

Responses to Comments by Reviewer 1

This manuscript is relevant for publication in Atmospheric Chemistry and Physics. The authors compile extensive datasets of ocean based observations of nitrate and ammonium concentrations from aerosols. They then compare and contrast observed aerosol concentrations and calculated dry deposition fluxes to a global model (TM4) and the mean product from a global model intercomparison project (ACCMIP). There are limitations, both in how the data are treated and in the model–observation comparisons, making it difficult to draw new conclusions beyond what is essentially already known. Still this represents an important compilation of data, an important recognition of the state of the field and recommendations on needs for significant improvements to advance this science. The work is well cited and includes a table in the supplement of all data used in the compilation, which is also available on a public database via the SOLAS website. Below I outline areas of the manuscript that could be improved, however, overall I recommend publication of the manuscript with minor revisions. The primary weaknesses include: a lack of discussion of the influence of meteorology on results; a need for a more representative abstract; and a need for clearer recommendations to the community to improve and make advancements. Finally, this manuscript is an important review of the state of this field, and as such should address a few basics that will be important to the broad readership of AC&P.

Response: We thank the reviewer for their thoughtful and constructive comments on our manuscript. We set out our responses (blue text) to these in detail below, together with proposed changes to the manuscript (indented text).

Abstract: The abstract could better represent the findings in the work. The last sentence of paragraph 1 (line 37-38) should mention how/why mineral dust alters deposition of N (thinking of a broader audience). The second paragraph should include some type of quantitative summary of the results.

Response: We have modified the Abstract to address the comments of both reviewers. For the point on dust see response to Reviewer 2.

It should be addressed here why the focus here is on comparison with TM4 (which is justifiable but why mention ACCMIP if not actually discussing the comparison here?).

Response: We focus the discussion on TM4 because of the availability of the calculated individual aerosol component concentrations and deposition fluxes (speciation), which is not the case for the ACCMIP data. In addition, TM4 model has a comprehensive representation of the N atmospheric cycle, including Fe redox reactions and organic nitrogen sources and fate (Kanakidou et al., 2012; 2016). On the other hand, ACCMIP deposition fluxes are the ensemble of several models and as such are a more robust model product than one model output. Therefore comparison of ACCMIP and TM4 results puts TM4 results in context. (For changes to manuscript, see revised paragraph of the Abstract below).

Indeed, the TM4 model over-estimates NO₃⁻ and underestimates NH₄⁺ - however, the comparison with NH₄⁺ is much better in all of the ocean basins. Can this be quantified/summarized more concretely here?

Response: In response to these comments we have added a more quantitative description of the model - observation comparison to the Abstract (see revised paragraph below) and further discussion has been added at the end of Section 3.3.

Revised text, Section 3.3:

Note that over land, NO_3^- and NH_4^+ levels are affected by the vicinity of the sources. In particular, biomass burning and dust emissions affect the partitioning of NO_3^- and NH_4^+ to the aerosol phase. Even small inaccuracies in the model simulations of this partitioning can lead to higher discrepancies between model results and observations over land than over the ocean. Indeed, Kanakidou et al. (2016) have compared NO_3^- and NH_4^+ concentrations in PM10 over Europe and found an overestimate in NO_3^- PM10 content of about 115% and an underestimate in NH_4^+ in PM10 of about 55% (Figure S4 in the Kanakidou et al. (2016) supplementary material), results that are consistent with, but larger than the 70% and 44% respectively reported here for oceanic regions (Fig. 4 of the present paper).

Also missing from the abstract is concrete suggestions or recommendations. The abstract makes it appear that little is concluded in this study beyond the clear limitations of our understanding of dry deposition velocities. What's needed to really address this or are there specific things the community should at least be worried about addressing in the near future? In other words, the abstract should address this a bit more to be more representative and garner community attention. At the very least, the clear recommendation that measured aerosol concentrations be reported for observation and models and that this be the key comparison that is made rather than dry deposition fluxes is an important point that belongs in the abstract.

Response: We have re-written the second paragraph of the Abstract to address the reviewer's comments (and those of Reviewer 2). In order to avoid overly increasing the size of an already long Abstract, we have chosen to draw the reader's attention to the existence of recommendations for improvements, but have only explicitly stated the conclusion regarding comparisons to modelled surface concentrations (as suggested by the reviewer).

Revised text, Abstract:

Assessment of the impacts of atmospheric N deposition on the ocean requires atmospheric chemical transport models to report deposition fluxes, however these fluxes cannot be measured over the ocean. Modelling studies such as the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP), which only report deposition flux are therefore very difficult to validate for dry deposition. Here the available observational data were averaged over a $5^\circ \times 5^\circ$ grid and compared to ACCMIP dry deposition fluxes (ModDep) of oxidised N (NO_y) and reduced N (NH_x) and to the following parameters from the TM4-ECPL (TM4) model: ModDep for NO_y , NH_x and particulate NO_3^- and NH_4^+ , and surface-level particulate NO_3^- and NH_4^+ concentrations. As a model ensemble, ACCMIP can be expected to be more robust than TM4, while TM4 gives access to speciated parameters (NO_3^- and NH_4^+) that are more relevant to the observed parameters and which are not available in ACCMIP. Dry deposition fluxes (CalDep) were calculated from the observed concentrations using estimates of dry deposition velocities. Model – observation ratios, weighted by grid-cell area and

numbers of observations, ($R_{A,n}$) were used to assess the performance of the models. Comparison in the three study regions suggests that TM4 over-estimates NO_3^- concentrations ($R_{A,n} = 1.4 - 2.9$) and under-estimates NH_4^+ concentrations ($R_{A,n} = 0.5 - 0.7$), with spatial distributions in the tropical Atlantic and northern Indian Ocean not being reproduced by the model. In the case of NH_4^+ in the Indian Ocean, this discrepancy was probably due to seasonal biases in the sampling. Similar patterns were observed in the various comparisons of CalDep to ModDep ($R_{A,n} = 0.6 - 2.6$ for NO_3^- , $0.6 - 3.1$ for NH_4^+). Values of $R_{A,n}$ for NH_x CalDep - ModDep comparisons were approximately double the corresponding values for NH_4^+ CalDep - ModDep comparisons due to the significant fraction of gas-phase NH_3 deposition incorporated in the TM4 and ACCMIP NH_x model products. All of the comparisons suffered due to the scarcity of observational data and the large uncertainty in dry deposition velocities used to derive deposition fluxes from concentrations. These uncertainties have been a major limitation on estimates of the flux of material to the oceans for several decades. Recommendations are made for improvements in N deposition estimation through changes in observations, modelling and model – observation comparison procedures. Validation of modelled dry deposition requires effective comparisons to observable aerosol-phase species concentrations and this cannot be achieved if model products only report dry deposition flux over the ocean.

Section 2.2: Include units in defining the variables for Equation (1).

Response: We have added units for these variables, as requested by the reviewer.

Revised text, Section 2.2:

Where possible, the observed aerosol concentrations (C : nmol m^{-3}) for NO_3^- and NH_4^+ were compared directly with corresponding particulate concentrations simulated by the models (i.e. for the TM4 model, see below). Dry deposition fluxes from the models were also compared to the observational database. In order to do so, dry deposition fluxes (F : $\text{mg N m}^{-2} \text{d}^{-1}$) were calculated from the observed concentrations of the two species using dry deposition velocities (v_d : m d^{-1}) (Eq. 1), with appropriate correction for the relative atomic mass of N. (Note that hereafter we quote v_d in units of cm s^{-1}).

Section 2.3 For each model description, it should be mentioned what is considered surface level in each model – i.e. what vertical resolution is the model output averaged over?

Response: It is not possible to give a unique surface level for the ACCMIP multi-model product, as the underlying models each have their specific coordinate systems. In general, the mid-level of the lowest layer in the models varies between 20-40 m. For TM4, the mid-level of the lowest layer is at 40 m.

Revised text, Section 2.3:

TM4:

The model's lowest level has a mid-level height of 40 m and its native resolution is 2° (lat.) x 3° (lon.), but for this study the model output was interpolated to a grid scale of 1° x 1° .

ACCMIP:

The fields used were MMM dry deposition from 10 (for NO_y) or 5 (for NH_x) individual atmospheric chemical-transport models, generally with surface mid-level heights of 20 - 40 m, and were reported by ACCMIP on a grid scale of 0.5° x 0.5°, although the resolution of individual models was coarser.

Lines 141-142: replace “sigma” with 1 sigma or 1 std dev or similar

Response: These values were 1 sigma. The text has been updated accordingly.

Line 152+ : It is not discussed whether ACCMIP includes a flux of NH₃ from the ocean similar to TM4 and how much is emitted on an annual basis.

Response: Most of the ACCMIP models include a prescribed NH₃ surface flux following very old recommendations by the GEIA community from 1996 (Bouwman et al., 1997). The emissions amount to some 8 Tg NH₃/yr. Much of these ocean emissions are recycled close to the sources, if no uptake by acidic aerosol is considered. This has been clarified in the text.

Revised text, Section 2.3:

The ACCMIP products used in this comparison were based on emissions for the year 2000 and average meteorology for the decade 2000 – 2009 (Lamarque et al., 2013a). The fields used were MMM dry deposition from 10 (for NO_y) or 5 (for NH_x) individual atmospheric chemical-transport models, generally with surface mid-level heights of 20 - 40 m, and were reported by ACCMIP on a grid scale of 0.5° x 0.5°, although the resolution of individual models was coarser. NO_y and NH_x dry deposition estimates were also available for TM4. (Neither particulate concentration nor dry deposition fields were available for NO₃⁻ or NH₄⁺ from ACCMIP). For both ACCMIP and TM4 model results, NH_x corresponds to the sum of NH₃ and NH₄⁺. Most models in the ACCMIP product included marine emissions of NH₃ based on Bouwman et al. (1997).

Is it possible to report what percentage of NO_y is NO₃⁻ in the ACCMIP products? In the comparisons this is brought up as a reason for disagreement between model and obs, but it would be interesting to note whether NO₃⁻ is a majority of the NO_y deposition or not.

Response: The percentage of NO_y in the ACCMIP product that is due to particulate NO₃⁻ deposition was not reported in the original publication of this product (Lamarque et al., 2013a). This was because not all of the models used to produce the ACCMIP multi-model mean specifically simulated particulate NO₃⁻ deposition (Lamarque, personal communication, 2017). The text has been amended to state this explicitly, and the implications of this for the ACCMIP NO_y deposition flux estimates are also discussed.

Revised text, Section 2.3:

Particulate NO₃⁻ was not simulated by all of the models contributing to ACCMIP, and hence the fractional contribution of NO₃⁻ to NO_y deposition was not reported by Lamarque et al. (2013a). In models without a specific simulation of particulate NO₃⁻, this species is likely to have been simulated as gas-phase HNO₃, whose dry deposition velocity is similar to that of

particulate NO_3^- (Pryor and Sorensen, 2002). Thus, the dry deposition flux of NO_y in the multi-model mean was not greatly affected by this factor. The ACCMIP NO_y dry flux was not substantially different from that computed in the TM4 model, which does specifically simulate dry particulate NO_3^- deposition (Kanakidou et al., 2016). Therefore, in the present study, TM4 speciated results are more appropriate for comparison to the observations and are put in context when used jointly with the more robust, but less speciated, ensemble model results of ACCMIP.

Discussion:

It would be useful to include some discussion on the influence of meteorology. ACCMIP output is based on average met fields for 2000-2009. TM4 uses ECMWF. The calculated deposition for variable v_d uses ECMWF wind speeds. But clearly, amongst all products and calculations, there is an important role of meteorology in determining deposition. Perhaps the variable v_d could be calculated with another, different year of meteorology to give an estimate of how uncertain the influence is of a model-data met product on the calculations?

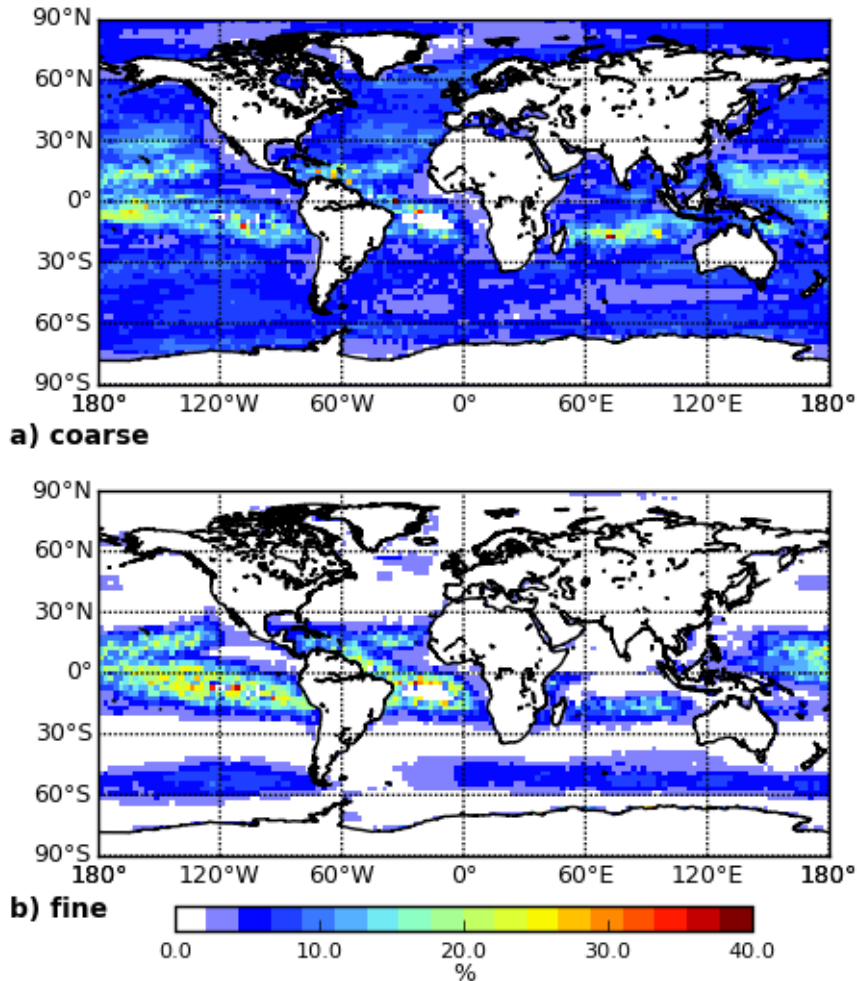

While analyzed met fields are useful, their utility over the open ocean where direct measurements are limited may be an issue. This should be better addressed here.

Response: In fact, deposition velocities were calculated using mean ECMWF wind fields for all the years that observational data was available for (1995-2012). We have clarified this in the text (see response to Reviewer 2). We have added text to Section 4.1 to discuss the uncertainty introduced by the choice of year of ECMWF wind speeds and the uncertainty in ECMWF wind fields themselves, including a new figure (S8 in the revised Supplementary material) of deposition velocity relative standard deviation derived from the individual ECMWF wind fields for the years studied here (below).

Revised text, Section 4.1:

Uncertainty in analysed meteorology introduces uncertainty into deposition velocities derived for the variable v_d CalDep calculation. This uncertainty was assessed by calculating v_d from mean ECMWF wind speeds for each of the individual years (1995 – 2012) and the relative standard deviations of these annual v_d values. Standard deviations were relatively high over the tropical oceans (up to ~25%) and lower elsewhere (<10% for coarse particles and <5% for fine particles) – see Fig. S8. While ECMWF wind fields are themselves subject to uncertainty, weather product skill continues to improve as a result of extensive use of global coverage satellite observations (Bauer et al., 2015).

Deposition velocity r_{sd}

Section 4.4: It is mentioned that the representation of mineral dust in models is limited. Can this be discussed specifically in the context of TM4 and ACCMIP? Are there direct model-obs comparison related to this from other studies? Is there some estimation of how poorly this might be represented in these models specifically?

Response: Indeed, dust simulations are rather uncertain. We added text to illustrate the variations in simulated dust fluxes for TM4, ACCMIP and in mineral dust atmospheric transport models in general.

Revised text, Section 4.4:

This is itself a considerable challenge. Dust emissions in TM4, simulated for the year 2008 using ECMWF meteorology, were 1181 Tg yr^{-1} (Myriokefalitakis et al., 2016), while Kanakidou et al. (2016) simulated emissions almost 30% higher

for the year 2005. In the case of ACCMIP, not all of the models involved included simulations of mineral dust aerosols (Lamarque et al., 2013b). In general, modelled dust deposition fluxes to remote ocean regions have been shown to vary by factors of 10 or more (Huneeus et al., 2011; Schulz et al., 2012) and to not reproduce key aspects of the dust cycle even in well-characterised regions (Prospero et al., 2010).

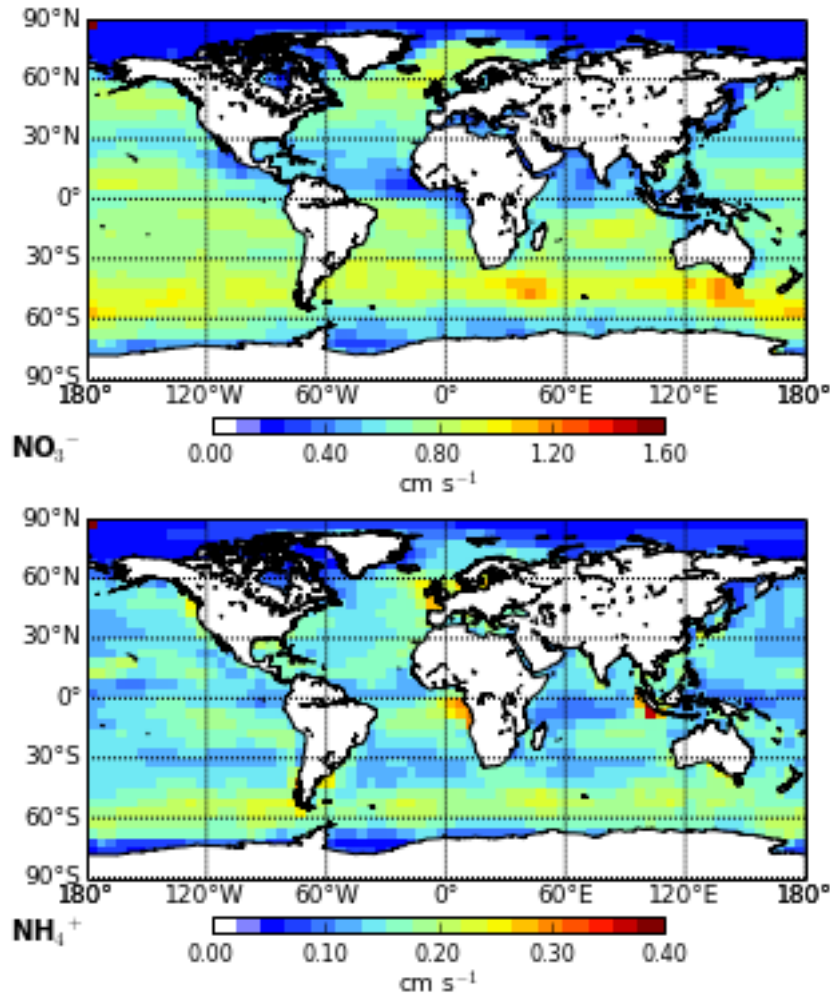

Section 4.5: There is great emphasis placed here and in the abstract and conclusions on the uncertainty associated with dry deposition velocities. How can new progress be made on this issue? Some type of recommendation, from the clear range of experts who appear here as co-authors, should be made. Also, it would be helpful to list the v_d in Table 2 for both model products and that used to calculate the observed dry deposition here. From the text, it appears that modeled v_d and assumed/calculated v_d are not so vastly different, yet the discussion here (and in the abstract and conclusions) makes this appear as a vital issue. Does this suggest that we need to constrain velocities to within +/- 25% or more (or less)? More can be spoken to/digested here from this model-calculated data comparison.

Response: With regard to model product deposition velocities, TM4 calculates deposition velocities using the Ganzeveld et al. (1998) parameterisation (the same parameterisation used in the variable v_d method for calculated deposition fluxes) every time that meteorology is changing (3-hours in TM4) and applies these to the concentrations of NH_4^+ and NO_3^- every model time-step. Therefore, it is unrealistic to calculate a 'mean' deposition velocity. Instead we have calculated the 2-D field of the 'effective mean deposition velocity' as the ratio of the annual deposition fluxes to the respective annual mean concentration, both for NH_4^+ and NO_3^- . These fields (Figure below) have been added to the manuscript's supplementary material (as a revised Fig. S1) and additional text on this issue added to Section 4.2. Information on effective mean deposition velocity is not available for the ACCMIP product. Due to the limited number of cases for which effective mean v_d is available, and because these values are not representative of the model function, we have added the available areal average v_d values to a new table (Table S3) in the supplementary material, rather than in Table 2 as the reviewer requested.

Overall though, agreement or disagreement between assumed / calculated deposition velocity fields and the effective mean deposition velocity fields of TM4 does not alter the fact that these deposition velocities are inherently uncertain.

The reviewer's other comments here are addressed in our responses to comments on Section 5 of the manuscript.

TM4 Effective deposition velocity

Revised text, Section 4.2:

Differences in the temporal scales of observations and model time-steps can also lead to biases. For instance, the variable v_d method for CalDep and dry particulate deposition in TM4 are both based on the parameterisation of Ganzeveld et al. (1998). The CalDep calculation involves the use of mean observed aerosol concentration and ECMWF wind speeds averaged over the period 1995 – 2012. In TM4, wind fields (also based on ECMWF meteorology) are updated every 3 hours in order to calculate v_d for each time step. In order to compare deposition velocities over similar time-scales, it is possible to calculate “effective mean deposition velocity” for NO_3^- and NH_4^+ in TM4 (the ratio of the annual deposition fluxes to the respective annual mean concentrations), but these values are not representative of the deposition velocities used at the model time-step. Maps of variable v_d used in CalDep calculations and effective deposition velocity for TM4

and areal average values of these for the study regions can be found in the Supplementary Information (Fig. S1 and Table S3).

Conclusions: Suggest renaming this to “Summary and Conclusions”

Line 469: See also above – suggest making some type of recommendations on actions that can be taken here to improve the state of the field. More studies in different places? Specific types of studies – i.e. laboratory vs field measurements? More passive sampling?

Response: The section has been renamed as the reviewer suggests. We have added a new paragraph to Section 5 in which we discuss measures that might be used improve models of atmospheric N input to the ocean. These include recommendations on observations, improvements to models and to model – observation comparisons.

Revised text, Section 5:

There are a number of steps that can be taken to improve model predictions of atmospheric N inputs to the ocean. Observations of N deposition that target key areas of uncertainty (such as regions with strong seasonal cycles; intense gradients in N concentrations / deposition; and with contrasting mineral dust regimes) are required and these field campaigns should include measurements that address the needs of the modelling community. Examples of such measurements include: gas-phase N speciation and deposition flux, in addition to particulate N speciation (in order to better constrain modelled N simulations); more detailed measurement of N species aerosol particle size distributions and measurement of aerosol particle deposition fluxes over the ocean (to help improve estimates of particulate N dry deposition over the ocean); long-term measurement of dry particulate deposition N species fluxes, concurrently with N species wet deposition measurements, at suitable remote island locations. In the future, reducing uncertainties in v_d from small-scale wind and aerosol property heterogeneity may help provide more certain v_d estimates. One way to do so might be to estimate larger-scale v_d from remote sensing observations, based on relationships between N concentrations and surface and remotely-sensed aerosol properties. To date, these relationships are still poorly constrained. Improvements in emissions estimates, such as through the use of satellite-derived fire radiative power to assess biomass burning emissions (Freeborn et al., 2014), are key to improvements in the performance of models. Most model simulations of marine NH_3 emissions are based on the very old inventory of Bouwman et al. (1997). Both observations and models of air – sea NH_3 exchange have progressed since that study (e.g. Johnson et al., 2008; Paulot et al., 2015) and these advances should be incorporated into N atmospheric chemistry transport models more widely. Organic N species have been shown to comprise a significant fraction of atmospheric N (Jickells et al., 2013). Explicit inclusion of organic N into models (e.g. Kanakidou et al., 2012) should therefore result in more effective simulations of the atmospheric N cycle. Future model – observation comparisons would be more effective were the observations compared directly to the corresponding absolute time in the model, rather than over time-averaged periods as done here. Ideally, sampling of comparative values from the models should be done over time intervals matched to the collection period of the observations.

Table 2: Suggest reporting dry deposition velocities (vd) for the models and the calculations for each ocean basin in this Table.

Response: See above.

Typos/minor edits: Line 121: “to” should be “for” Line 123: “associated” should be “association” Line 124: missing ‘with’ prior to “final aerosol fractions”

Response: These corrections have been made.

Responses to Comments by Reviewer 2

Based on an extensive ship-based observations of aerosol NO_3 and NH_4 concentrations in globe, this manuscript assesses the performance of simulated N concentration and deposition fluxes over three remote oceans. This is a very impressive manuscript that reports on the model-observation comparisons and is generally well written. This manuscript is thus a significant contribution to understanding state-of-the-art model limitations for annual average, seasonality, and spatial patterns. The primary shortcomings in the manuscript include: clarification of the methodology of models used, uncertainties due to emissions and meteorological forcing data, sensitivity of the model-observation comparisons on the size of spatial window, rationality of model-observation comparison analysis on deposition fluxes, implications for atmospheric community in improving models. I presented the review of the paper into separate main topics corresponding to different section of the manuscript.

Response: We thank the reviewer for their thoughtful and constructive comments on our manuscript. We set out our responses (blue text) to these in detail below, together with proposed changed to the manuscript (indented text).

Abstract: The first paragraph should be shortened as much as possible to indicate the importance of model-observation comparisons as well as the influence of mineral dust on N depositions.

Response: We have shortened this paragraph as much as possible, while adding the information on the influence of mineral dust requested by the reviewer.

Anthropogenic nitrogen (N) emissions to the atmosphere have increased significantly the deposition of nitrate (NO_3^-) and ammonium (NH_4^+) to the surface waters of the open ocean, with potential impacts on marine productivity and the global carbon cycle. Global-scale understanding of the impacts of N deposition to the oceans is reliant on our ability to produce and validate models of nitrogen emission, atmospheric chemistry, transport and deposition. In this work, ~2900 observations of aerosol NO_3^- and NH_4^+ concentrations, acquired from sampling aboard ships in the period 1995 - 2012, are used to assess the performance of modelled N concentration and deposition fields over the remote ocean. Three ocean regions (the eastern tropical North Atlantic, the northern Indian Ocean and northwest Pacific) were selected, in which the density and distribution of observational data were considered sufficient to provide effective comparison to model products. All of these study regions are affected by transport and deposition of mineral dust, which alters the deposition of N, due to uptake of nitrogen oxides (NO_x) on mineral surfaces.

The methodology in the second paragraph is much hard to follow: why choose TM4? How about the two commonly applied methods to calculate N deposition fluxes for CalDep? Does CalDep have the results of deposition fluxes of NO_y and NH_x ? Are NO_y and NH_x derived from wet and dry depositions? Is it possible to compare nitrate and ammonium with ACCMIP means? In addition, is it possible to separate the contributions of

deposition velocities and N concentration to model-observation discrepancy? I believe that it is much importance for scientific community to improve the model-related works in the future.

Response: We have completely rewritten this paragraph, in response to comments by both reviewers (see response to Reviewer 1).

Introduction: Line 71-73: A few of global atmos. Models has been applied for large scale assessment of N deposition over oceans, such as Dentener et al. (2006), Wang et al. (2015), etc. such works should be cited: Dentener, F., Drevet, J., Lamarque, J. F., Bey, I., Eickhout, B., & Fiore, A. M., et al. (2006). Nitrogen and sulfur deposition on regional and global scales: a multimodel evaluation. *Global Biogeochemical Cycles*, 20(4), 16615-16615; Wang, R., Balkanski, Y., Bopp, L., Aumont, O., Boucher, O., & Ciais, P., et al. (2015). Influence of anthropogenic aerosol deposition on the relationship between oceanic productivity and warming. *Geophysical Research Letters*, 42(24), 10745-10754.

Response: We have added some citations of modelling studies of N deposition to the ocean, as the reviewer suggests.

Lin 88-89: again, please explain why choose TM4 in this study

Response: We chose to incorporate results from TM4 into the study because the model has a comprehensive atmospheric N cycle description, including Fe redox reactions and organic nitrogen (Kanakidou et al., 2012; Kanakidou et al., 2016) and it allowed us access to parameters associated with particulate NO_3^- and NH_4^+ , which were not available from ACCMIP.

Therefore, in the present study, TM4 speciated results are more appropriate for comparison to the observations and are put in context when used jointly with the more robust, but less speciated, ensemble model results of ACCMIP.

Lin 105-108: Sampling biases due to multiple sources should be discussed in details. Is any type of samples excluded based on sampling regulation related to N deposition in this study? It is better to describe the sampling regulation (sampler, period, temporal resolution, size fractions, sampling method, analytical method, etc) in main text or SI file or the dataset SOLAS

Response: We have added further information on the methodologies for the source observations to Table S1 in the Supplementary Material and added more text to the main manuscript to explain the rationale for selecting data to include in the database.

Since the data originate from multiple sources, the samples were acquired using a variety of sampling devices (e.g. bulk filtration or in size fractions using cascade impactors), collection substrates (e.g. Whatman 41, glass fibre or quartz) and sampling intervals and were analysed using different techniques (commonly ion chromatography or automated spectrophotometry) in many different laboratories. (A summary of the available information on sample collection procedures is given in Table S1). Standard procedures for aerosol inorganic N sampling and analysis have not yet been established, and nor have inter-laboratory intercomparison / intercalibration exercises (e.g. Morton et al., 2013) been

commonly held. In the absence of such procedures, datasets were accepted into the database that had either already been published in the peer-reviewed literature or that originated from laboratories with established publication records. Under these conditions, the presence of biases within the observational database cannot be ruled out. Sampling intervals varied between 12 and 48 hours, but the majority of samples were collected over ~24 hours.

Methods: Line 127: Explain the abbreviation ECMWF first, and justify why choose ECMWF. Actually a few of reanalysis datasets including surface wind speed could be used for estimating V_d . Could you please discuss more on the uncertainties due to the choice of meteorology dataset?

Response: We have added “European Centre for Medium-Range Weather Forecasts” for ECMWF and included a discussion of the uncertainties introduced through the choice of meteorology (see responses to Reviewer 1).

Line 128: what is the difference between variable V_d model and well-tested deposition velocity model in previous works? How to calculate aerodynamic resistance and quasi laminar boundary layer resistance? A detail of variable V_d model should be provided in SI file.

Response: We think the reviewer has concluded that we developed a new model for V_d , but we in fact used the well-established model of Ganzeveld et al. (1998). We have altered the text describing our use of this V_d model to explain this more clearly.

Dry deposition fluxes were also calculated using wind speed-dependent values of v_d for particles of 7 μm (coarse mode) and 0.6 μm (fine mode) diameter using the parameterisation of Ganzeveld et al. (1998). This “variable v_d ” method is similar to the approach used previously to estimate dry deposition of N species to the Atlantic Ocean by Baker et al. (2010) and Powell et al. (2015). In this case, European Centre for Medium-Range Weather Forecasts (ECMWF) ERA Interim reanalysis dataset surface wind speeds were obtained for the years 1995 – 2012 and the mean wind speed for these years was used to calculate v_d for each grid cell.

2.3 model products: I strongly suggest introducing the methodology of TM4 model in SI file, forcing data, emissions of N, simulation setup, etc

Response: The information requested by the reviewer is covered in detail in Kanakidou et al. (2016) and references therein. There is no need to repeat that information in the SI.

Line 139: how to compare modeled N deposition at coarse scale with site-scale observations?

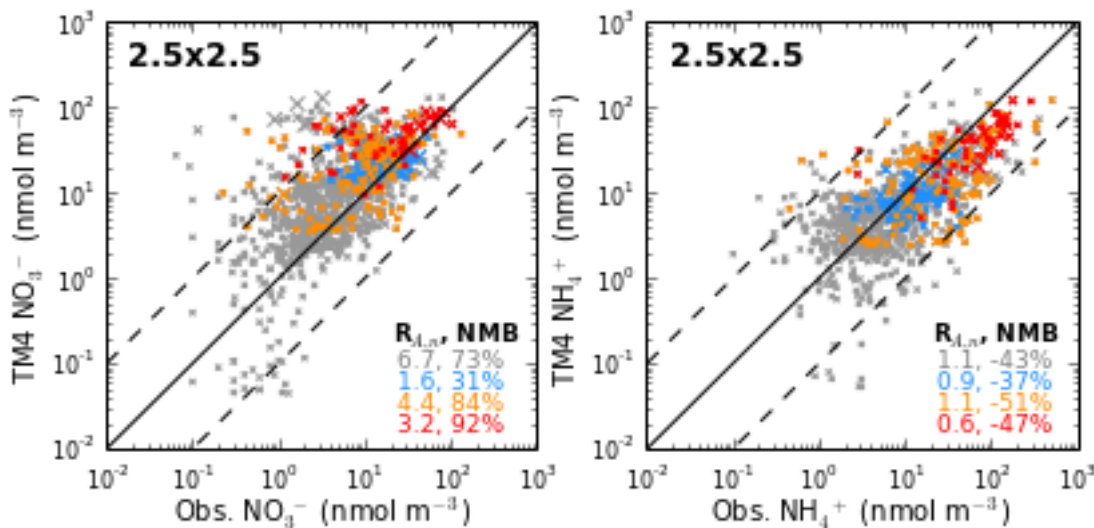

Response: This is a perennial problem for model – observation comparisons. The underlying assumption in all such cases is that the available observations are representative of the model grid scale, which is a plausible assumption for the open ocean. The manuscript contains considerable discussion of the validity of that assumption for the present study.

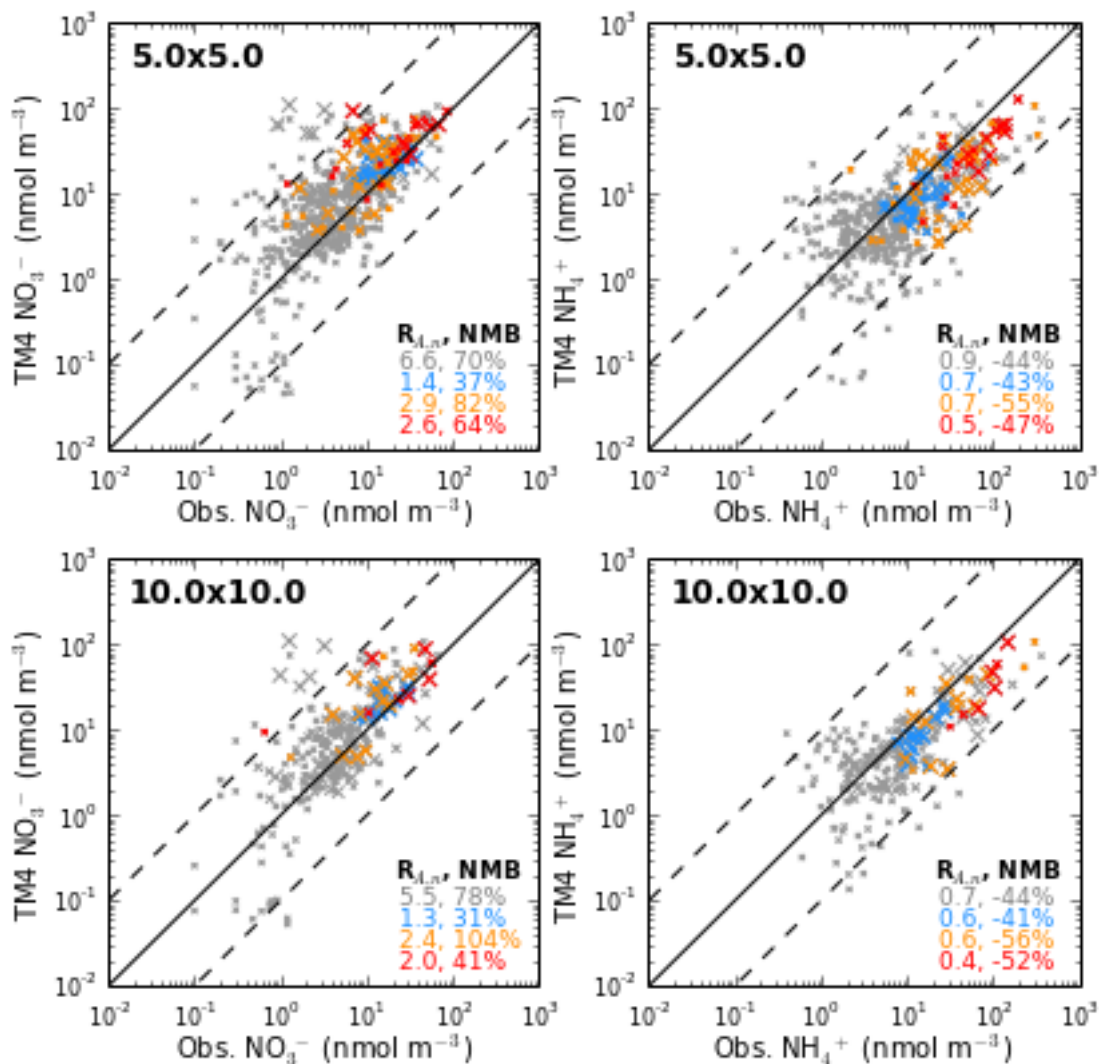

Line 152-153: CalDep is based on the observations for the period of 1995 to 2012, but ModelDep is simulated for a specific year (2005 for TM4, 2000 for ACCMIP MMM).

Response: Yes, that is correct. Had sufficient observations been available for us to focus the comparison on the model simulation periods, we would have done so. Unfortunately remote ocean observations of aerosol composition are not so abundant.

Line 172: Spatial window of 5°x5° is used for model-observation comparisons. Could you please check whether the result is independent of the size of spatial windows?

Response: In order to illustrate the impact of grid scale on the comparisons we make in the manuscript, we have repeated the observation – model comparisons for aerosol nitrate and ammonium concentrations at three different resolutions (2.5°x2.5°, 5°x5° and 10°x10°). The results of that analysis are shown below (note that, in order to examine the 10°x10° resolution, the boundaries of the study regions were expanded to 0, 40, -40, -10 (NEAtl), -10, 30, 50, 90 (NInd) and 10, 40, 110, 140 (NWPac) (all °S, °N, °W, °E). While there were some differences in values of $R_{A,n}$ and NMB between resolutions, these did not impact the conclusions of the study and we therefore consider that our results are robust to changes in grid resolution.

Results and Discussion Line 203: explain the abbreviations TEAtI, NInd and NWPac. I suggest to use the full name of study regions in main text, but abbreviations in Tables or Figures.

Response: The abbreviations TEAtI, NInd and NWPac were defined at the end of Section 1 (lines 94-95 of the Discussion manuscript). We prefer to leave the use of these abbreviations as they were.

Line 333: I am not sure if it is necessary to have subtitles in the main text according to ACP style.

Response: The use of subtitles is consistent with ACP style. We have left these as they were, because we feel that they aid the reader.

Line 340-349: the total columns of NH₃ retrieved from IASI satellite observations would be an effective way to validate the spatio-temporal patterns of ammonia, referring to: Van Damme, M.; Clarisse, L.; Heald, C. L.; Hurtmans, D.; Ngadi, Y.; Clerbaux, C.; Dolman, A. J.; Erisman, J. W.; Coheur, P. F. Global distributions, time series and error characterization of atmospheric ammonia (NH₃) from IASI satellite observations. *Atmos. Chem. Phys.* 2014, 14 (6), 2905–2922.

Response: We appreciate the reviewer's suggestion, but we do not feel that total column gas-phase ammonia satellite retrievals are likely to prove effective in helping to constrain the exclusively surface-level processes considered in our manuscript.

Line 350-353: Besides of the effect of pH, the inconsistency of sampling regulation for ship-based observation would be another source of biases. Please discuss in details on it.

Response: We already discussed the likely bias introduced through losses on cascade impactor samplers (lines 334-339 of Discussion document). Although the text highlighted by the reviewer focuses on effects driven by pH, the impacts of those effects vary primarily according to sampling methodology (e.g. whether, or not, aerosol particulates are size-segregated at the point of collection). We have added text to emphasise this.

Thus, there are a variety of processes, particularly in the marine environment, that can lead to positive and negative biases in measured aerosol NO₃⁻ and NH₄⁺ concentrations, and the extent to which a given dataset is affected by these processes is greatly influenced by sampling methodology. If such effects have influenced the database used here, biases are unlikely to be uniform across all the observations, since the observations come from a very wide variety of sources with many different sample collection protocols (see Table S1).

Subsection 4.2: Model-observation comparisons should focus on the difference in aerosol concentrations, but not on that in deposition fluxes. Actually CalDep deposition fluxes are also derived based on two simple methods, where the uncertainty of dry deposition velocity cannot be rationally quantified in this study.

Response: We agree with the reviewer. The lack of species concentrations reported in the ACCMIP product forces us to use a deposition comparison in this case. The concentration comparisons we report for TM4 are clearly preferable, but the inclusion of deposition comparisons for TM4 allows us to draw parallels with the less than optimal evaluation of ACCMIP that we have been forced to make. We have amended the Abstract to emphasise this point (see response to Reviewer 1).

Subsection 4.3: I guess that the discrepancy in seasonality between modeled and observed N depositions would be due to the uncertainties of emission source and meteorological data. It would be of use to discuss in details on their influences.

Response: We have added additional text to discuss the potential influences on seasonality in N deposition in the northern Indian Ocean region.

Differences in N deposition seasonality between models and observations in this region might arise as a result of a number of factors. These include: seasonal variations in N emissions used in the models (see for instance discussion in Daskalakis et al. (2015) for seasonal and spatial differences in biomass burning emission databases, Figs. 1 and S2 of that paper), biases in seasonal variations in meteorology (e.g. in precipitation rates (Srinivas and Sarin, 2013) and wind fields), and seasonal changes in mineral dust composition, in particular calcium content, over the region (Srinivas and Sarin, 2013) affecting the uptake of NO_x onto dust particles.

Subsection 4.4: please extend the discussion on the role of mineral dust on N deposition. It would be better to specify the limitation of models, such as TM4 and ACCMIP multi-model ensemble?

[Response: See our response to the comments by Reviewer 1 on this issue.](#)

Conclusions: it is too long to follow as conclusion of the manuscript. I suggest to shorten it and focus on the main findings on the limitation of current models in estimating particulate N depositions and the recommendations on improving the models for atmospheric modeling community.

[Response: We altered the text in this section \(now titled “Summary and Conclusions”, as suggested by Reviewer 1\) in order to address the comments of both reviewers. \(See response to Reviewer 1\).](#)

27 **Abstract**

28 [Anthropogenic nitrogen](#) (N) emissions to the atmosphere have increased [significantly](#) the deposition of nitrate (NO_3^-) and
29 ammonium (NH_4^+) to the surface waters of the open ocean, with potential impacts on marine productivity and the global carbon
30 cycle. Global-scale understanding of [the impacts of N](#) deposition to the oceans is reliant on our ability to produce and validate
31 models of nitrogen emission, atmospheric chemistry, transport and deposition. In this work, ~2900 observations of aerosol
32 NO_3^- and NH_4^+ concentrations, acquired from sampling aboard ships in the period 1995 - 2012, are used to assess the
33 performance of modelled N concentration and deposition fields over the remote ocean. Three ocean regions (the eastern
34 tropical North Atlantic, the northern Indian Ocean and northwest Pacific) were selected, in which the density and distribution
35 of observational data were considered sufficient to provide effective comparison to model products. All of these study regions
36 are affected by transport and deposition of mineral dust, which alters the deposition of N, [due to uptake of nitrogen oxides](#)
37 [\(\$\text{NO}_x\$ \) on mineral surfaces](#).

38 [Assessment of the impacts of atmospheric N deposition on the ocean requires atmospheric chemical transport models to report](#)
39 [deposition fluxes, however these fluxes cannot be measured over the ocean. Modelling studies such as the Atmospheric](#)

59 observable aerosol-phase species concentrations and this cannot be achieved if model products only report dry deposition flux
60 over the ocean.
61

62 **1 Introduction**

63 Global emissions of inorganic nitrogen (i.e. all nitrogen (N) species, excluding N₂) to the atmosphere have likely increased by
64 factors of 3-4 since the onset of industrialisation in the mid-nineteenth century (Duce et al., 2008; Galloway et al., 2008).
65 Major sources include the emission of nitrogen oxides (NO_x) as a by-product of combustion (Galloway et al., 2004) and
66 ammonia (NH₃) emissions resulting from fertilizer application and intensive livestock-rearing practices (Bouwman et al., 1997).
67 On-going implementation of emission controls (mostly affecting NO_x) and global economic development will lead to further
68 changes in both the magnitude and spatial distribution of nitrogen emissions over the coming decades (e.g. Dentener et al.,
69 2006; Lamarque et al., 2013a).

70 Nitrogen deposition impacts both terrestrial and marine ecosystems. N is a limiting nutrient for primary producers over ~70%
71 of the global ocean (Duce et al., 2008). Its deposition enhances primary productivity in low-nitrogen marine ecosystems (e.g.
72 Zamora et al., 2010; Singh et al., 2012) and potentially drives ecological shifts through changes in nutrient regimes (Kim et
73 al., 2011; Chung et al., 2011; Shi et al., 2012; Mourino-Carballido et al., 2012; Chien et al., 2016). Export of atmospheric N
74 into sub-oxic or anoxic zones of, for example, the Arabian Sea will lead to non-linear effects on the marine and atmospheric
75 N cycle through the processes of denitrification and N₂O production and consumption (Suntharalingam et al., 2012; Landolfi
76 et al., 2013; Somes et al., 2016).

77 In order for these impacts to be understood, it is necessary to quantify the deposition of nitrogen species from the atmosphere.
78 At a local scale this can be achieved through sustained observations of nitrogen species concentrations in deposition, and in a
79 very few terrestrial cases (North America, western Europe and East Asia) networks of observational stations have been
80 established that allow N deposition to be monitored on regional scales. Outside of these regions, and especially over the oceans,
81 large-scale assessment of atmospheric N deposition is almost exclusively achieved through the use of global atmospheric
82 chemical-transport modelling (Dentener et al., 2006; Krishnamurthy et al., 2010; Lamarque et al., 2013a; Wang et al., 2015;
83 Kanakidou et al., 2016).

84 The utility of these models (both for estimating current N deposition and in predicting future deposition rates) is dependent on
85 their skill in replicating many complex parameters, including nitrogen species' emission rates and distributions, chemical
86 interactions, transport pathways and deposition mechanisms. A number of such models have been inter-compared as part of
87 the Atmospheric Chemistry and Climate Model Intercomparison Project, ACCMIP (Lamarque et al., 2013b), and modelled
88 deposition fields have been used in a number of studies (e.g. Lamarque et al., 2013a). ACCMIP produced multi-model mean
89 (MMM) estimates of both oxidised (NO_y) and reduced (NH_x) inorganic N deposition for the present-day due to both dry and
90 wet deposition. The skill of these ACCMIP MMM deposition estimates was assessed principally by comparison against the
91 North American, European and East Asia wet deposition networks on land (see Lamarque et al., 2013a) using a benchmark
92 dataset described in Vet et al. (2014).

93 Deposition monitoring does occur at some remote marine locations (e.g. Mace Head, Ireland, Bermuda, Barbados, Amsterdam
94 Island (Keene et al., 2015)), but it is impractical to establish deposition networks over wide areas of the open ocean, due to the
95 limitations of suitable sites and the challenges of maintaining rigorous sampling programmes at such remote locations. Thus,
96 assessment of the impacts of atmospheric N deposition on oceanic processes, including primary production, CO₂ uptake, and
97 species diversity, has so far been reliant on the fidelity of deposition models that have not been validated for the oceans.

98 In this work, the abilities of the ACCMIP MMM (Lamarque et al., 2013a) and the TM4-ECPL model, hereafter TM4
99 (Kanakidou et al., 2016; Myriokefalitakis et al., 2015), to estimate atmospheric N dry deposition to the ocean are evaluated.
100 The evaluation was done by comparison to a substantial database of aerosol N observations collected during ships' voyages
101 over all the major ocean basins. Similar evaluations of dry deposition of organic N and wet deposition of inorganic N were not
102 possible because there was very little observational data available over the oceans in these cases. This manuscript describes
103 the database of aerosol N species (nitrate, NO₃⁻ and ammonium, NH₄⁺) concentrations that was assembled and the results of
104 comparing this database to the models at the global scale, as well as in three specific regions: the tropical eastern Atlantic
105 (TEAtl), the northern Indian Ocean (NInd) and the margins of the Northwest Pacific (NWPac).

106 2 Methods

107 2.1 The aerosol nitrate and ammonium concentration database

108 Aerosol NO₃⁻ and NH₄⁺ concentration data were acquired for 2890 samples collected from >120 ship-based studies over the
109 period 1995 – 2012. The spatial distributions of these samples is shown in Fig. 1a and a description of the individual cruises,
110 the data sources and contributors is given in the supplementary material for this manuscript (Table S1). The database itself
111 (aerosol concentrations and sample locations) is also available in the supplementary material. In general, the data were accessed
112 from publicly available data archives (i.e. the SOLAS aerosol and rain chemistry database
113 (http://www.bodc.ac.uk/solas_integration/implementation_products/group1/aerosol_rain/), the NOAA-PMEL Atmospheric
114 Chemistry Data Server (<http://saga.pmel.noaa.gov/data/>)), were provided directly by the originator or were unpublished results
115 from the authors. Since the data originate from multiple sources, the samples were acquired using a variety of sampling devices
116 (e.g. bulk filtration or in size fractions using cascade impactors), collection substrates (e.g. Whatman 41, glass fibre or quartz)
117 [and sampling intervals](#) and were analysed using different techniques (commonly ion chromatography or automated
118 spectrophotometry) in many different laboratories. [\(A summary of the available information on sample collection procedures](#)
119 [is given in Table S1\). Standard procedures for aerosol inorganic N sampling and analysis have not yet been established, and](#)
120 [nor have inter-laboratory intercomparison / intercalibration exercises](#) (e.g. Morton et al., 2013) [been commonly held. In the](#)
121 [absence of such procedures, datasets were accepted into the database that had either already been published in the peer-](#)
122 [reviewed literature or that originated from laboratories with established publication records. Under these conditions, the](#)
123 [presence of biases within the observational database cannot be ruled out. Sampling intervals varied between 12 and 48 hours.](#)

124 [but the majority of samples were collected over ~24 hours.](#) In cases where the observations were obtained for multiple size
125 fractions for a given sample, the fraction concentrations were summed and stored in the database only as total NO_3^- or NH_4^+
126 concentrations for that sample.

127 The database contains ~1420, ~680 and ~770 samples collected over the Atlantic, Indian and Pacific Oceans respectively.
128 Overall, 81% of the samples contain observations of both NO_3^- and NH_4^+ , 16% observations of NO_3^- alone and 3% of NH_4^+
129 alone. The distributions of these samples are non-uniform with time (by year and by month) through the [18](#)-year period that
130 we examined, as illustrated for the major ocean basins in Fig. 1b & c.

131 2.2 Parameters to be compared to model output

132 Where possible, the observed aerosol concentrations (C : [nmol m⁻³](#)) for NO_3^- and NH_4^+ were compared directly with
133 corresponding particulate concentrations simulated by the models (i.e. for the TM4 model, see below). Dry deposition fluxes
134 from the models were also compared to the observational database. In order to do so, dry deposition fluxes (F : [mg N m⁻² d⁻¹](#))
135 were calculated from the observed concentrations of the two species using dry deposition velocities (v_d : [m d⁻¹](#)) (Eq. 1), [with](#)
136 [appropriate correction for the relative atomic mass of N. \(Note that hereafter we quote \$v_d\$ in units of cm s⁻¹\).](#)

$$137 F = v_d C \quad (1)$$

138 Two approaches were used [for](#) the calculation of F . In one case, fixed values for v_d of 0.9 cm s^{-1} for NO_3^- and 0.1 cm s^{-1} for
139 NH_4^+ were used to calculate F in all grid cells (hereafter referred to as the “fixed v_d ” method). For NO_3^- , the relatively high v_d
140 value used reflects its [association](#) over the ocean with coarse sea-salt particles (and is similar to the v_d for gaseous HNO_3). The
141 lower v_d value of NH_4^+ is due to its association [with](#) fine aerosol fractions. Similar methods have been applied to the calculation
142 of dry deposition fluxes in many previous studies (e.g. Markaki et al., 2003; Buck et al., 2013; Baker et al., 2016). Dry
143 deposition fluxes were also calculated using wind speed-dependent values of v_d [for particles of 7 \$\mu\text{m}\$ \(coarse mode\) and 0.6](#)
144 [\$\mu\text{m}\$ \(fine mode\) diameter using the parameterisation of](#) Ganzeveld et al. (1998). [This “variable \$v_d\$ ” method is similar to the](#)
145 [approach used previously to estimate dry deposition of N species to the Atlantic Ocean](#) by Baker et al. (2010) and Powell et
146 al. (2015). [In this case, European Centre for Medium-Range Weather Forecasts \(ECMWF\) ERA Interim reanalysis dataset](#)
147 [surface wind speeds were obtained for the years 1995 – 2012 and the mean wind speed for these years was used to calculate](#)
148 [\$v_d\$ for each grid cell.](#) In this case, the total NO_3^- and NH_4^+ concentrations in the database were artificially separated into coarse
149 and fine modes using the median fractions of each species in coarse mode aerosol reported for 210 aerosol samples collected
150 over the Atlantic Ocean (Baker et al., 2010). These fractions were 0.90 and 0.14 for NO_3^- and NH_4^+ respectively. (For
151 comparison, in TM4 on a global scale, these fractions were 0.92 and 0.08 respectively for the year 2005). The mean values of
152 v_d for NO_3^- and NH_4^+ calculated using the variable method over the global ocean were 0.81 cm s^{-1} and 0.15 cm s^{-1} respectively
153 and their distribution is shown in Fig. S1 of the Supplementary Material. Hereafter, deposition fluxes derived from measured
154 aerosol concentrations and dry deposition velocities are referred to as “Calculated Deposition (CalDep)”.

155 2.3 Model products

156 For the TM4 model, surface level particulate NO_3^- and NH_4^+ concentrations and dry deposition fluxes of these species were
157 simulated for the nominal year 2005 (for details see Kanakidou et al., 2016; Myriokefalitakis et al., 2015). The model's [lowest](#)
158 [level has a mid-level height of 40 m and its](#) native resolution is 2° (lat.) x 3° (lon.), but for this study the model output was
159 interpolated to a grid scale of 1° x 1° . The TM4 model also applies the Ganzeveld et al. (1998) parameterisation to compute
160 v_d for each grid cell using ECMWF ERA interim meteorology for the year 2005 [and accounts for organic nitrogen sources and](#)
161 [fate in the atmosphere](#) (see Kanakidou et al., 2012). TM4 also assumes dry mass diameters of $0.34\ \mu\text{m}$ ($\sigma_{1.59}$) and 6.71
162 μm ($\sigma_{2.00}$) for sea-salt aerosol and $0.68\ \mu\text{m}$ ($\sigma_{1.59}$) and $3.5\ \mu\text{m}$ ($\sigma_{2.00}$) for dust aerosol that are in
163 agreement with those used here to calculate dry deposition based on measured aerosol concentrations. Furthermore, TM4
164 accounts for $8.15\ \text{Tg-N yr}^{-1}$ of NH_3 emissions from the ocean to the atmosphere, taken from the Bouwman et al. (1997) emission
165 inventory and are used in the model based on annual mean fluxes. Although this reduced nitrogen is of marine origin and thus
166 does not constitute an external source of N to the ocean, its consideration is needed when comparing to atmospheric aerosol
167 observations in the marine environment. TM4 also accounts for marine emissions of amines as discussed in Kanakidou et al.
168 (2016). The present TM4 model configuration explicitly considers the atmospheric iron cycle (Myriokefalitakis et al., 2015)
169 and uses the ISORROPIA II thermodynamic equilibrium module (Fountoukis and Nenes, 2007) to calculate the partitioning
170 of $\text{NH}_3/\text{NH}_4^+$ and $\text{HNO}_3/\text{NO}_3^-$ accounting for the impact of sea-salt and dust elements on this partitioning (Myriokefalitakis et
171 al., 2015) assuming stable conditions (Karydis et al., 2016).

172 The ACCMIP products used in this comparison were based on emissions for the year 2000 and average meteorology for the
173 decade 2000 – 2009 (Lamarque et al., 2013a). The fields used were MMM dry deposition from 10 (for NO_y) or 5 (for NH_x)
174 individual atmospheric chemical-transport models, [generally with surface mid-level heights of 20 - 40 m](#), and were reported
175 by ACCMIP on a grid scale of 0.5° x 0.5° , although the resolution of individual models was coarser. NO_y and NH_x dry
176 deposition estimates were also available for TM4. (Neither particulate concentration nor dry deposition fields were available
177 for NO_3^- or NH_4^+ from ACCMIP). For both ACCMIP and TM4 model results, NH_x corresponds to the sum of NH_3 and NH_4^+ .
178 [Most models in the ACCMIP product included marine emissions of \$\text{NH}_3\$ based on](#) Bouwman et al. (1997). However, NO_y
179 differs between the two model products. NO_y is derived from TM4 results as the sum of all inorganic oxidized N species in
180 the model, i.e. NO , NO_2 , NO_3^- , N_2O_5 , HONO , HNO_4 and HNO_3 (Kanakidou et al., 2016), since organic oxidized N is explicitly
181 studied (Kanakidou et al., 2012). For the ACCMIP models, NO_y also contains some gas-phase organic nitrates and peroxyacyl
182 nitrates (PAN) (Lamarque et al., 2013a). Thus the NO_y and NH_x deposition estimates from both models include contributions
183 from gas-phase, as well as particulate, deposition. (On a global scale, TM4 simulates that particulate NO_3^- and NH_4^+ account
184 for 80% and 35% of inorganic NO_y and NH_x deposition, respectively, while particulate NH_4^+ deposition comprises ~25% of
185 NH_x deposition in the ACCMIP MMM (Lamarque et al., 2013a). Note that these global numbers are dominated by deposition
186 over continents, where particulate NH_4NO_3 is a much more significant component of aerosol N than over the oceans. [Particulate](#)
187 [\$\text{NO}_3^-\$ was not simulated by all of the models contributing to ACCMIP, and hence the fractional contribution of \$\text{NO}_3^-\$ to \$\text{NO}_y\$](#)

188 [deposition was not reported by Lamarque et al. \(2013a\)](#). In models without a specific simulation of particulate NO_3^- , this
189 [species is likely to have been simulated as gas-phase \$\text{HNO}_3\$, whose dry deposition velocity is similar to that of particulate \$\text{NO}_3^-\$](#)
190 [\(Pryor and Sorensen, 2002\)](#). Thus, the dry deposition flux of NO_y in the multi-model mean was not greatly affected by this
191 [factor](#). The ACCMIP NO_y dry flux was not substantially different from that computed in the TM4 model, which does
192 [specifically simulate dry particulate \$\text{NO}_3^-\$ deposition \(Kanakidou et al., 2016\)](#). Therefore, in the present study, TM4 speciated
193 [results are more appropriate for comparison to the observations and are put in context when used jointly with the more robust,](#)
194 [but less speciated, ensemble model results of ACCMIP](#)). Modelled NO_y and NH_x deposition estimates are therefore not directly
195 comparable to the observationally-derived deposition estimates examined here. For information, Table S2 presents the total
196 annual emissions of NO_x and NH_3 (and their emissions from Africa, India and southeast Asia / Japan) used by the ACCMIP
197 models and by TM4 for the present study.

198 Dry deposition fluxes simulated by the TM4 and ACCMIP model products are referred to below as “Modelled Deposition
199 (ModDep)”.

200 2.4 Comparison methods

201 Observations and model products were compared using a $5^\circ \times 5^\circ$ grid. This represents a compromise between the desire to
202 undertake the comparison at a high spatial resolution and the need to ensure that the amount of observational data available in
203 each grid cell was sufficient to adequately represent the deposition in that cell.

204 For the observations, means of all available NO_3^- and NH_4^+ concentrations were calculated for each grid cell. Values of CalDep
205 for each species were then calculated from these mean concentrations using the methods described above. Annual mean model
206 products were prepared for comparison by removing outputs from grid cells that contained land using a ($0.5^\circ \times 0.5^\circ$ or $1^\circ \times 1^\circ$,
207 as appropriate) land-mass mask. This was done in order to prevent high deposition fluxes of N species over land biasing the
208 comparison to the marine observations for grid cells along continental margins. The model outputs were then averaged from
209 their input resolution to the same $5^\circ \times 5^\circ$ grid that was used to bin the observational data.

210 The following parameters were then compared: observed aerosol concentrations of NO_3^- and NH_4^+ with their simulated
211 concentrations from TM4; CalDep for NO_3^- and NH_4^+ with their respective ModDep from TM4 and with ModDep of NO_y and
212 NH_x from ACCMIP and TM4. Comparisons over regions larger than individual grid cells were made using the area- and
213 sample number-averaged ratio ($R_{A,n}$) of modelled to observation-based parameter (concentration or deposition flux), as shown
214 in Eq. 2, and normalised mean bias (NMB; Eq. 3) (where M is the modelled concentration or ModDep, O is the observed
215 concentration or CalDep, A is the surface area and n is the number of observations for each grid cell).

$$216 R_{A,n} = \frac{\sum(M/O) A n}{\sum A n} \quad (2)$$

217
$$NMB = 100 \frac{\Sigma(M-o)}{\Sigma o} \quad (3)$$

218 Thus the value of $R_{A,n}$ would be equal to unity in the ideal case of perfect agreement between the model annual average and
219 observations in the region in question. When the model deviates from observations, the ratio reflects the model to
220 measurements agreement, favouring the grid cells where most measurements exist compared to the grid cell areas with fewer
221 measurements. Ratios larger than unity indicate over-estimate of observations and lower than unity an under-estimate of the
222 observations.

223 **3 Results**

224 **3.1 Observational Database**

225 While the database contains observations that cover wide regions of the global ocean (Fig. 1), for NO_3^- only 550 grid cells
226 (~28% of oceanic grids cells) contain observations. Of those grid cells containing observations, only 65 contained 10 or more
227 NO_3^- observations, and 72 contained observational data acquired over 4 or more calendar months. For NH_4^+ , there were
228 observations in 478 grid cells (~24% of oceanic cells), with 57 of those containing 10 or more observations, and 50 with
229 observations acquired over 4 or more months (Table 1). Summaries of the data available for each grid cell over the global
230 ocean (numbers of observations, number of calendar months with observations, mean and relative standard deviation aerosol
231 concentrations) are shown in Fig. S2 and S3 for NO_3^- and NH_4^+ respectively.

232 In the following, the global dataset was retained, but detailed analysis focused on the TEAtl, NInd and NWPac study regions
233 (the number of NO_3^- or NH_4^+ observations in each cell and the number of calendar months represented by those observations
234 for these regions are shown in Fig. 9 – 14). Data coverage was best in the TEAtl region (Fig. 2a), where many grid cells had
235 both relatively large numbers of observations and observations covering 6 or more months of a calendar year. In the NInd
236 region (Fig. 2b), there were several grid cells containing many observations, but only one grid cell with observations spanning
237 more than 6 months. Data coverage in most of the NWPac region (Fig. 2c) was poor compared to the other two regions, with
238 high sample numbers and relatively good temporal coverage only in cells close to the coast of China. The NWPac region had
239 the additional benefit that it is adjacent to the Acid Deposition Monitoring Network in East Asia (EANET) that has already
240 been used to assess the skill of the ACCMIP and TM4 modelled wet deposition products (Lamarque et al., 2013a; Kanakidou
241 et al., 2016). The observational data available in these three regions were considered most likely to be representative of the
242 annual N concentration and deposition fields represented by the models, although even here it is apparent that the distribution
243 of observations is non-uniform in and between individual grid cells (Fig. 2). Where possible, the ship-based observations were
244 compared to longer-term records obtained at remote island sites located in specific grid cells (see Sect. 3.2). Where observation
245 – model comparisons are reported outside of those regions (i.e. for the global database) this is on the understanding that these
246 comparisons are likely to be rather uncertain.

247 3.2 Comparison to Concentrations at Island Monitoring Stations

248 Figure 3 shows box and whisker plots of NO_3^- and NH_4^+ concentrations grouped according to calendar month for cells
249 containing relatively high numbers (16 – 73) of observations for each of the TEAtl, NInd and NWPac study regions. For two
250 of these cells the monthly and annual mean concentrations are directly compared to observations from remote island monitoring
251 sites situated within those cells (see below). Similar independent records have not been identified in any other grid cell that
252 also contains high numbers of observations in the database.

253 In the TEAtl region, the data obtained for the $15^\circ\text{-}20^\circ\text{N}$, $25^\circ\text{-}20^\circ\text{W}$ cell were compared to results reported for the Cape Verde
254 Atmospheric Observatory (CVAO: $16^\circ51'49''\text{N}$, $24^\circ52'02''\text{W}$) for the years 2007-2011 (Fomba et al., 2014). Here agreement
255 between the ship-based observations and the island station was rather good for NO_3^- , with the range of the 42 ship-based
256 concentrations falling entirely within the range of the 671 observations at CVAO (Fig. 3a). The mean NO_3^- concentration for
257 the ship observations was 20.7 nmol m^{-3} , compared to the 5-year mean concentration of 17.7 nmol m^{-3} for the island
258 observations, with neither dataset showing significant seasonal variation. There was also generally good agreement between
259 the ship and island observations of ammonium in this cell, with the exception of July, where the ship data (2 samples) were
260 approximately a factor of 2 higher than the upper limit of the island data (Fig. 3g). Mean NH_4^+ concentrations were 13.9 nmol
261 m^{-3} for the ship observations ($n = 35$) and 5.0 nmol m^{-3} (5-year average) for the island observations. Fomba et al. (2014)
262 reported a small seasonal cycle for NH_4^+ at CVAO, with higher concentrations during March – June than during the rest of the
263 year. There was not enough ship data available to independently confirm this seasonal pattern.

264 In the NWPac region, there was also good agreement between the 73 ship-based observations from 2005 - 2008 in the 25°-
265 30°N , $120^\circ\text{-}125^\circ\text{E}$ cell and the 173 daily observations made during 2010 at Pengchiayu Island ($25^\circ37'44''\text{N}$, $122^\circ4'4''\text{E}$) in
266 the East China Sea (Hsu et al., 2014). The Pengchiayu dataset indicated that there was some seasonality in aerosol NO_3^-
267 concentrations at this site (Fig. 3e), with mean concentration values being approximately twice as high during the months of
268 December to April, than during May to October. Mean NO_3^- concentrations were 67.8 nmol m^{-3} for the ship-based observations
269 and 71.0 nmol m^{-3} at Pengchiayu Island. Except for January and September, there was little monthly variation in NH_4^+
270 concentrations at Pengchiayu (Fig. 3k). Mean NH_4^+ concentrations were 88.7 nmol m^{-3} and 91.4 nmol m^{-3} for the ship and
271 island observations respectively.

272 3.3 Comparison of Observed and Modelled Concentrations

273 Comparisons of observed aerosol concentrations for NO_3^- and NH_4^+ with modelled surface level particulate concentrations
274 from TM4 for these species are shown in Fig. 4. The sample number weighting included in the calculation of $R_{A,n}$ is illustrated
275 in Fig. 4 using crosses of different sizes to represent the amount of data available in each cell.

276 For NO_3^- , TM4 generally over-estimated aerosol concentrations ($R_{A,n} = 6.6$ for the global dataset), although the model appears
277 to significantly under-estimate NO_3^- concentrations in the Atlantic sector of the Southern Ocean (see Fig. S4a: note that there

278 was relatively little observational data in this region). Over-estimation of aerosol NO_3^- concentrations was particularly
279 noticeable over the Bay of Bengal, the northwest Pacific around Japan and for some areas of the northwest Atlantic, including
280 for a number of coastal grid cells around North America that contained relatively large numbers of observations (Fig. 4a).
281 Spatial gradients in aerosol concentrations over coastal areas are likely to be strong and this may contribute to the large
282 observation – model discrepancies for these grid cells. For the TEAtl region, TM4 reproduced the regional average aerosol
283 NO_3^- concentration better than was the case for the global comparison ($R_{A,n} = 1.4$). However, TM4 did not reproduce the spatial
284 distribution of NO_3^- in this region, particularly around the margins of West Africa (Fig. 5). Regional concentration over-
285 estimates by TM4 in the NInd ($R_{A,n} = 2.9$) and NWPac ($R_{A,n} = 2.6$) regions appear to be due to over-estimation over the Arabian
286 Sea and Bay of Bengal and the seas around Korea and Japan respectively (Fig. 5).

287 Over the global dataset, agreement between the observations and TM4 concentrations was better for NH_4^+ than for NO_3^- ($R_{A,n}$
288 = 0.9, indicating a slight model under-estimation). However, under-estimation of NH_4^+ concentrations by TM4 was greater in
289 all of the three study regions and the global value of $R_{A,n}$ appears to be influenced by model over-estimation in regions with
290 low observed NH_4^+ concentrations (Fig. 4b). Specifically, TM4 appears to over-estimate NH_4^+ concentrations in the western
291 South Atlantic and equatorial Pacific Oceans, while under-estimation occurred in the NWPac region and southeastern South
292 Atlantic (Fig. S4b). Although TM4 appeared to under-estimate NH_4^+ concentrations across the TEAtl ($R_{A,n} = 0.7$) and NWPac
293 ($R_{A,n} = 0.5$) regions, the spatial distributions of NH_4^+ in the observations and model were similar (Fig. 6). In the NInd region
294 ($R_{A,n} = 0.7$), TM4 did not appear to reproduce the spatial distribution of NH_4^+ , with observed concentrations in the Bay of
295 Bengal and in the cells around $5^\circ\text{S} - 10^\circ\text{N}$, $65^\circ - 80^\circ\text{E}$ being higher than those simulated by the model.

296 [Note that over land, \$\text{NO}_3^-\$ and \$\text{NH}_4^+\$ levels are affected by the vicinity of the sources. In particular, biomass burning and dust](#)
297 [emissions affect the partitioning of \$\text{NO}_3^-\$ and \$\text{NH}_4^+\$ to the aerosol phase. Even small inaccuracies in the model simulations of](#)
298 [this partitioning can lead to higher discrepancies between model results and observations over land than over the ocean. Indeed,](#)
299 [Kanakidou et al. \(2016\) have compared \$\text{NO}_3^-\$ and \$\text{NH}_4^+\$ concentrations in PM10 over Europe and found an overestimate in](#)
300 [\$\text{NO}_3^-\$ PM10 content of about 115% and an underestimate in \$\text{NH}_4^+\$ in PM10 of about 55% \(Figure S4 in the Kanakidou et al.](#)
301 [\(2016\) supplementary material\), results that are consistent with, but larger than the 70% and 44% respectively reported here](#)
302 [for oceanic regions \(Fig. 4 of the present paper\).](#)

303 **3.4 Comparison of Dry Deposition Estimates**

304 Figure 7 shows the comparison between CalDep from the variable v_d method for NO_3^- and NH_4^+ and ModDep of $\text{NO}_y / \text{NO}_3^-$
305 and $\text{NH}_x / \text{NH}_4^+$ from the models for all grid cells which contained observations. (A similar figure for CalDep from the fixed
306 v_d method is shown in Fig. S5).

307 The comparison to NO_3^- CalDep for the global oceanic dataset indicates that the models generally over-estimated the flux
308 (Table 2), with values of $R_{A,n}$ of at least 4 in all cases (Figs. 7 & S5). The ACCMIP simulation appeared to over-estimate NO_y

309 deposition in the northern hemisphere and under-estimate in the southern hemisphere, while TM4 showed a less pronounced
310 difference in performance between the northern and the southern hemisphere with over- and under-estimates in both
311 hemispheres and a clear under-estimate in $\text{NO}_y / \text{NO}_3^-$ deposition over the Southern Ocean (Fig. S6). Values of $R_{A,n}$ for the
312 global TM4 deposition comparison (4.4 – 5.6) were all slightly lower than that for the TM4 concentration comparison (6.6).
313 This must be due to differences between the average dry deposition velocity used for $\text{NO}_y / \text{NO}_3^-$, which is lower in TM4 than
314 in either CalDep method. For NO_3^- , the use of the variable v_d CalDep method led to lower observation-based deposition fluxes
315 and higher values of $R_{A,n}$ (i.e. generally worse overall agreement to the models), when compared to the fixed v_d method. This
316 indicates that the average deposition velocity for $\text{NO}_y / \text{NO}_3^-$ used by the models was closer to the value used in the fixed v_d
317 case (0.9 cm s^{-1}) than to the average deposition velocity used in the variable v_d case, but does not necessarily imply that the
318 models or fixed v_d case are more accurate representations of aerosol nitrate dry deposition. For TM4, values of $R_{A,n}$ were
319 generally closer to unity for simulated NO_3^- than for NO_y (i.e. agreement was better when the simulation more closely matched
320 the measured parameter).

321 For NH_4^+ , the global comparison (Figs. 7 & S5) indicates that the modelled NH_x deposition results were considerably higher
322 than NH_4^+ CalDep ($R_{A,n} = 3.0 - 5.4$). This is primarily due to the large component of gas-phase NH_3 deposition in the modelled
323 NH_x fluxes (for ACCMIP $\text{NH}_x : \text{NH}_4^+ = \sim 4$ (Lamarque et al., 2013a), while in TM4 this ratio is ~ 2.5). The greatest disagreement
324 between NH_x ModDep and CalDep was at the lowest NH_4^+ deposition fluxes ($< 0.01 \text{ mg N m}^{-2} \text{ d}^{-1}$), which were over-estimated
325 in the models by 1 – 2 orders of magnitude, generally over the tropical open oceans (Fig. S7). This mismatch between NH_4^+
326 CalDep and NH_x ModDep makes meaningful comparison between these fields rather difficult. Therefore NH_4^+ CalDep - NH_x
327 ModDep comparisons for the three study regions are not discussed below. TM4 NH_4^+ ModDep fluxes agreed better (in the
328 global comparison) with the corresponding CalDep fluxes ($R_{A,n} = 1.1 - 1.4$, Figs. 7f & S5f) than the NH_x ModDep results. Use
329 of the variable v_d method led to higher CalDep fluxes for NH_4^+ and hence lower values of $R_{A,n}$ and better overall agreement to
330 the models, when compared to the fixed v_d method. The fixed v_d flux comparison for TM4 was also worse ($R_{A,n}$ was higher)
331 than the TM4 concentration comparison, which was caused by the value of v_d used in the calculation being higher than the
332 average deposition velocities used in TM4 or the variable v_d calculation.

333 Figures 8 – 13 show the spatial distribution of CalDep for each of the three study regions, together with the corresponding
334 ModDep fields from ACCMIP and TM4. From these figures it is clear that the CalDep calculation method (fixed- and variable
335 v_d methods) influences both the magnitude and spatial distribution of N deposition estimates, and that this will, in turn,
336 influence assessments of the impacts of that deposition on the marine environment.

337 **3.4.1 Tropical Eastern Atlantic**

338 For NO_3^- , this was the region with the best overall agreement between CalDep and the modelled fluxes ($R_{A,n}$ values of 0.6 –
339 1.1). However, as with the concentration comparison (Fig. 5), the spatial distributions of CalDep and ModDep were rather
340 different. All of the models predicted a decreasing gradient in $\text{NO}_y / \text{NO}_3^-$ deposition from northeast to southwest across the

341 region, while the CalDep fluxes were greatest off the coast of North Africa in the latitude band 10° - 25° N (Fig. 8). The TM4
342 NO_3^- deposition field did indicate slightly higher fluxes in this area, but did not reproduce the magnitude of the CalDep fluxes
343 there.

344 The NH_4^+ CalDep fields show rather uniform distributions in the TEAtl region (Fig. 9). Both the spatial distribution and
345 magnitude of the observed fluxes appear to be rather well reproduced by the TM4 NH_4^+ simulation ($R_{A,n} = 0.9 - 1.1$).

346 **3.4.2 Northern Indian Ocean**

347 In the NInd region, all of the models indicate a strong north – south gradient in $\text{NO}_y / \text{NO}_3^-$ deposition (Fig. 10). While there
348 is a north – south gradient in NO_3^- CalDep over the Arabian Sea, CalDep fluxes over the Bay of Bengal were as low as those
349 in the south of the region. This discrepancy over the Bay of Bengal contributes to the general over-estimation by the models
350 over the region as a whole ($R_{A,n}$ values of 1.2 – 2.6).

351 NH_4^+ CalDep fluxes were relatively high in the Bay of Bengal and to the southwest of southern India, but low in most of the
352 Arabian Sea. The TM4 NH_4^+ simulation (Fig. 11f) indicated deposition further to the northwest of the Arabian Sea than the
353 CalDep fluxes and slightly underestimated deposition to the Bay of Bengal, but gave good agreement for the region as a whole
354 ($R_{A,n}$ values of 0.9 – 1.1).

355 **3.4.3 Northwest Pacific margins**

356 Although there were rather few grid cells with good data coverage in this region, for most cells the modelled $\text{NO}_y / \text{NO}_3^-$
357 deposition was similar to NO_3^- CalDep (Fig. 7; $R_{A,n} = 1.5 - 2.2$). The CalDep fluxes appear to show a strong northwest –
358 southeast gradient in deposition, as indicated by the models (Fig. 12). However, the models appear to over-estimate the
359 deposition of NO_3^- around the south and east of Korea and the south of Japan. The highest NO_3^- CalDep fluxes occurred closer
360 to the coast of China than was simulated in the models.

361 The spatial distribution of NH_4^+ deposition (CalDep and ModDep) appears to be dominated by a similar northwest – southeast
362 gradient to NO_3^- (Fig. 13). Agreement between CalDep for NH_4^+ and ModDep from TM4 was relatively good in this region,
363 with slight under-estimation by the model ($R_{A,n}$ values of 0.6 – 0.8).

364 **4 Discussion**

365 The comparisons presented above highlight a number of cases where the spatial distribution or magnitude of observed
366 concentrations or CalDep were not reproduced by the model products. In most cases, there is not sufficient information
367 available to make a detailed analysis of these discrepancies. However, a discussion of potential sources of bias and divergence
368 between observations and models is set out below.

369 4.1 Bias in observed concentrations and calculated deposition fluxes

370 Inertial segregation of larger particles at inlets of aerosol sampling systems, particularly at higher wind velocities, can result
371 in relatively low passing/collection efficiencies and thus negative bias for super-micron aerosol constituents including NO_3^- .
372 Cascade impactors are associated with significant internal losses (typically ranging from 25% to 40%) of large particles (e.g.
373 Young et al., 2013; Marple et al., 1991). Because virtually all NO_3^- in marine air is associated with super-micron diameter
374 particles, NO_3^- concentrations summed over all impactor size fractions correspond to lower limits for ambient concentrations
375 and dry deposition fluxes estimated from those concentrations.

376 The pH of marine aerosol varies significantly as a function of size. In addition, based on their thermodynamic properties, the
377 gas-aerosol phase partitioning of nitric acid (HNO_3) and NH_3 vary as a function of pH. HNO_3 partitions preferentially with the
378 less acidic super-micron size fractions, while NH_3 partitions preferentially with the highly acidic sub-micron size fractions.
379 When chemically distinct aerosol size fractions are sampled in bulk, the pH of the bulk mixture differs from that of the size
380 fractions with which HNO_3 and NH_3 partition preferentially in air. This drives artefact phase changes of both HNO_3 and NH_3 ,
381 resulting in negative measurement bias. Because of their relatively short atmospheric lifetimes, low surface-to-volume ratios,
382 and corresponding slow rates of thermodynamic equilibrium, the upper-end of the marine aerosol size distribution is often
383 under-saturated with respect to gaseous HNO_3 . Following collection on filters, HNO_3 can continue to condense from the sample
384 air stream into these particle deposits resulting in positive measurement bias. In addition, a number of aerosol collection media
385 have been reported to be susceptible to uptake of gas-phase species such as HNO_3 and NH_3 (e.g. Keck and Wittmaack, 2005).

386 Thus, there are a variety of processes, particularly in the marine environment, that can lead to positive and negative biases in
387 measured aerosol NO_3^- and NH_4^+ concentrations, and the extent to which a given dataset is affected by these processes is
388 greatly influenced by sampling methodology. If such effects have influenced the database used here, biases are unlikely to be
389 uniform across all the observations, since the observations come from a very wide variety of sources with many different
390 sample collection protocols (see Table S1).

391 Uncertainty in analysed meteorology introduces uncertainty into deposition velocities derived for the variable v_d CalDep
392 calculation. This uncertainty was assessed by calculating v_d from mean ECMWF wind speeds for each of the individual years
393 (1995 – 2012) and the relative standard deviations of these annual v_d values. Standard deviations were relatively high over the
394 tropical oceans (up to ~25%) and lower elsewhere (<10% for coarse particles and <5% for fine particles) – see Fig. S8. While
395 ECMWF wind fields are themselves subject to uncertainty, weather product skill continues to improve as a result of extensive
396 use of global coverage satellite observations (Bauer et al., 2015). Dry deposition velocities, however derived, are subject to
397 high levels of uncertainty (up to a factor of 2 - 3 (Duce et al., 1991)), due to their strongly non-linear variation with parameters
398 such as particle size, wind speed and deposition surface properties (Slinn and Slinn, 1980). Their use to estimate CalDep fluxes
399 here therefore introduces substantial uncertainty into the CalDep – ModDep flux comparison.

4.2 Divergence between modelled and actual aerosol concentrations and deposition fluxes

In addition to the sampling-related biases discussed above, differences between observations and model calculations for a given grid cell can originate from several other inter-related processes. These include differences between the following modelled and actual processes: upwind emissions (including long-term trends in emissions) of NO_x and NH_3 and associated transport regimes; upwind chemical transformations and removal; phase partitioning of HNO_3 and NH_3 with size-resolved particles in near-surface marine air and the corresponding size distributions of particulate NO_3^- and NH_4^+ . In the latter case, if simulated concentrations of total NO_3 ($\text{HNO}_3 + \text{NO}_3^-$) and NH_3 ($\text{NH}_3 + \text{NH}_4^+$) were in agreement with actual concentrations but gas-phase concentrations were over-estimated, particulate-phase concentration (and dry fluxes) would be under-estimated. In addition, even if the total concentrations of particulate NO_3^- and NH_4^+ were modelled correctly, incorrectly simulated or assumed size distributions would lead to incorrect dry deposition fluxes, because dry deposition velocities vary greatly as a function of particle size. Gas-aerosol phase partitioning is highly parameterized in most global models. For particulates with deposition velocity of the order of 1 cm s^{-1} (i.e. NO_3^-), the short vertical turnover time of the surface atmospheric layer can lead to strong surface concentration gradients. This can lead to biases in the comparison of vertically averaged (for instance over 50 m in TM4) modelled surface layer concentration (or deposition flux) with observations made at heights that vary depending on the ships used for sampling (typically 10-20 m).

As stated above, dry deposition velocities are highly uncertain. If modelled and observed aerosol concentrations were in agreement, differences between modelled dry deposition velocities for size-resolved particles and those used to calculate dry deposition fluxes from observed aerosol concentrations would lead to model – observation divergence. In addition, bias in estimated deposition velocities for gases also impacts lifetimes of modelled total NO_3 and NH_3 , which would in turn influence the concentrations and dry fluxes of particulate N. [Differences in the temporal scales of observations and model time-steps can also lead to biases. For instance, the variable \$v_d\$ method for CalDep and dry particulate deposition in TM4 are both based on the parameterisation of Ganzeveld et al. \(1998\). The CalDep calculation involves the use of mean observed aerosol concentration and ECMWF wind speeds averaged over the period 1995 – 2012. In TM4, wind fields \(also based on ECMWF meteorology\) are updated every 3 hours in order to calculate \$v_d\$ for each time step. In order to compare deposition velocities over similar time-scales, it is possible to calculate “effective mean deposition velocity” for \$\text{NO}_3^-\$ and \$\text{NH}_4^+\$ in TM4 \(the ratio of the annual deposition fluxes to the respective annual mean concentrations\), but these values are not representative of the deposition velocities used at each model time-step. Maps of variable \$v_d\$ used in CalDep calculations and effective deposition velocity for TM4 and areal average values of these for the study regions can be found in the Supplementary Information \(Fig. S1 and Table S3\).](#)

Differences between modelled and actual deposition modes for $\text{HNO}_3/\text{NO}_3^-$ and $\text{NH}_3/\text{NH}_4^+$ can also influence model – observation comparison. For instance, over-estimation of modelled wet fluxes of total NO_3 and NH_3 , would lead to under-estimation of their modelled dry fluxes. Wet deposition is also highly parameterized in most global models.

432 The extent to which the available observations represent the actual conditions of the areas studied will also influence the
433 effectiveness of the model – observation comparison. Ideally, the observations should capture the spatial variability of aerosol
434 concentrations across the area to be compared (particularly for regions with large gradients, such as those across coasts), and
435 should also be representative of temporal variations (i.e. observations distributed throughout the year are required to capture
436 the annual mean concentration for species / regions with high seasonality). The 18-year period over which the observational
437 database was acquired may also influence the effectiveness of the comparison to the shorter timescales represented by the
438 model products.

439 **4.3 Influence of seasonality**

440 Because there were few grid cells for which the observational data covered the majority of a calendar year, it was possible that
441 unrepresentative sampling of seasonal variations in aerosol concentrations might lead to apparent biases in the annual-based
442 observation – model comparisons reported in this paper.

443 The potential impact of seasonality was examined for the TEAtl, NInd and NWPac study regions, by comparing monthly mean
444 NO_3^- and NH_4^+ concentrations simulated by TM4 to observations in individual grid cells that contained relatively large
445 numbers of observations (Fig. 3). For most cells, the TM4 simulation of both N species was very similar to the available ship-
446 and island-based observations. However, in the Indian Ocean cells (C and D) there appeared to be relatively strong seasonality
447 that was not always well-reproduced by the model. For instance, TM4 appeared to under-estimate observed median NH_4^+
448 concentrations in cell C during the months of January to March by factors of 2 – 3 (Fig. 3i), and over-estimated observed
449 median NO_3^- concentrations in cell D by factors of at least 4, with the seasonal changes indicated by the model not being
450 evident in the observations (Fig. 3d).

451 On the scale of the whole study regions, observed seasonality was reproduced best by TM4 in the TEAtl region (Fig. 14 a &
452 d). In the NInd region, TM4 predicted a strong seasonal cycle for NO_3^- (particularly in the Arabian Sea (Fig. S9)) which was
453 not entirely reflected in the observed concentrations (Fig. 14b). Observed NH_4^+ seasonality in the NInd appears to be more
454 pronounced than simulated in the model (Fig. 14e). Note that the uneven distribution of sample numbers through the year is a
455 potential source of bias in the monthly mean observed concentrations used to infer seasonal cycles here. Since the comparisons
456 of annual mean observed concentrations with those simulated by TM4 indicated differences over the Arabian Sea and Bay of
457 Bengal (Fig. 5 and 6), observed and TM4 monthly concentrations and monthly total numbers of observations for these two
458 regions ($5^\circ\text{-}25^\circ\text{N}$, $55^\circ\text{-}75^\circ\text{E}$ and $5^\circ\text{-}25^\circ\text{N}$, $80^\circ\text{-}90^\circ\text{E}$ respectively) are shown in Fig. 15. This shows clear differences in the
459 temporal distribution of sample collection between the Arabian Sea and Bay of Bengal, with sampling over the latter dominated
460 by the period of outflow from the Indo-Gangetic Plain (Srinivas et al., 2014). There were also differences in the extent to which
461 the model predicted seasonal variations in NO_3^- and NH_4^+ concentrations (Fig. 15). For NO_3^- , TM4 simulated a strong seasonal
462 variation over the Arabian Sea (and the observed months cover the full range of predicted concentration change), but a much
463 weaker seasonality over the Bay of Bengal. The available observations suggest that the NO_3^- seasonal cycles are more

464 pronounced than predicted for the Arabian Sea and Bay of Bengal and that TM4 over-predicts mean NO_3^- concentrations in
465 the Bay of Bengal by factors of 2 – 25 in all months with observations. For NH_4^+ , there was strong seasonality in the TM4
466 concentration over both areas, but almost all the observations from the Arabian Sea were from months when TM4 predicted
467 low concentrations, while the period of lowest concentrations predicted over the Bay of Bengal was almost entirely missing
468 from the observations. Differences in N deposition seasonality between models and observations in this region might arise as
469 a result of a number of factors. These include: seasonal variations in N emissions used in the models (see for instance discussion
470 in Daskalakis et al. (2015) for seasonal and spatial differences in biomass burning emission databases, Figs. 1 and S2 of that
471 paper), biases in seasonal variations in meteorology (e.g. in precipitation rates (Srinivas and Sarin, 2013a) and wind fields),
472 and seasonal changes in mineral dust composition, in particular calcium content, over the region (Srinivas and Sarin, 2013a)
473 affecting the uptake of NO_x onto dust particles.

474 Thus, it seems very likely that seasonality contributed to divergence between the models and observations over the NInd region
475 for NH_4^+ , but was less important for NO_3^- there. (Note that these analyses of seasonality at the regional-scale allow investigation
476 of the model – observation comparison, but cannot provide assurance that either the ship-based observations, or the model,
477 reproduce accurately the annual mean aerosol concentrations, especially in the NInd region, where there are no independent
478 seasonal records available).

479 **4.4 Role of mineral dust in modifying N deposition fluxes**

480 It is not entirely coincidental that all three of the study regions examined in this paper are impacted strongly by transport and
481 deposition of mineral dust. Interest in the impact of dust deposition on marine productivity (Jickells et al., 2005) has stimulated
482 a great deal of research into aerosol chemistry at the outflows of the world's major deserts over the past few decades (e.g. Gao
483 et al., 2007; Baker et al., 2013; Srinivas and Sarin, 2013b; Srinivas et al., 2014; Powell et al., 2015). Much of the observational
484 work on dust has generated data on aerosol N concentrations, augmenting the data available in these regions, but the presence
485 of dust adds extra complexity to the comparison performed here. Uptake of nitric acid onto suspended mineral dust particles
486 alters the size distribution and deposition velocity of aerosol nitrate, as well as changing the gas-phase composition of N
487 (Hanisch and Crowley, 2001; Rubasinghege and Grassian, 2009). Atmospheric chemical-transport models for N must therefore
488 also incorporate effective simulations of mineral dust. This is itself a considerable challenge. Dust emissions in TM4, simulated
489 for the year 2008 using ECMWF meteorology, were 1181 Tg yr^{-1} (Myriokefalitakis et al., 2016), while Kanakidou et al. (2016)
490 simulated emissions almost 30% higher for the year 2005. In the case of ACCMIP, not all of the models involved included
491 simulations of mineral dust aerosols (Lamarque et al., 2013b). In general, modelled dust deposition fluxes to remote ocean
492 regions have been shown to vary by factors of 10 or more (Huneus et al., 2011; Schulz et al., 2012) and to not reproduce key
493 aspects of the dust cycle even in well-characterised regions (Prospero et al., 2010).

494 4.5 Challenges posed by uncertainty in dry deposition velocities

495 As noted above, dry deposition velocities are probably the largest sources of uncertainty in estimates of dry deposition fluxes
496 of aerosol components. Thus the comparisons of observed and modelled aerosol concentrations presented in Fig. 4 – 6 are
497 preferable to comparisons of dry deposition flux because they avoid the uncertainty associated with conversion of measured
498 aerosol concentrations into CalDep. However, modelled aerosol concentrations at a given location are dependent on the
499 parameterisation of dry deposition velocity (together with a number of other factors of varying degrees of uncertainty) applied
500 by the model all along the simulated aerosol transport pathway. Uncertainty in modelled v_d therefore also impacts the
501 effectiveness of the concentration comparison, although gross errors in v_d in models are unlikely to result in good agreement
502 between observed and simulated aerosol concentrations.

503 5 [Summary and](#) Conclusions

504 A unique dataset of particulate NO_3^- and NH_4^+ concentrations in the marine atmosphere was compiled, based on 2890 samples
505 from oceanographic cruises between 1995 and 2012. The data were mapped to $5^\circ \times 5^\circ$ grid cells and annual average
506 concentrations were calculated for each cell. Dry deposition fluxes for each cell were calculated from these average
507 concentrations. Gridded concentrations and calculated dry deposition fluxes were compared with two different model products:
508 The ACCMIP multi-model mean products of NO_y and NH_x dry deposition, and the TM4 model of NO_y and NH_x deposition
509 fluxes and NO_3^- and NH_4^+ aerosol concentrations and deposition fluxes.

510 Comparisons of deposition fluxes of NO_y and NH_x from the ACCMIP MMM product and from TM4 with observation-derived
511 fluxes (CalDep) show similar performances for both products, with significant over-estimation of the lower levels of observed
512 NH_4^+ deposition fluxes. ModDep of NO_3^- and NH_4^+ from TM4 show much better agreement with CalDep than did NO_y and
513 NH_x , which is consistent with significant contributions of gaseous deposition to NO_y and NH_x deposition fluxes.

514 Given the uncertainties involved in the observations and modelling, it may be that the large scatter in the observation – model
515 comparisons (Figs. 4, 7 and S5) are the best that can be achieved currently in this type of comparison. Uncertainties in dry
516 deposition velocities remain a serious obstacle to improving observation- and modelling-based estimates of the atmospheric
517 flux of material into the ocean. For example, if a given observation of aerosol NO_3^- concentration leads to a value of CalDep
518 of $0.1 \text{ mg N m}^{-2} \text{ d}^{-1}$, that value represents, at best, a flux in the range of $0.05 - 0.2 \text{ mg N m}^{-2} \text{ d}^{-1}$. When considering modelled
519 dry N deposition, the uncertainty in v_d (when compounded with the other sources of uncertainty in the modelling) probably
520 implies that fluxes can be estimated to within no better than an order of magnitude. The uncertainty in modelled dry deposition,
521 in turn, leads to uncertainty in modelled wet deposition estimates. This limitation has consequences for the usefulness of
522 models in predicting the impacts of N deposition fluxes on the ocean, both in the present and into the future (Duce et al., 2008;

523 Jickells et al., 2017). Understanding of the dry deposition of particulate matter to the ocean surface has not advanced for several
524 decades (Slinn and Slinn, 1980) and concerted community action is required if further progress is to be made.

525 There are a number of steps that can be taken to improve model predictions of atmospheric N inputs to the ocean. Observations
526 of N deposition that target key areas of uncertainty (such as regions with strong seasonal cycles; intense gradients in N
527 concentrations / deposition; and with contrasting mineral dust regimes) are required and these field campaigns should include
528 measurements that address the needs of the modelling community. Examples of such measurements include: gas-phase N
529 speciation and deposition flux, in addition to particulate N speciation (in order to better constrain modelled N simulations);
530 more detailed measurement of N species aerosol particle size distributions and measurement of aerosol particle deposition
531 fluxes over the ocean (to help improve estimates of particulate N dry deposition over the ocean); long-term measurement of
532 dry particulate deposition N species fluxes, concurrently with N species wet deposition measurements, at suitable remote island
533 locations. In the future, reducing uncertainties in v_d from small-scale wind and aerosol property heterogeneity may help provide
534 more certain v_d estimates. One way to do so might be to estimate larger-scale v_d from remote sensing observations, based on
535 relationships between N concentrations and surface and remotely-sensed aerosol properties. To date, these relationships are
536 still poorly constrained. Improvements in emissions estimates, such as through the use of satellite-derived fire radiative power
537 to assess biomass burning emissions (Freeborn et al., 2014), are key to improvements in the performance of models. Most
538 model simulations of marine NH_3 emissions are based on the very old inventory of Bouwman et al. (1997). Both observations
539 and models of air – sea NH_3 exchange have progressed since that study (e.g. Johnson et al., 2008; Paulot et al., 2015) and these
540 advances should be incorporated into N atmospheric chemistry transport models more widely. Organic N species have been
541 shown to comprise a significant fraction of atmospheric N (Jickells et al., 2013). Explicit inclusion of organic N into models
542 (e.g. Kanakidou et al., 2012) should therefore result in more effective simulations of the atmospheric N cycle. Future model –
543 observation comparisons would be more effective were the observations compared directly to the corresponding absolute time
544 in the model, rather than over time-averaged periods as done here. Ideally, sampling of comparative values from the models
545 should be done over time intervals matched to the collection period of the observations.

546 The approach to assessing the performance of N deposition models used here has some obvious limitations. It does, however,
547 offer additional benefits to those provided by comparison to land-based wet deposition networks, in terms of both increasing
548 the geographical distribution of comparative data and in extending the comparison to dry deposition. In the case of N deposition
549 to the ocean, it is very unlikely that a coherent geographically-dispersed database of wet deposition observations will ever be
550 available for this purpose. It is recommended strongly that future model validation and intercomparison exercises should
551 incorporate comparisons to directly-measured aerosol concentrations, rather than to calculated dry deposition fluxes, which
552 are currently subject to large uncertainties. Reporting of surface-level aerosol concentrations should therefore be considered a
553 core requirement for future model intercomparison exercises.

554 **Author Contribution**

555 Study was designed by participants in a GESAMP WG38 workshop in 2013 (ARB, MK, KEA, GSO, FD, MU, MMS, RAD,
556 AS, LZ, JMP), led by ARB. ARB, MU, MMS and SCH contributed data and MK, ND, SM, FD and JFL contributed model
557 products. The workshop participants and ND established the observation – model comparison protocol. SSR helped to establish
558 the COST735 Aerosol and Rainfall Chemistry Database, from which much of the data used was obtained. ARB and MK
559 drafted the manuscript with contributions from all authors.

560 **Competing Interests**

561 The authors declare that they have no conflict of interest.

562 **Acknowledgments**

563 This paper resulted from the deliberations of GESAMP Working Group 38, the Atmospheric Input of Chemicals to the Ocean.
564 We thank the ICSU Scientific Committee on Oceanic Research (SCOR), the US National Science Foundation (NSF), the
565 Global Atmosphere Watch (GAW) and the World Weather Research Programme (WWRP) of the World Meteorological
566 Organization (WMO), the International Maritime Organization (IMO), the University of Crete and the University of East
567 Anglia for support of this work. ARB's contribution to this work was supported by grant NE/H00548X/1 from the UK Natural
568 Environment Research Council. Thanks to several colleagues, named in Table S1, who contributed data to this work [and two](#)

Table 2. Summary of areal average CalDep and ModDep fluxes (F, mg N m⁻² d⁻¹) of NO₃⁻/NO_y and NH₄⁺/NH_x for grid cells containing observations for the whole ocean and the TEAtl, NInd and NWPac regions.

	CalDep				ModDep			
	Fixed v _d		Variable v _d					
	NO ₃ ⁻	NH ₄ ⁺	NO ₃ ⁻	NH ₄ ⁺	NO ₃ ⁻	NO _y	NH ₄ ⁺	NH _x
<i>Whole Ocean</i>								
F	0.098	0.024	0.079	0.031				
F ACCMIP						0.098		0.060
F TM4					0.101	0.116	0.022	0.074
<i>TEAtl</i>								
F	0.182	0.021	0.139	0.026				
F ACCMIP						0.107		0.046
F TM4					0.133	0.142	0.019	0.042
<i>NInd</i>								
F	0.149	0.060	0.099	0.067				
F ACCMIP						0.116		0.098
F TM4					0.132	0.151	0.040	0.112
<i>NWPac</i>								
F	0.280	0.080	0.233	0.108				
F ACCMIP						0.335		0.144
F TM4					0.265	0.311	0.064	0.116
