Abstract. Ozone is a species of primary interest as it performs a key role in the middle atmosphere and its monitoring is thus necessary.

At the Institute of Applied Physics of the University of Bern, Switzerland, we built a new ground based microwave radiometer, GROMOS-C (GRound based Ozone MOnitoring System for Campaigns). It has a compact design and can be operated at re-
5 mote places with very little maintenance requirements, being therefore suitable for remote deployments. It has been conceived to measure the vertical distribution of ozone in the middle atmosphere, by observing pressure broadened emission spectra at a frequency of 110.836 GHz. In addition, meridional and zonal wind profiles can be retrieved, based on the Doppler shift of the ozone line measured in the 4 directions of observation (North-East-South-West).

In June 2014 the radiometer was installed in the Maïdo observatory, on La Réunion Island (21.2°S, 55.5°E). High resolution
10 ozone spectra were continuously recorded during 7 months. Vertical profiles of ozone have been retrieved through an optimal estimation inversion process, using the Atmospheric Radiative Transfer Simulator ARTS2 as the forward model. ~~The best estimate of the vertical profile is done by means of the optimal estimation method.~~ The validation is performed against ozone profiles from the Microwave Limb Sounder (MLS) on the Aura satellite, the ozone lidar located in the observatory and with ozone profiles from weekly radiosondes. Zonal and meridional winds retrieved from GROMOS-C data are validated against
15 another wind radiometer located in situ, WIRA. In addition, we compare both ozone and winds with ECMWF model data. Results show that GROMOS-C provides reliable ozone profiles between 30 to 0.02 hPa. The comparison with lidar shows a very good agreement at all levels. The accordance with MLS is within less than 10% for pressure levels between 25 and 0.2 hPa.

1 Introduction

20 The stratospheric ozone layer absorbs ultraviolet radiation from the sun, protecting life at the surface of the Earth and, through heating by the absorbed radiation, determines the thermal state of the middle atmosphere. Variations in its concentration can significantly alter the radiative balance of the middle atmosphere and consequently influence climate through resulting cir-

Something should be said regarding the comparison of wind profiles as well.

culation changes. Besides, it is well known ozone abundance is linked to climate change through the stratospheric cooling consequence of the greenhouse effect.

The monitoring of ozone is necessary and interesting by itself, but additionally because it can be used as a tracer to study atmospheric dynamics processes (Scheiben et al., 2012). Ozone spectra can further be used to retrieve middle atmospheric hor-

5   izontal wind from the Doppler shift between the spectra measured from opposite azimuthal directions (Rüfenacht et al., 2014). Wind information is crucial to study dynamical processes in the atmosphere. However the measurement of wind between 30 and 70 km remains a difficult challenge.

Nowadays there is a wide variety of techniques to measure ozone profiles, from in situ aircraft and radiosondes, to remote sensing tech, both satellite-borne and ground-based active and passive techniques. Among all the methods, ground-based

10   microwave radiometry is the only one that provides high temporal resolution ozone profiles up to the mesopause, continuously during ~~daily periods of light and dark~~ and under most weather conditions. It is a passive technique based on the observation of the radiation emitted by rotational transitions of the ozone mol.

Ground based ozone radiometer sites in the world are scarce. Most are part of the NDACC (Network for the Detection of Atmospheric Composition Change) with permanent instruments located at meteorological observatories in Spitsbergen, Switzerland,

15   Hawai, New Zeland and Japan. However, many regions are not covered by this network. Continuous ozone time series measurements are needed in these regions, particularly the southern hemisphere.

The Institute of Applied Physics of the University of Bern has developed in ~~the last~~ years a new generation of transportable radiometers to be used in measurement campaigns. GROMOS-C is one of three mobile instruments built by ~~our institute~~ along with the wind radiometer WIRA (Rüfenacht et al., 2012) and the water vapour radiometer MIAWARA-C (Straub et al., 2010).

20   These 3 instruments have been measuring together in a campaign at the Maïdo observatory (see Fig. 1).

The Maïdo observatory is located on La Réunion island, in the Indian ocean, at an altitude of 2200 m.a.s.l. It has been inaugurated in 2012, and hosts various instruments for atmospheric measurements, including wind and ozone lidars (Baray et al., 2013). Ozone sondes are deployed by Météo-France from a station nearby, Saint-Denis, at sea level. La Réunion is an important measurement site as it provides a multi-instrumented station in the southern hemisphere tropics.

25   The tropical region historically suffers from a lack of ground based ozone measurements with high vertical and temporal resolution. Recent papers have shown a significant negative ozone trend in the tropical stratosphere (Randel and Thompson, 2011), which is likely related to modifications in the Brewer-Dobson circ tion. T udy was based on satellite observations combined with ozonesondes.

Diurnal variations of stratospheric ozone in the tropics have recently been studied by ground based microwave radiometry at the Mauna Loa Observatory in Hawaii (Parrish et al., 2014).

With the data collected during this campaign we have been able to validate GROMOS-C performance as an ozone profiler by co g to ozone lidar and radiosondes, and as a wind profiler by comparison to the wind radiometer WIRA, as well as to satellite and model data. The goal of this manuscript is to present this validation. The paper is organized as follows: Section 2 provides a brief description of the microwave radiometer and the retrieval technique used. Section 3 presents the measure-

2 GROMOS-C

GROMOS-C is a ground-based compact radiometer that measures the spectral intensity of the pressure broadened rotational emission line of ozone at 110.836 GHz. A detailed description of the instrument can be found in Fernandez et al. (2015). The main characteristics of GROMOS-C are summarized in Table 1.

2.1 The instrument

The purpose of a microwave radiometer is to spectrally resolve the sky brightness temperature. The receiver of GROMOS-C has a noise temperature of 1080 K and offers the possibility to observe different emission lines: O_3 at 109.559 and 110.836 GHz, and CO at 115.271 GHz. The signal is spectrally analyzed by a fast Fourier transform spectrometer (FFTS), with a bandwidth of 1 GHz and a resolution of 30.5 kHz. One of GROMOS-C main features is the existence of multiple calibration methods, which allows to choose the most convenient to use under different conditions. The whole instrument is placed inside a sealed aluminum housing thermally insulated. A window with very low losses for microwave radiation has been built above the optics. In order to operate GROMOS-C we just have to connect it to power and the internet. It is then remotely controlled with very little maintenance requirements.

2.2 Retrieval method

The vertical distribution of ozone is retrieved from the pressure dependence of the line width of the observed spectrum. The upper limit for the retrieval from the 110.836 GHz line is circa 70 km and our lower boundary is about 23 km.

For the retrievals of GROMOS-C we use the Atmospheric Radiative Transfer Simulator ARTS2 (Eriksson et al., 2011) together with Qpack2 (Eriksson et al., 2005). The estimate of the ozone profile is done by means of the optimal estimation method (OEM) (Rodgers, 1976).

3 The campaign

La Réunion island is an overseas department of France located in the Indian ocean (21.2 °S, 55.5 °E). The Maïdo observatory was built on top of one of the highest mountains of the island, the Maïdo mountain, at 2200 m.a.s.l. It houses a large variety of atmospheric instruments, including lidars, radiometers and in situ gas and aerosol sensors. This site is important and rare because it is a multi-instrumented meteorological station in the southern hemisphere tropics. Moreover, its high elevation above sea level constitutes an advantage for lidars and microwave radiometers as they benefit from the drier atmosphere at higher altitude and therefore ensuring lower tropospheric attenuation.

I would remove the organization in subsections for this Section 2. Also, I suggest to repeat the citation Fernandez et al., 2015 when appropriate.

GROMOS-C was installed on the terrace of the Maïdo observatory in June 2014, and remained until the end of January 2015. High temporal resolution ozone spectra were continuously recorded during those 7 months. The main goal of this measurement campaign was to validate the performance of GROMOS-C as an ozone and wind profiler by comparing to profiles from other reliable sources. Further, the high resolution ozone spectra constitute a valuable data set not previously available for this

5   location. These data can be used to study the diurnal cycle of ozone in the tropics (Studer et al., 2014). An accurate knowledge of diurnal ozone variation is needed for reliable trend detection in the global ozone distribution. Merging ozone data from different satellites without properly accounting for the diurnal ozone cycle would result in a systematic bias in the calculated ozone trend.

Our campaign instruments WIRA and MIAWARA-C were also involved in the campaign with measurements starting in

10   September 2013.

During the campaign, from June to January, the weather was quite stable with minimum temperatures of $6\,^\circ$C and maximum close to $20\,^\circ$C. Atmospheric opacity was calculated periodically with the tipping curves, and were found to be between 0.1 and 1 except for very humid days (Fig. 2), which occur mainly towards the summer (December-January). The specific humidity increased considerably during the summer (Fig. 2 middle plot). An opacity value lower than 0.5 is considered to be very good.

15   Spikes in the opacity plot correpond to clouds passing by.

The operation cycle of GROMOS-C includes 4 directions of sky view, North-East-South-West. All sky measurements are performed at an elevation angle of $22\,^\circ$. Afterwards the rotating mirror points to the Peltier and hot loads for calibration. The noise diode is turned on when the optics are pointing to the Peltier target. The integration time for each measurement is 1s. Tipping curves are performed every 15 minutes.

20   ## 3.1   Reference intruments

Aura-MLS

The Earth Observing System Microwave Limb Sounder, EOS MLS, is a mm-wave radiometer onboard Aura satellite, which was launched in July 2004. Aura-MLS covers latitudes between $82\,^\circ$S and $82\,^\circ$N. It is in a Sun-synchronous near-polar orbit at an altitude of 705 km, with two overpasses at each geographic location at fixed local times per day. MLS observes emitted

25   microwave radiation in limb geometry from the ground up to 96 km. Atmospheric limb scans and radiometric calibration are performed routinely every 25 seconds. Vertical profiles are retrieved every 165 km along the suborbital track. A detailed description of Aura-MLS can be found in Waters et al. (2006).

Ozone is observed at 240 GHz. The retrieved profiles of version v3.3 are used for this comparison. The altitude range covered goes from the upper troposphere, 260 hPa, to the mesosphere, 0.02 hPa. The vertical resolution is 3 km at 260 hPa, increasing

30   to 5.5 km at 0.02 hPa, and the horizontal resolution goes from 300 km to 500 km, depending on the pressure level (Froidevaux et al., 2008).

Page: 4

DIAL Lidar

A Differential Absorption ozone Lidar (DIAL) was installed in the Maïdo observatory in 2013. It requires the use of 2 different emitted wavelengths. The laser sources are a tripled Nd:Yag laser, which provides the non-absorbed beam at 355 nm, and a XeCl excimer laser, which provides the absorbed beam at 308 nm. The receiving telescope is composed of 4 parabolic mirrors.

5   The backscattered signal is collected by 4 optical fibers located at the focal point of each mirror. A Jobin Yvon holographic grating is used in the spectrometer.

The lidar provides ozone profiles over 15-45 km altitude. The lidar signals are recorded every 3 min but averaged over the whole night to increase the signal-to-noise ratio. It is necessary to apply a number of corrections to the signal. The background signal is estimated and removed using a linear regression in the high altitude range where the useful lidar signal is negligible

10   (over 80 km). Ozone number density is retrieved from the slope of the signals after derivation (Godin-Beekmann et al., 2003). Lidar signals are corrected for the Rayleigh extinction using a pressure temperature profile from nearby radiosondes and a meteorological model.

Ozone Radiosondes

15   Ozone soundings are performed weekly since 1998, launched from Gillot, the Météo-France station near the airport of La Réunion Island, at 8 m.a.s.l. A profile is obtained up to the altitude where the balloon bursts at approximately 30 km. Ozone is measured with an electrochemical concentration cell (ECC) (Stübi et al., 2008). The ozonesonde currently used is a ECC Z Ensci type with a 0.5% KI buffered solution from Droplet Measurement Technology. It is coupled to a meteorological radiosonde M10 from MeteoModem.

20   The effective vertical resolution of the ozone data is between 50 and 100 m. The ozone measurement accuracy is approximately 4% in the stratosphere below 10 hPa pressure level and the precision in total ozone column measured by the sonde is approximately 5%. These ozone measurements are part of the SHADOZ (Southern Hemisphere Additional Ozonesondes) (Thompson et al., 2003) and the NDACC networks.

WIRA

25   WIRA is the first ground-based microwave wind radiometer. It was built at IAP and measures the Doppler shift in the emission spectrum of middle atmospheric ozone at 142 GHz in order to derive middle atmospheric meridional and zonal wind profiles. In routine operation, a cycle contains the measurement of signals from two calibration targets as well as from four cardinal directions for the wind retrieval. The retrieval of wind profiles combines the calibrated spectra obtained at two opposite viewing directions (i.e. east and west for zonal and north and south for meridional wind). The prototype of the instrument as well as its

30   operation mode and calibration scheme are described in detail in Rüfenacht et al. (2012). The retrieval method is presented in Rüfenacht et al. (2014). It covers an altitude range from 35 to 75 km, with a vertical resolution between 10 and 16 km.

The European Centre for Medium-Range Weather Forecasts (ECMWF) provides global analyses of atmospheric ozone from the ground to the lower mesosphere. Ozone profiles can be obtained from 2 different products from ECMWF: operational analysis or reanalysis. ERA-Interim (Dee et al., 2011) is their latest global atmospheric reanalysis dataset and provides profiles

5   every 6 hours, for 60 pressure levels between the surface and 0.1 hPa. The altitude range of the operational analysis reaches pressure levels up to 0.01 hPa with a vertical resolution of 137 levels. For the validation of GROMOS-C we compare with the operational data, because our retrieval altitude range goes up to 0.03 hPa.

4   Results of ozone measurements

10   ### 4.1   Ozone retrievals

Before the spectra is fed to the inversion process a preprocessing is performed in order to correct the measurement for atten- uation arising from the microwave window and tropospheric absorption. Water vapour inhomogeneities in the troposphere are difficult to model and therefore it is important to correct the measured spectra for the tropospheric effect. Tropospheric opacity is calculated from the wings of the measured spectra (Navas-Guzmán et al., 2015) and substracted from it. Afterwards the lower

15   limit for the retrieval is located at the tropopause level. The spectra baseline is removed by allowing the optimal estimation method to fit a polynomial of degree 2.

For the standard retrieval of GROMOS-C, we use the whole frequency resolution of the spectrometer, and a bandwidth of 300 MHz. Reduction of the noise level of the spectra is performed by integration in time, being the minimum time resolution used 1 hour. Ozone profiles are retrieved from the resulting averaged spectra, yielding a reliable profile from roughly 23 to 70 km,

20   with a vertical resolution of 10-15 km depending on the pressure level.

The inversion process requires an a priori knowledge of the vertical ozone profile. This a priori information is taken from a zonal mean climatology using monthly mean Aura MLS data from 2004-2013. The a priori covariance matrix used has a fixed maximum value for the diagonal elements of 0.4 ppm and a Gaussian correlation decay at neighbouring levels. The covariance matrix of the measurement is built as a diagonal matrix, where the elements in the diagonal are the square of the noise level of

25   the spectra, which are assumed constant for all channels. Forward model calculations require a temperature-pressure-altitude profile. This data is taken from the ECMWF model for the corresponding time and location, interpolated to the pressure grid. Spectroscopic parameters for the ozone line are taken from the JPL and HITRAN catalogs. We used the oxygen and water continuum and peaks from the Rosenkranz model (Rosenkranz, 1998). We used water vapour profiles from the ECMWF model and oxygen and nitrogen mixing ratios are assumed to be constant.

30   An example of a daily mean retrieved ozone profile is shown in Fig. 3a, the a priori profile used for the retrieval is plotted with a dashed line. The corresponding averaging kernels and measurement response are shown in Fig. 3b. The averaging kernel matrix represents the sensitivity of the retrieved profile to the true atmospheric profile. The area of the kernels, called measurement

What O3 data are provided as input to the ECMWF model? What's the time resolution of operational profiles? Also 6 hours? It would be helpful if you could spell out the vertical resolution in km, which of course varies with altitude. Is there a reference for the operational data set which also would tell us something about the reliability of this model? Any information on the uncertainties?
The reader can't really evaluate how important it is a discrepancy between GROMOS-C and ECMWF data unless he/she knows how accurate the ECMWF model is.

Although you did reference to Fernandez et al, 2015 (F15) previously, it would be useful to the reader do keep doing it whenever you refer to procedures or technical details explained in F15. Given the strong ties between this manuscript and F15, maybe you could even cite the specific page or section of F15 where the topic at hand is discussed. In this specific case, concerning window and tropospheric absorptions, I would cite section 3 of F15.

Sequence number: 4
Author:
Subject: Note
Date: 01/04/2016 09:44:02
It would be interesting to see the amplitude of this 2nd order polynomial

response, is used as an indicator of the sensitive altitude range of the retrieval. We assume this altitude range delimited by the levels where the measurement response is larger than 0.8, which corresponds to pressure levels between 30 and 0.02 hPa (24 to 75 km). The full width at half maximum of the averaging kernels gives a measure of the vertical resolution. The averaging kernels width (Fig. 3c) go from 7 km in the lower stratosphere, increasing with altitude up to 17 km in the middle mesosphere.

5 Fig. 3d shows the altitude peak of the corresponding kernels maximized at their nominal altitude for the altitude range under consideration.

The operative cycle of GROMOS-C contains the measurement of the sky signal from 4 directions of view. The spectra of 2 opposite view directions (East-West and North-South) are combined in order to retrieve zonal and meridional wind profiles. Ozone retrievals can also be performed individually for each direction, to study possible inhomogeneities of the ozone distri-

10 bution, which are neglected for the wind retrievals. All sky measurements are performed at an elevation angle of $22°$, which implies that two points located at the stratopause level in North and South directions are separated horizontally by a distance of circa 250 km. In stable conditions this constitutes a reasonable range over which to neglect ozone inhomogeneities.

Fig. 4 shows 4 ozone profiles corresponding to the 4 directions of view of GROMOS-C. Each of them has been calculated taking the mean of the daily mean profiles for the whole campaign period, from mid-June to mid-January. The right plot shows

15 the mean relative difference profile, calculated in percent and with respect to the East. From 60 hPa to roughly 0.02 hPa the differences are within 2%, except for the South, and higher up they appear to increase with altitude. The increases in differences with altitude is consistent with an increase in horizontal distance between points in opposite directions. Therefore these discrepancies could be explained as differences in the ozone distribution. A positive bias of nearly 5% in ozone is notable at all altitudes in measurements toward the South. This bias is a result of an offset in elevation angle present only in the measurements

20 toward the South.

4.2 Comparing the calibration methods

As mentioned above, multiple calibration techniques are used to generate GROMOS-C data; these are hot load, Peltier load, noise diode and tipping curve. In this section, we compare the influence of these calibration methods on the retrievals.

Fig. 5 displays the spectrum and retrieved profile for a day at the beginning of the campaign, the 23rd of June, for the 3 dif-

25 ferent calibration methods. A tropospheric correction has been applied to all spectra, so the retrieval starts at the tropopause

level. Both the noise diode and hot-Peltier spectra have similar noise levels, which results in similar retrievals. We added the equivalent MLS ozone profile (in red) to use as a reference. The averaging kernels and measurement response present the same characteristics as in Fig. 3. However, the spectrum calibrated with the tipping curve exhibits a higher noise level, therefore the retrieval takes more information from the a priori. That could be the reason why this retrieved profile is closer to the reference

30 MLS profile, since we use a MLS climatology as a priori profile. The upper limit of the measurement response is also lower, 0.035 hPa, compared to 0.02 hPa in the other cases. The higher noise level in the tipping curve calibration is likely a result of zenith sky measurements, which are not long enough zenith measurement is taken only every 15 minutes. Therefore, the cold sky integration time is relatively short and the noise in this measurement is larger than the noise in the $22°$ measurement. This problem could likely be eliminated by raising the frequency of the tippings or increasing the integration time for the

Subject: Note
Date: 01/04/2016 09:46:07
Is this result different from what showed in F15?

retrievals.

We started the campaign in winter (June) with good atmospheric conditions, i.e., low humidity, frequent clear skies and, therefore, low optical thickness (Fig. 2). However, towards the summer the temperature and humidity increased leading to higher opacity. Under these conditions, a baseline emerged on the calibrated ozone spectra. We found that its origin was at the Peltier

5 load and we believe it could be due to the condensation of water on the window of the load if the dew point was reached. As water is not transparent to microwave radiation, part of the radiation would be backscattered and a standing wave would be created between the load and the antenna, which added a baseline to the spectra. Performing inversions of spectra with such a ripple would have considerable impact on the retrieval. Therefore, in such conditions we prefer other methods of calibration. It is important to point out that the baseline effect can be circumvented by the use of other calibration technique and this ability

10 to alternate calibration methods is an important advantage of the measurement approach.

4.3 Validation of the ozone timeseries

In this section we validate GROMOS-C retrieved profiles against other ozone profiles measured with different techniques. We have used tipping curve calibrated spectra for the daily mean comparison, but for shorter integration time we have considered

15 the noise diode calibration because the altitude range where the measurement response is larger than 0.8 goes up to higher layers, allowing for a fair comparison also in the mesosphere.

The timeseries of ozone profiles measured by GROMOS-C during the Maïdo campaign are shown in Fig. 6 (above). They correspond to retrieved profiles run with an integration time of 2 hours, calibrated with the noise diode, for the East direction. Ozone concentration is expressed as volume mixing ratio, in parts per million volume (ppm). The data gap in September

20 corresponds to a week where we shifted the frequency range to measure carbon monoxide instead of ozone, and the gap in December corresponds to a very high opacity period where the inversions did not work. The white lines represent the limits where the measurement response is larger than 0.8, identifying the altitude range where profiles can be reliable. In most cases these limits range from 30 to 0.03 hPa. Before a spectrum is fed to the retrieval, it has to pass a noise level test and be taken within certain limits of opacity and system temperature. If a spectrum fails any of these tests, it is discarded. In that case, the

25 considered integration time will present a higher noise, affecting the averaging kernels of the inversion and decreasing the boundaries for the reliable profiles. We observed a decreased altitude range for the last month of data, which corresponds to the very humid period and with high opacity.

A comparable plot of Aura MLS ozone profiles is shown in Fig. 6 (below). The similarity is striking. The annual cycle increase in ozone in the middle stratosphere from winter to summer due to increased solar radiation is obvious. The diurnal cycle is also

30 perceptible. Special features of this dataset are discussed below, in section 6.

For a more quantitative comparison we have divided the profiles into 3 pressure levels, and plotted the mean volume mixing ratio for each layer (Fig. 7). Each point corresponds to a daily mean value; this time we have opted for the tipping curve calibration for the comparison. We chose altitude levels at 25-10 hPa, 10-2 hPa and 2-0.5 hPa, which correspond roughly to the lower, middle and upper stratosphere. We compared our measurements to those from MLS, lidar, radiosondes and

Page: 8

I would avoid using terms such as "striking" or "obvious". The main information I gain from Fig. 6 is the time variation of the altitude range of GROMOS-C, whereas the agreement between GROMOS-C and MLS can be evaluated only in Figure 7. As a matter of fact, I would consider removing the MLS contour map.

with the model data from ECMWF. The radiosonde comparison is only available for the first layer because the balloons normally burst at circa 30 km. The lidar is not available for the highest layer under comparison. ECMWF and MLS are comparable at all levels. On the right plot we display the relative differences with respect to GROMOS-C. Until mid-December, all measurement are within 10%. After mid-December, large fluctuations due to high opacity are problematic for GROMOS-C

5 measurements. We cannot explain an apparent bias in ECMWF model results in the middle and higher stratosphere with respect to the measurements of MLS, GROMOS-C and lidar.

A more detailed comparison is shown in Fig. 8, where we plot a single GROMOS-C daily mean profile together with the equivalent profiles obtained from MLS, ECMWF, lidar and radiosonde. All of the profiles present a higher vertical resolution than GROMOS-C retrievals. We therefore have to convolve each of them with the averaging kernels of our inversions according

10 to:

$$x_{conv} = A \cdot (x - x_a) + x_a$$

where A is the averaging kernels matrix, x stands for O_3 profile, being x_a the a priori profile of our retrievals. The convolution decreases the vertical resolution of the measured profiles and allows for an adequate comparison.

Fig. 8 includes both the original unconvolved profiles plus the convolved ones. The relative differences between the convolved

15 profiles relative to GROMOS-C is clear in the right plot in Fig 8. Results show an agreement with the satellite profile within the 5% up to 0.2 hPa and within 10% for the ECMWF profile. The agreement with lidar data is goo the comparison to the radiosonde data shows more discrepancies, especially at lower altitude levels ever, keep in mind, GROMOS-C data reliability range starts at an altitude of 30 hPa. The bias decreases from 13% to 4% with increasing altitude. Above 0.1 hPa, the GROMOS-C retrieval appears to overestimate the volume mixing ratio of ozone. In the mesosphere the ozone concentration

20 becomes so low a small discrepancy affects the relative difference in a significant way.

5 Result and validation of wind measurements

Although GROMOS-C was primarily designed for observations of ozone and carbon monoxide profiles its setup includes the capacity for middle-atmospheric wind measurements. Thanks to its relatively low noise temperature, to its sufficient spectral

25 resolution, and to its ability to observe the atmosphere in the four cardinal directions zonal and meridional wind profiles can be assessed. The wind profiles are determined from the Doppler shifts of different parts of the Doppler shifted spectrum through an optimal estimation inversion which was first described by Rüfenacht et al. (2014). The retrieval is performed with the ARTS/QPACK software package (Eriksson et al., 2011, 2005). The atmospheric parameters of the forward and inverse model for the GROMOS-C wind retrieval were set analogously to the ones of the retrieval for the wind radiometer WIRA (see Sect.

30 4 of Rüfenacht et al. (2014)), taking into account that GROMOS-C measures the 110 GHz ozone emission line rather than 142 GHz.

The time series of GROMOS-C daily average wind profiles for a test phase of 6 months are shown in Fig. 9. For comparison,

measurements by the co-located wind radiometer (WIRA) and ECMWF model data are also shown. The grey lines in the upper panels represent the upper and lower limit of the trustworthy altitude range. This range is defined to be the region where the measurement response is higher than 0.8, the altitude resolution ~~higher~~ than 20 km, and the altitude accuracy (defined as the offset between the peak altitude and the nominal altitude of the averaging kernel) is better than 4 km. In the vast majority of

5   cases, the trustable altitude range for GROMOS-C is delimited by the averaging kernel criterion. Data outside the trustable altitude range should not be considered.

The overall agreement between GROMOS-C, WIRA and ECMWF is clearly visible. The principal features such as the stratospheric wind reversal in July 2014 are captured by GROMOS-C. Due to the design and operation mode, which is not optimized for wind measurements, the uncertainties of the GROMOS-C observations are larger and the altitude range is smaller than ~~that~~

10   of WIRA. Nevertheless, this comparison indicates the potential of GROMOS-C to perform zonal wind measurements over the altitude range of 40 to 60 km.

6   Special case study

Fig 6 shows an increase of ozone in early July between 4 and 1 hPa. This increase is evident in data from both GROMOS-C

15   and MLS. This feature is presented in more detail in Fig. 10. The timeseries of ozone profiles measured by GROMOS-C have been plotted together with the isentropes (lines of equal potential temperature) taken from the ECMWF model. As air parcels travel on surfaces of equal potential temperature, the isentropes can be used to study the airflow and to identify vertical displacements. In Fig. 10, an updraft is identified by dashed lines and by deviations of the isentropes at 1200, 1400, and 1600 K. The updraft has higher ozone mixing ratios and results in higher ozone at the correspondent pressure levels.

20   The timeseries of temperature profiles from the ECMWF model are shown in the middle plot. A substantial decrease of temperature is observed within the same time period mainly at pressure levels between 4 and 1 hPa, which is also explained by the updraft of air from colder layers. During this event strong zonal winds of up to 90 km/h are observed in the ECMWF model (Fig. 10, below) followed by an intense East to West wind reversal.

7   Conclusions

The first validation campaign of GROMOS-C took place at the Maïdo observatory in La Réunion island, from June 2014 till January 2015. We validated its capability to measure continuous ozone profiles with high temporal resolution for a broad altitude range.

We have confirmed different calibration methods lead to equivalent retrieved profiles as long as the spectra is baseline free

30   demonstrated the advantages of using multiple calibration methods. When the Peltier load method failed due to high humidity, we had the option to use a different approach. The tipping curve method works well at very low brightness temperatures. It

I understand that wind data are in a test phase, but if you aim at validate them (as the title of the section states) you need to show a little more than a qualitative comparison among contour maps (which, again, I am not fond of, as I stated for Figure 6). If you only want to show that GROMOS-C can potentially measure stratospheric winds but not yet accurately enough, then I would suggest you to change the title of the section and write why the measurements are not yet good enough and what you plan to do to improve them.

It is interesting that GROMOS-C observed a rapid vertical displacement of stratospheric air, but what it is shown in this section is not really sufficient to make a case study. From a scientific standpoint, why do we care about this updraft? What originated it? Where did the air come from?

Again, already in F15?

is easy to implement. However, the calculation is time consuming and less accurate for cloud conditions. Further, the tipping curve method produces noisier spectra because the integration time for the cold sky measurements was short. This approach should be used when longer integration times are possible. The noise diode approach needs recalibration if the system temperature fluctuates. This approach should be used when the system is thermally stable. The Peltier and hot loads are thermally stabilized and not weather dependent. They constitute the default calibration technique of GROMOS-C. During this campaign, when temperatures dropped below the dew point, water condensed on a window interfering with the measurement. This problem was fixed after the campaign by displacing moist air with dry nitrogen.

The measurement response of the retrievals of GROMOS-C is larger than 80% for pressure levels between 30 and 0.02 hPa (24 to 75 km). The vertical resolution goes from 7 km in the lower stratosphere, increasing with altitude up to 17 km in the middle mesosphere. The averaging kernels peak at its nominal altitude over this altitude range.

Validation has been performed using ozone profiles from Aura MLS satellite, the ozone lidar located in the observatory and with ozone profiles from weekly radiosondes, as well as with data from the ECMWF model. Results show an agreement with MLS profiles within 5% up to 0.2 hPa and within 10% for the ECMWF profile. Agreement with the lidar is within 5% at all levels of comparison. Radiosonde data shows more discrepancies especially at lower altitudes. The bias in the ozone measurements decreases from 13 to 4% with increasing altitude in the trustworthy range.

Although GROMOS-C was mainly designed for ozone observations its setup allows for middle-atmospheric wind profile measurements. The 4 directions of view allow retrieval of zonal and meridional winds from the Doppler shift. Winds measured by GROMOS-C have been validated using data from another co-located wind radiometer (WIRA) and using output from the ECMWF model. The overall agreement between GROMOS-C, WIRA and ECMWF is clearly visible. Important meteorological features such as the stratospheric wind reversal in July are clearly evident in GROMOS-C data. Thus GROMOS-C measurements can also be used to measure middle atmospheric wind profiles.

We also identified an updraft event from an increase of ozone measured by GROMOS-C.

The high temporal resolution ozone dataset presented here is unique for this location and will be useful given the dearth of such data from tropical locations. In a future study it would be interested to investigate the ozone diurnal cycle which has not been studied for such a tropical location.

The plot of the AVK for the three different cases doesn't really provide useful information to the reader. They look very similar to one another. Maybe it would be more helpful a plot of the vertical MR uncertainty for the three cases, if that changes, or else just a mention in the text of what critical parameter changes with the three different calibrations (altitude of 80% levels? vertical resolution? uncertainty of profile MR?)

Figure 6. Timeseries of ozone profiles measured by GROMOS-C during the Maïdo campaign (above); the white lines represents the limits where the measurement response is larger than 0.8. Equivalent plot with Aura-MLS ozone profiles (below).

Please, indicate explicitly in the caption what is intended with relative difference. The legend of the right panels is also not correct as the names of plotted data sets should indicate they are relative differences.

Figure 8. Comparison of a daily mean GROMOS-C ozone profile with MLS, ECMWF, lidar and radiosonde. We have included both the original and the convolved profiles. The right plot shows the relative differences of the convolved profiles with respect to GROMOS-C.

Sequence number: 1
Author:
Subject: Note
Date: 04/04/2016 12:22:13

At first I was really surprised by the difference between the o3 sondes and the lidar/MLS pair that can be seen in the original (not convolved) profiles. It seemed to imply that the O3 sondes were steadily overstimating the O3 content upwards of 30 mb. On the other hand, from Figure 7 it appears that the O3 sonde averages over the 25-10 hPa range do not show a clear offset. My conclusion is that this figure based on one single day of data is not representative of the overall comparison among the datasets and a better representation of the overall profiles differences should be shown.

Sequence number: 2
Author:
Subject: Note
Date: 01/04/2016 16:31:48

Is this one single daily mean? What day is it? Maybe it would be useful to show daily mean comparisons for, say, 3 different values of sky opacity (e.g., low, medium, high)

Figure 9. Middle-atmospheric zonal wind profiles measured by the radiometers GROMOS-C and WIRA as well as model data from ECMWF.

The grey horizontal lines delimit the trustable altitude range which is basically equivalent to a measurement response larger than 0.8.

Sequence number: 1
Author:
Subject: Note
Date: 04/04/2016 12:24:00

By looking at the 0.8 levels of the GROMOS-C wind data, there doesn't seem to be a substantial degradation of the data set with summer, as there is in the O3 profiles. Can you say why?

Figure 10. Zoom in the timeseries of ozone profiles measured by GROMOS-C plotted together with the isentropes from ECMWF (above), temperature profiles from ECMWF (middle) and zonal wind profiles from ECMWF (below). The black dashed lines delimit the time period when the air updraft happened.
