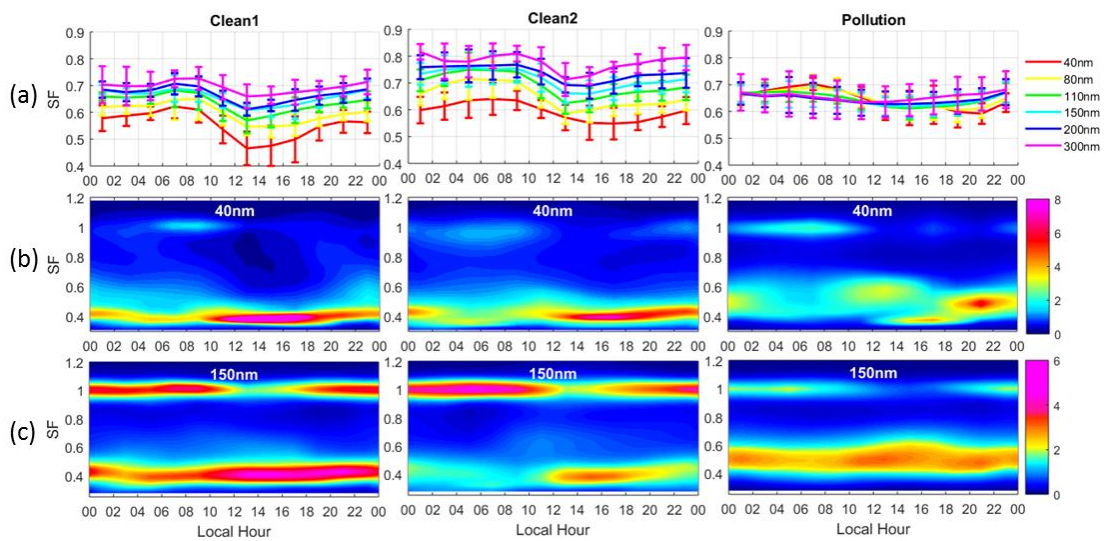

715

716 **Figure 5.** Diurnal variations in (a) mean κ (κ_{mean}) for different mobility diameters, (b)

717 κ -PDF for particles with D_p equal to 40 nm, and (c) κ -PDF for particles with D_p equal

718 to 150 nm during the Clean1, Clean2, and Pollution periods.

719

720 **Figure 6.** Diurnal variation of (a) mean SF (SF_{mean}) for different mobility diameters,

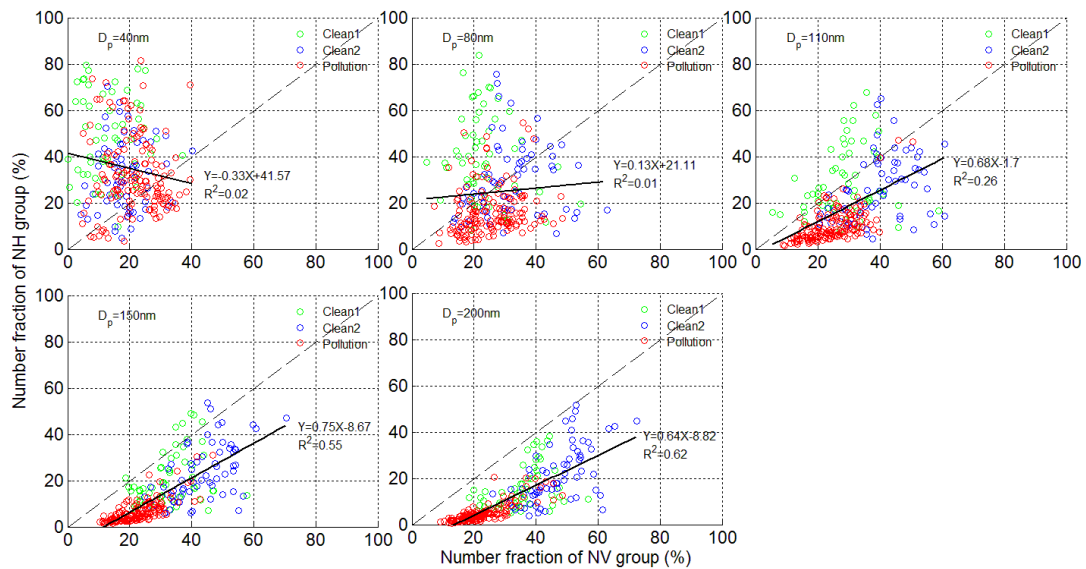

721 (b) SF-PDF for particles with D_p equal to 40 nm, and (c) SF-PDF for particles with D_p

722 equal to 150 nm during the Clean1, Clean2, and Pollution periods.

723

724 **Figure 7.** Size-resolved **(a)** κ and **(b)** SF during Clean1 (C1), Clean2 (C2), and
 725 Pollution (P) periods. The figure shows the mean κ or SF (solid square markers) with
 726 boxes showing the 25th, 50th, and 75th percentiles. The extremities show the 5th and
 727 95th percentiles.

728

729 **Figure 8.** Comparisons between the number fractions of the nearly-hydrophobic
 730 group (NF_{NH}) and the non-volatile group (NF_{NV}) for the Clean1 (in green), Clean2 (in
 731 blue), and Pollution (in red) periods.
