14

15 **Abstract:** Continuous measurements of airborne particles and their chemical compositions were
16 conducted in May, June, October, and November 2014 at an urban site in Wuhan, central China.
17 The results indicate that particle concentrations remained at a relatively high level in Wuhan,
18 with averages of 135.1 ± 4.4 (mean \pm 95% confidence interval) and $118.9 \pm 3.7 \mu\text{g}/\text{m}^3$ for PM_{10}
19 and 81.2 ± 2.6 and $85.3 \pm 2.6 \mu\text{g}/\text{m}^3$ for $\text{PM}_{2.5}$ in summer and autumn, respectively. Moreover,
20 $\text{PM}_{2.5}$ levels frequently exceeded the National Standard Level II (i.e., daily average of $75 \mu\text{g}/\text{m}^3$),
21 and six $\text{PM}_{2.5}$ episodes (i.e., daily $\text{PM}_{2.5}$ averages above $75 \mu\text{g}/\text{m}^3$ for 3 or more consecutive days)
22 were captured during the sampling campaign. Potassium was the most abundant element in $\text{PM}_{2.5}$,
23 with an average concentration of $2060.7 \pm 82.3 \text{ ng}/\text{m}^3$; this finding indicates intensive biomass
24 burning in and around Wuhan during the study period, because almost no correlation was found
25 between potassium and mineral elements (iron and calcium). The source apportionment results
26 confirm that biomass burning was the main cause of episodes 1, 3, and 4, with contributions to
27 $\text{PM}_{2.5}$ of $46.6\% \pm 3.0\%$, $50.8\% \pm 1.2\%$, and $44.8\% \pm 2.6\%$, respectively, whereas fugitive dust
28 was the leading factor in episode 2. Episodes 5 and 6 resulted mainly from increases in vehicular
29 emissions and secondary inorganic aerosols, and the mass and proportion of NO_3^- both peaked
30 during episode 6. The high levels of NO_x and NH_3 and the low temperature during episode 6
31 were responsible for the increase of NO_3^- . Moreover, the formation of secondary organic carbon

32 was found to be dominated by aromatics and isoprene in autumn, and the contribution of
33 aromatics to secondary organic carbon increased during the episodes.

34 **Keywords:** PM_{2.5}; NO₃⁻; SOA; biomass burning; formation mechanism

35

36 **1. Introduction**

37 Airborne particulate pollution, also called “haze,” has swept across China in recent years,
38 particularly over its northern, central, and eastern parts (Cheng et al., 2014; Kang et al., 2013;
39 Wang et al., 2013). Due to its detrimental effects on human health (Anderson et al., 2012;
40 Goldberg et al., 2001), the atmosphere (Yang et al., 2012; White and Roberts, 1977), acid
41 precipitation (Zhang et al., 2007; Kerminen et al., 2001), and climate change (Ramanathan et al.,
42 2001; Nemesure et al., 1995), particulate pollution has become a major concern of scientific
43 communities and local governments. China’s national ambient air quality standards issued in
44 2012 regulate the annual upper limit of PM₁₀ (i.e., particulate matter with an aerodynamic
45 diameter of less than 10 μm) and PM_{2.5} (i.e., particulate matter with an aerodynamic diameter of
46 less than 2.5 μm) as 70 μg/m³ and 35 μg/m³ and 24-h averages as 150 μg/m³ and 75 μg/m³,
47 respectively (GB 3095-2012).

48 Numerous studies have been conducted in China to understand the spatiotemporal variations in
49 particle concentrations, the chemical composition, and the causes of haze events (Cheng et al.,
50 2014; Cao et al., 2012; Zheng et al., 2005; Yao et al., 2002). In general, particulate pollution is
51 more severe in winter due to additional emissions (e.g., coal burning) and unfavorable dispersion
52 conditions (Lyu et al., 2015a; Zheng et al., 2005). Northern China often suffers heavier, longer,
53 and more frequent haze pollution than southern China (Cao et al., 2012). Chemical analysis
54 indicates that secondary inorganic aerosol (SIA; i.e., sulfate [SO₄²⁻], nitrate [NO₃⁻], and
55 ammonium [NH₄⁺]) and secondary organic aerosol (SOA) dominate the total mass of airborne
56 particles (Zhang et al., 2014; Zhang et al., 2012). However, the composition differs among the
57 size-segregated particles. In general, secondary species and mineral or sea salt components are
58 prone to be apportioned in fine and coarse particles (Zhang et al., 2013; Theodosi et al., 2011).
59 Indeed, the general characteristics of particles (e.g., toxicity, radiative forcing, acidity) are all
60 tightly associated with their chemical compositions and physical sizes, which therefore have
61 been extensively studied in the field of aerosols. To better understand and control airborne
62 particulate pollution, the causes and formation mechanisms have often been investigated (Wang

63 et al., 2014a and b; Kang et al., 2013; Oanh and Leelasakultum, 2011). Apart from the
64 unfavorable meteorological conditions, emission enhancement was often the major culprit. There
65 is little doubt that industrial and vehicular emissions contributed greatly to the particle mass via
66 direct emission and secondary formation of particles from gaseous precursors, such as sulfur
67 dioxide (SO₂), nitrogen oxides (NO_x), and volatile organic compounds (VOCs; Guo et al., 2011a).
68 In addition, some other sources in specific regions or during specific time periods have also built
69 up the particle concentrations to a remarkable degree, e.g., coal combustion in north China (Cao
70 et al., 2005; Zheng et al., 2005) and biomass burning in Southeast Asia (Deng et al., 2008; Koe et
71 al., 2001). Furthermore, some studies have explored the possible formation mechanisms of the
72 main particle components (SIA and SOA) and distinguished the contributions of different
73 formation pathways. For example, Wang et al. (2014) demonstrated that heterogeneous oxidation
74 of SO₂ on aerosol surfaces was an important supplementary pathway to particle-bound SO₄²⁻ in
75 addition to gas phase oxidation and reactions in clouds. In contrast, it was reported that
76 homogeneous and heterogeneous reactions dominated the formation of NO₃⁻ during the day and
77 night, respectively (Pathak et al., 2011; Lin et al., 2007; Seinfeld and Pandis, 1998). Furthermore,
78 biogenic VOCs and aromatics were shown to be the main precursors of SOA (Kanakidou et al.,
79 2005; Forstner et al., 1997).

80 Despite numerous studies, the full components of airborne particles have seldom been reported
81 due to the cost of sampling and chemical analysis, resulting in a gap in our understanding of the
82 chemical characteristics of particles. In addition, although the causes of particle episodes have
83 been discussed in many case studies (Wang et al., 2014; Deng et al., 2008), the contributions
84 have rarely been quantified. Furthermore, the formation mechanisms might differ in various
85 circumstances. Therefore, an overall understanding of the chemical characteristics of airborne
86 particles, the causes of the particle episodes, and the formation mechanisms of the enhanced
87 species would be of great value. In addition, the frequent occurrence of haze pollution has
88 become a regular phenomenon in central China during warm seasons, but the causes have not
89 been identified and the contributions have not been quantified. Wuhan is the largest megacity in
90 central China and has suffered from severe particulate pollution in recent years. The data indicate
91 that the frequency of days in which PM_{2.5} exceeded the national standard level II (i.e., a daily
92 average of 75 µg/m³) in Wuhan reached 55.1% in 2014 (Wuhan Environmental Bulletin, 2014).
93 In the warm seasons of 2014, the hourly maximum PM_{2.5} (564 µg/m³) was even higher than that

94 in winter ($383 \mu\text{g}/\text{m}^3$), as shown in Figure S1 in the Supplementary Material. Moreover, because
95 the air quality in Wuhan is strongly influenced by the surrounding cities, the pollution level in
96 Wuhan also reflects the status of the city clusters in central China. However, previous studies
97 (Lyu et al., 2015a; Cheng et al., 2014) did not allow a complete understanding of the properties
98 of airborne particles in this region, particularly during the warm seasons, nor could they guide
99 control strategies. It is therefore urgent to understand the chemical characteristics of airborne
100 particles and to explore the causes and formation mechanisms of the particle episodes in Wuhan.
101 This study comprehensively analyzed the chemical characteristics of $\text{PM}_{2.5}$ in Wuhan from a full
102 suite of component measurement data: SO_4^{2-} , NO_3^- , NH_4^+ , organic carbon (OC), including
103 primary organic carbon (POC) and secondary organic carbon (SOC), elemental carbon (EC), and
104 elements. Furthermore, based on the analysis of meteorological conditions, chemical signatures,
105 source apportionment, and distribution of wildfires, the causes of the $\text{PM}_{2.5}$ episodes are
106 identified and their contributions quantified. Finally, this study used a photochemical box model
107 incorporating a master chemical mechanism (PBM-MCM) and theoretical calculation to
108 investigate the formation processes of NO_3^- and SOC. Ours is the first study to quantify the
109 contribution of biomass burning to $\text{PM}_{2.5}$ and examine the formation mechanisms of both
110 inorganic and organic components in $\text{PM}_{2.5}$ in central China.

111

112 **2. Methods**

113 **2.1 Data collection**

114 The whole set of air pollutants were continuously monitored at an urban site in the largest
115 megacity of central China, i.e., Wuhan. The measurement covered two periods: May and June in
116 summer and October and November in autumn of 2014. The measured species included particle-
117 phase pollutants such as PM_{10} , $\text{PM}_{2.5}$, and particle-bound components and gas-phase pollutants,
118 including VOCs, SO_2 , CO, NO, NO_2 , O_3 , HNO_3 (g), NH_3 (g), and HCl (g). Hourly data were
119 obtained for each species. The sampling site (30.54°N , 114.37°E) was located in the Hubei
120 Environmental Monitoring Center Station, as shown in Figure 1, located in a mixed commercial
121 and residential area in which industries are seldom permitted. The instruments were housed in a
122 room in a six-story building (~ 18 m above ground level) adjacent to a main road at a straight-line
123 distance of ~ 15 m. The traffic volume of the road was around 200 vehicles per hour. However, a
124 wall (~ 2 m high) and several rows of trees (7 to 8 m high) were located between the road and the

125 sampling site.

126 PM₁₀ and PM_{2.5} were measured with a continuous ambient particulate monitor (Thermo Fisher-
127 1405D, USA) integrated with a filter dynamics measurement system to minimize the loss of
128 semivolatile particulate matter. The water-soluble ions (WSIs) in PM_{2.5} and gases including
129 HNO₃, HCl, and NH₃ were detected with an online ion chromatography monitor (Metrohm-
130 MARGA 1S, Switzerland). However, data were not available in May and June, because the
131 instrument was initially deployed in September. An aerosol OC/EC online analyzer (Sunset-RT-4,
132 USA); the NIOSH thermal-optical transmission method was used to resolve the carbonaceous
133 aerosols (OC and EC). In addition, the elements in PM_{2.5} were measured with a customized
134 metal analyzer. This instrument used a PM_{2.5} impactor to collect the airborne particulate samples,
135 which were analyzed by the β -ray in terms of mass concentrations. The filters loaded with
136 particles were then sent to an x-ray fluorescence analysis system for quantitative analysis. K⁺
137 monitored by the online ion chromatography correlated well ($R^2 = 0.88$; slope = 0.80) with K
138 monitored by the customized metal analyzer. To keep consistency with other elements, K rather
139 than K⁺ was used to do the following analyses in this study. For the analysis of trace gases (SO₂,
140 CO, NO, NO₂, and O₃), we used a suite of commercial analyzers developed by Thermo
141 Environmental Instruments Inc., which have been described in detail (Lyu et al. 2016; Geng et al.,
142 2009). Furthermore, a gas chromatography–flame ionization detector–mass spectrometry system
143 (TH_PKU-300) was used to resolve the real time data of the ambient VOCs. The details of the
144 analysis techniques, resolution, detection limits, and the protocol of quality assurance/control
145 were provided by Lyu et al. (2016) and Wang et al. (2014).

146

147
 148 Figure 1. Geographic location of the sampling site. White blocks in left panel represent total
 149 distribution of wildfires in autumn 2014, and urban area in Wuhan is highlighted in gray in the
 150 right panel.

151
 152 **2.2 Theoretical calculation and model simulation**

153 Theoretical calculation and model simulation were applied in this study to examine the formation
 154 mechanisms of NO_3^- and SOC. The particle-bound NO_3^- was generally combined with NH_3 or
 155 presented as HNO_3 in the ammonia-deficient environment, following the processes described in
 156 R1 through R3 after HNO_3 was formed by the oxidation of NO_x (Pathak et al., 2011, Lin et al.,
 157 2010). The production of NO_3^- can be calculated with Equations 1-4.

158 $\text{NH}_3(\text{g}) + \text{HNO}_3(\text{g}) \leftrightarrow \text{NH}_4\text{NO}_3(\text{s}) \quad k_1 = \exp [118.87 - 24084/T - 6.025\ln(T)] \text{ (ppb}^2\text{)} \quad (\text{R1})$

159 $\text{NH}_3(\text{g}) + \text{HNO}_3(\text{g}) \leftrightarrow \text{NH}_4^+ + \text{NO}_3^- \quad k_2 = (P_1 - P_2(1 - a_w) + P_3(1 - a_w)^2) \times (1 - a_w)(1 - a_w)^{1.75} k_1 \text{ (ppb}^2\text{)} \quad (\text{R2})$

161 $\text{N}_2\text{O}_5 + \text{H}_2\text{O} \rightarrow 2\text{HNO}_3 \quad k_3 = \gamma/4(8kT/\pi m_{\text{N}_2\text{O}_5})0.5 A_p \text{ (s}^{-1}\text{)} \quad (\text{R3})$

162 $\ln(P_1) = -135.94 + 8763/T + 19.12 \ln(T) \quad (\text{Eq.1})$

163 $\ln(P_2) = -122.65 + 9969/T + 16.22 \ln(T) \quad (\text{Eq.2})$

164 $\ln(P_3) = -182.61 + 13875/T + 24.46 \ln(T) \quad (\text{Eq.3})$

165 $[\text{NO}_3^-] = 0.775 \left(\frac{[\text{NH}_3] + [\text{HNO}_3] - \sqrt{([\text{NH}_3] + [\text{HNO}_3])^2 - 4([\text{NH}_3][\text{HNO}_3] - k_1(k_2))}}{2} \right) \quad (\text{Eq.4})$

166 where R1 and R2 describe the homogeneous formation of NO_3^- in humidity conditions lower
 167 and higher than the deliquescence relative humidity of NH_4NO_3 (i.e., 62%; Tang and Munkelwitz,
 168 1993), respectively. R3 presents the heterogeneous reaction of N_2O_5 on the preexisting aerosol

169 surfaces. k_{I-3} represents the rate of reactions R1-3. T , a_w , and P are the temperature, the relative
170 humidity, and the temperature-related coefficient, respectively. In R3, γ is the reaction
171 probability of N_2O_5 on aerosol surfaces, assigned as 0.05 and 0.035 on the surface of sulfate
172 ammonia and element carbon, respectively (Aumont et al., 1999; Hu and Abbatt, 1997). k is the
173 Boltzmann constant (1.38×10^{-23}), $m_{N_2O_5}$ is the molecular mass of N_2O_5 (1.79×10^{-22} g), and A_p
174 is the aerosol specific surface area (cm^2/cm^3).

175 Furthermore, the PBM-MCM model was used to simulate the oxidation products in this study,
176 i.e., O_3 , N_2O_5 , the semi-volatile oxidation products of VOCs (SVOCs), and radicals such as OH,
177 HO_2 , and RO_2 . With full consideration of photochemical mechanisms and real meteorological
178 conditions, the model has been successfully applied in the study of photochemistry. Details about
179 the model construction and application were published by Lyu et al. (2015b), Ling et al. (2014),
180 and Lam et al. (2013).

181 **2.3 Source apportionment model**

182 The positive matrix factorization (PMF) model (EPA PMF v5.0) was used to resolve the sources
183 of $PM_{2.5}$. As a receptor model, PMF has been extensively used in the source apportionment of
184 airborne particles and VOCs (Brown et al., 2007; Lee et al., 1999). Detailed introductions of the
185 model can be found in Paatero (1997) and Paatero and Tapper (1994). Briefly, it decomposes the
186 input matrix (X) into matrices of factor contribution (G) and factor profile (F) in p sources, as
187 shown in Equation 5. The hourly concentrations of $PM_{2.5}$ components were included in the input
188 matrix. Values below the detection limit (DL; see Table S1 in the Supplement) were replaced
189 with $DL/2$. The uncertainties were $\sqrt{(10\% \times \text{concentration})^2 + DL^2}$ and $5/6 \times DL$ for the
190 samples with concentrations higher and lower than DL, respectively. The signal-to-noise (S/N)
191 ratios were all greater than 1, indicating “good” signal for all the species involved in source
192 apportionment, according to the PMF 5.0 User Guide. Samples with any missing values were
193 excluded. In total, 807 and 806 samples were applied for source apportionment in summer and
194 autumn, respectively.

195 The selection of the factor number and the best solution depended upon the following criteria. (1)
196 A lower Q value (Equation 6; a function to evaluate the model runs) was preferable. (2) The ratio
197 between Q_{robust} and Q_{true} was lower than 1.5. In this study, the ratios were 0.8 and 0.9 for the
198 summer and autumn data simulation, respectively. (3) Good agreement was shown between the
199 predicted and observed $PM_{2.5}$. The slope and correlation coefficient (R^2) for the linear regression

200 were 0.91 and 0.86 in summer and 0.95 and 0.98 in autumn, respectively, as shown in Figure S2
 201 in the Supplement. The lower R^2 value seen during the summer might be due to the lack of WSI
 202 data. (4) The residuals were normally distributed between -3 and 3 . Table S2 summarizes the
 203 percentage of samples with residuals between -3 and 3 for each species; the lowest percentages
 204 were 92.9% and 96.0% for Ni in summer and autumn, respectively. The scaled residuals for
 205 $PM_{2.5}$ are shown in Figure S3 in the Supplement. The percentage of residuals between -3 and 3
 206 was comparable between summer (97.5%) and autumn (98.1%). Data points not confirming to
 207 the residual range (-3 to $+3$) were removed from the analysis. Finally (5), no correlation was
 208 found between the factors, which was achieved by examining the G-space plots and controlled
 209 by the FPEAK model runs. Figures S4 and S5 in the Supplement present the G-space plots in
 210 summer and autumn, respectively. The low factor contributions and poor correlations indicated
 211 that rotational ambiguity was effectively controlled.

212 A bootstrap method was used to estimate the model errors, according to which 95% confidence
 213 intervals (CIs) were calculated. The 95% CI for $PM_{2.5}$ was $0.6 \mu\text{g}/\text{m}^3$ (0.7% of predicted $PM_{2.5}$)
 214 in summer and $2.6 \mu\text{g}/\text{m}^3$ (3.2% of predicted $PM_{2.5}$) in autumn.

$$215 \quad x_{ij} = \sum_{k=1}^p g_{ik} f_{kj} + e_{ij} \quad (\text{Eq.5})$$

$$216 \quad Q = \sum_{i=1}^n \sum_{j=1}^m \left[\frac{x_{ij} - \sum_{k=1}^p g_{ik} f_{kj}}{u_{ij}} \right]^2 \quad (\text{Eq.6})$$

217 where x_{ij} and u_{ij} are the concentration and uncertainty of j species (total of m) in i sample (total
 218 of n), g_{ik} represents the contribution of k_{th} source to i sample, f_{kj} indicates the fraction of j
 219 species in k_{th} source, and e_{ij} is the residual for j species in the i sample.

220

221 **3. Results and discussion**

222 **3.1 Concentrations of PM_{10} and $PM_{2.5}$**

223 Table 1 shows the mean concentrations of PM_{10} and $PM_{2.5}$ in Wuhan and other Chinese cities and
 224 regions. The mean, maximum and minimum values, and standard deviation or 95% CI were
 225 provided if available. In general, the concentrations of airborne particles in Wuhan (135.1 ± 4.4
 226 and $118.9 \pm 3.7 \mu\text{g}/\text{m}^3$ for PM_{10} ; 81.2 ± 2.6 and $85.3 \pm 2.6 \mu\text{g}/\text{m}^3$ for $PM_{2.5}$ in summer and
 227 autumn, respectively) were lower than those in northern China (i.e., Beijing and Xi'an),
 228 comparable to those in eastern China (i.e., Shanghai and Nanjing), and higher than those in
 229 southern China (i.e., Guangzhou and Hong Kong) and Taiwan. Bearing in mind that the sampling

230 site, period, method, and instrument all interfere with comparisons, the ambient particulate
 231 pollution in Wuhan was severe.

232 From summer to autumn, PM₁₀ levels declined considerably from 135.1 ± 4.4 to 118.9 ± 3.7
 233 µg/m³, whereas PM_{2.5} remained statistically stable (*p* > 0.05). The higher summer PM₁₀
 234 concentration was probably related to a higher load of fugitive dust. In Wuhan, the temperature
 235 (25.6 °C ± 0.2 °C) in summer was considerably higher than that (17.5 °C ± 0.3 °C) in autumn (*p* <
 236 0.05), which led to lower water content in the soil and a higher tendency of dust suspension. In
 237 addition, the average wind speed in summer (1.2 ± 0.04 vs. 0.8 ± 0.03 m/s in autumn) was also
 238 higher (*p* < 0.05), which could also have favored the generation of fugitive dust.

239
 240 Table 1. Comparisons of PM₁₀ and PM_{2.5} (in µg/m³) between Wuhan and other Chinese cities and
 241 regions.

	PM ₁₀	PM _{2.5}	Sampling period
Wuhan	135.1 ± 4.4 ^I	81.2 ± 2.6 ^I	May-Jun. 2014 (this study)

245
 246 Figure 2 presents the daily concentrations of PM₁₀ and PM_{2.5} during the sampling period in

247 Wuhan, with the National Standard Level II (daily averages of 150 and 75 $\mu\text{g}/\text{m}^3$ for PM_{10} and
 248 $\text{PM}_{2.5}$, respectively). It was found that the concentrations of PM_{10} and $\text{PM}_{2.5}$ frequently exceeded
 249 the standard levels, indicating the significance of ambient particulate pollution in Wuhan.
 250 Because smaller particles tend to pose more harm to human health and to the atmosphere due to
 251 their larger specific surface areas (Yang et al., 2012; Goldberg et al., 2001), and because the
 252 chemical compositions in PM_{10} were not analyzed, this study focused mainly on $\text{PM}_{2.5}$. During
 253 the sampling campaign, six $\text{PM}_{2.5}$ episodes, named episodes 1 through 6, with daily averages of
 254 $\text{PM}_{2.5}$ in excess of 75 $\mu\text{g}/\text{m}^3$, were captured (Figure 2). It should be noted that to ensure the data
 255 size of each episode, only the cases in which the daily $\text{PM}_{2.5}$ average was consecutively higher
 256 than 75 $\mu\text{g}/\text{m}^3$ for 3 days or longer were treated as $\text{PM}_{2.5}$ episodes.
 257 Table 2 summarizes the concentrations of PM_{10} and $\text{PM}_{2.5}$ and the percentage of $\text{PM}_{2.5}$ in PM_{10} ,
 258 referred to as $\text{PM}_{2.5}/\text{PM}_{10}$, during the summer and autumn episodes and non-episodes. PM_{10} and
 259 $\text{PM}_{2.5}$ concentrations increased significantly ($p < 0.05$) during the episodes in both summer and
 260 autumn. The $\text{PM}_{2.5}/\text{PM}_{10}$ value also increased remarkably on episode days compared to that on
 261 non-episode days, except for episode 2 ($45.9\% \pm 2.5\%$), which suggests that more secondary
 262 species and/or primary fine particles (e.g., primary OC and EC generated from combustion) were
 263 generated or released during the episodes. In contrast, the lower $\text{PM}_{2.5}/\text{PM}_{10}$ value during
 264 episode 2 might imply a strong source of coarse particles. Indeed, this inference was confirmed
 265 by the source apportionment analysis in section 3.3.3.

266

267

268 Figure 2. Daily concentrations of PM_{10} and $\text{PM}_{2.5}$ in May, June, October, and November 2014.

269 Episode 1, May 16 to 22; episode 2, May 25 to 30; episode 3, June 5 to 15; episode 4, October
 270 15 to 20; episode 5, October 24 to 28; Episode 6, November 14 to 23.

271
 272 Table 2. Mean PM₁₀, PM_{2.5}, and PM_{2.5}/PM₁₀ with 95% CI during PM_{2.5} episodes and non-
 273 episodes in Wuhan. Non-episode 1 and Non-episode 2 represent the non-episode periods in
 274 summer and autumn, respectively.

	PM ₁₀ (μg/m ³)	PM _{2.5} (μg/m ³)	PM _{2.5} /PM ₁₀ (%)
Episode 1	154.3 ± 10.1	123.0 ± 9.1	72.8 ± 2.6
Episode 2	230.1 ± 19.1	98.9 ± 5.7	45.9 ± 2.5
Episode 3	191.4 ± 9.8	126.7 ± 7.0	66.9 ± 1.8
Non-episode 1	98.5 ± 3.9	56.6 ± 1.7	58.9 ± 1.5
Episode 4	221.8 ± 8.9	148.6 ± 5.2	67.9 ± 2.0
Episode 5	154.2 ± 10.4	108.2 ± 6.8	69.3 ± 3.1
Episode 6	157.3 ± 9.0	120.0 ± 7.6	71.2 ± 2.1
Non-episode 2	88.7 ± 3.4	64.2 ± 2.2	65.3 ± 1.3

275
 276 **3.2 Chemical composition of PM_{2.5}**
 277 Figure 3 shows the daily variations of PM_{2.5} and its composition. As the instrument for the
 278 analysis of WSIs was initially deployed in September 2014, data are not available for May and
 279 June. The carbonaceous aerosol (18.5 ± 1.2 μg/m³) and elements (6.0 ± 0.3 μg/m³) accounted for
 280 19.1% ± 0.6% and 6.2% ± 0.2% of PM_{2.5} in summer, respectively. In autumn, WSIs were the
 281 most abundant component in PM_{2.5} (64.4 ± 2.5 μg/m³; 68.6% ± 1.9%), followed by carbonaceous
 282 aerosol (24.3 ± 1.0 μg/m³; 25.5% ± 0.8%) and elements (4.5 ± 0.2 μg/m³; 4.6% ± 0.1%). The
 283 secondary inorganic ions SO₄²⁻ (18.8 ± 0.6 μg/m³), NO₃⁻ (18.7 ± 0.8 μg/m³), and NH₄⁺ (12.0 ±
 284 0.4 μg/m³) dominated the WSIs, with the average contribution of 34.0% ± 0.6%, 30.1% ± 0.5%,
 285 and 20.4% ± 0.1%, respectively.

286

287
 288 Figure 3. Daily variations of PM_{2.5} and its components. Pie charts represent the composition of
 289 elements and water-soluble ions, respectively. Pink shaded areas represent episodes.

290
 291 The charge balance between the anions and cations was usually used to predict the existing forms
 292 of SIAs and the acidity of PM_{2.5}. Figure 4 shows the relative abundance of molar charges of SIAs,
 293 which were located fairly close to the one-to-one line on both episode and non-episode days.
 294 This finding suggests that NH₄NO₃ and (NH₄)₂SO₄ were coexisting forms of the SIAs in PM_{2.5} in
 295 Wuhan. When extending NH₄⁺ to total cations (NH₄⁺, Ca²⁺, Mg²⁺, Na⁺, and K⁺) and NO₃⁻ and
 296 SO₄²⁻ to total anions (NO₃⁻, SO₄²⁻, and Cl⁻), the molar charges of the cations and anions were
 297 balanced (slope, 0.98; R² = 0.98), as shown in Figure S6 in the Supplement, indicating that PM_{2.5}
 298 was neutralized during autumn in Wuhan.

299

300
 301 Figure 4. Relative abundance of molar charges of PM_{2.5} during autumn in Wuhan.

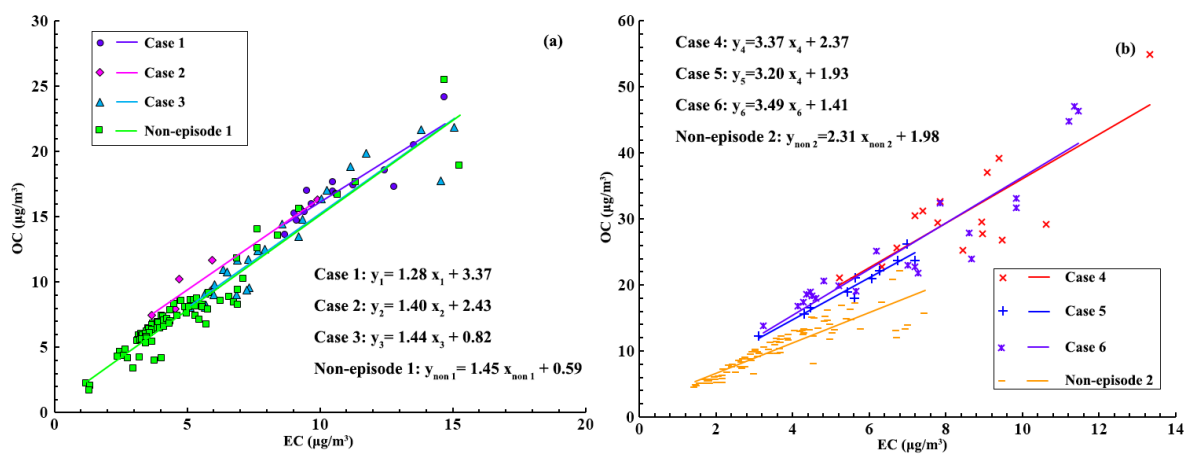

302
 303 For the carbonaceous aerosol, OC ($14.8 \pm 0.5 \mu\text{g}/\text{m}^3$) and EC ($3.6 \pm 0.1 \mu\text{g}/\text{m}^3$) accounted for
 304 $79.9\% \pm 0.3\%$ and $20.2\% \pm 0.3\%$ of the total carbon, respectively. In general, SOC was expected
 305 to exist when the OC/EC ratio was greater than 2 (Duan et al., 2005; Chow et al., 1996), and the
 306 proportion of SOC increased with the increase in OC/EC ratio. The average OC/EC ratio was 4.8
 307 ± 0.1 in Wuhan, which suggests that SOC (i.e., carbon fraction of SOA) was an important
 308 component in PM_{2.5}. Indeed, as the constituents of OC, SOC and POC can be distinguished with
 309 the EC-tracer method, following Equations 7 and 8 (Cabada et al., 2004):

310
$$\text{POC} = (\text{OC}/\text{EC})_{\text{prim}} \times \text{EC} + \text{OC}_{\text{non-comb}} \quad (\text{Eq.7})$$

311
$$\text{SOC} = \text{OC} - \text{POC} \quad (\text{Eq.8})$$

312 where $(\text{OC}/\text{EC})_{\text{prim}}$ was the ratio of primary OC to EC, obtained from the pairs of OC and EC
 313 with the OC/EC ratios among the 10% lowest; and $\text{OC}_{\text{non-comb}}$ was the primary OC that was not
 314 related to combustion activities. These values were determined by the slope and intercept of the
 315 linear regression between primary OC and EC, respectively (Figure 5). Because the abundance
 316 of SOC depended largely upon the oxidative capacity of the atmosphere, the oxidative radical
 317 (HO_2) was simulated with the PBM-MCM model and compared with the pattern of SOC. More
 318 details about the simulation are provided in section 3.4. Figure 6 shows the hourly concentrations
 319 of SOC and POC and the average diurnal patterns of SOC, POC, and HO_2 . In general, the POC
 320 levels ($8.6 \pm 0.2 \mu\text{g}/\text{m}^3$) were slightly higher than those of SOC ($6.4 \pm 0.3 \mu\text{g}/\text{m}^3$; $p < 0.05$). The
 321 difference was greatest in November, when the concentration was 9.5 ± 0.4 and $4.7 \pm 0.3 \mu\text{g}/\text{m}^3$
 322 for POC and SOC, respectively. Because the production of SOC was closely related to the

323 atmospheric oxidative capacity, the lowest fraction of SOC in November might be attributable to
 324 the weakest oxidative capacity; for example, the O₃ level was lowest in November (14.3 ± 1.0
 325 ppbv). Two peaks were found for the simulated diurnal pattern of HO₂, which might be caused
 326 by strong solar radiation at noon and in the early afternoon and by reactions among alkenes and
 327 O₃ and NO₃ at night (Emmerson et al., 2005; Kanaya et al., 1999). The diurnal patterns of POC
 328 and SOC revealed that POC levels were relatively stable throughout the day. The increase in the
 329 POC level in the early morning (06:00 to 08:00) and late afternoon and early evening (16:00 to
 330 20:00) was likely related to increases in vehicular emissions during rush hours, and the decrease
 331 from 08:00 to 15:00 might be caused by the extension of the boundary layer. In contrast, the
 332 SOC level showed two peaks at around 12:00 and 19:00, which was consistent with the diurnal
 333 variation of the simulated HO₂, suggesting that the formation of SOC was closely related to the
 334 oxidative radicals in the atmosphere. (A detailed relationship is discussed in section 3.4.3.)
 335

336
 337 Figure 5. Regression between OC and EC with the 10% lowest OC/EC ratios during (a) summer
 338 and (b) autumn in Wuhan.

339
 340 Figure 6. Hourly concentrations of SOC and POC. Insert graph presents average diurnal
 341 variations of SOC, POC, and HO₂.

342
 343 Among the elements, potassium (K; $2060.7 \pm 82.3 \text{ ng/m}^3$), iron (Fe; $996.5 \pm 34.3 \text{ ng/m}^3$), and
 344 calcium (Ca; $774.1 \pm 39.4 \text{ ng/m}^3$) were the most abundant species, accounting for $47.0\% \pm 2.2\%$,
 345 $21.4\% \pm 0.3\%$, and $15.6\% \pm 0.3\%$ of the total analyzed elements, respectively. Correlation
 346 analysis indicated that Fe had good correlation with Ca ($R^2 = 0.66$; Figure S7 in the Supplement),
 347 whereas weak correlations of K with Fe ($R^2 = 0.14$) and Ca ($R^2 = 0.09$) were found, suggesting
 348 that Fe and Ca shared common sources that were different from the sources of K. Because Fe
 349 and Ca are typical crustal elements, fugitive dust (e.g., dust from traffic, construction and
 350 demolition works, yards, and bare soil) was their most likely source. In contrast, apart from
 351 emissions from mineral sources, K is also emitted from biomass burning. As such, K was
 352 believed to be mainly emitted from biomass burning in this study, which is further supported by
 353 the moderate correlations of K with OC ($R^2 = 0.52$) and EC ($R^2 = 0.48$) because biomass burning
 354 also emits OC and EC (Saarikoski et al., 2007; Echalar et al., 1995).

355 3.3 Causes of PM_{2.5} episodes

356 3.3.1 Meteorological conditions

357 The processes of particle formation, dispersion, and deposition are closely related to
 358 meteorological conditions. To interpret the possible causes of the PM_{2.5} episodes, Figure 8 shows
 359 the patterns of wind direction and speed, temperature, relative humidity, and atmospheric
 360 pressure in Wuhan during the monitoring period. In general, southeast winds prevailed at the
 361 sampling site with a wind speed of approximately 1.0 m/s. The low wind speed indicates the

362 dominance of local air masses. However, due to the high stability and long lifetime of PM_{2.5}, the
 363 regional and superregional impact could not be eliminated. In comparison with those in summer,
 364 the wind speed (summer, 1.1 ± 0.04 m/s; autumn, 0.8 ± 0.03 m/s) and temperature (summer, 25.6
 365 ± 0.2 m/s; autumn, 17.5 ± 0.3 m/s) were significantly (*p* < 0.05) lower in autumn, whereas the
 366 atmospheric pressure (summer, 1006.9 ± 0.2 hPa; autumn, 1020.9 ± 0.2 hPa) was much higher.
 367 During the episodes, the wind speed was generally lower than during non-episodes, with the
 368 exception of episode 5. This might be one cause for the episodes, but it does not fully explain the
 369 great enhancements of PM_{2.5}, because the wind speeds were very low and the differences
 370 between the episodes and non-episodes were minor. The atmospheric pressure was not very high
 371 during episodes 1 through 5, suggesting that the synoptic system was not responsible for the
 372 occurrence of these PM_{2.5} episodes. However, the atmospheric pressure was remarkably higher
 373 (*p* < 0.05) in episode 6 (1024 ± 1 hPa) than in non-episode 2 (1021 ± 0.3 hPa), which might have
 374 suppressed the diffusion of PM_{2.5} and the gaseous precursors. In addition, the temperature was
 375 lower (episode 6, 14.0 °C ± 0.4 °C; non-episode 2, 17.2 °C ± 0.3 °C; *p* < 0.05), which favors the
 376 gas-to-particle partitioning of semivolatile and non-thermal stabilized species. As a consequence,
 377 these effects might have elevated the PM_{2.5} concentrations in episode 6, which is discussed
 378 further in section 3.4.2.

379

380
 381 Figure 8. Meteorological patterns in Wuhan during the monitoring period. Pink shaded areas
 382 represent PM_{2.5} episodes.

383

384 3.3.2 Chemical signatures

385 Table 3 summarizes the mass concentrations and percentages of the main components in PM_{2.5}.
386 The mass concentrations of PM_{2.5} components significantly increased from non-episode days to
387 episode days ($p < 0.05$). In contrast, the percentages of the chemical components in PM_{2.5} varied
388 by species. In summer, the fractions of EC and K in PM_{2.5} experienced significant increases from
389 non-episode 1 (EC, 4.8% \pm 0.2%; K, 2.0% \pm 0.1%) to episode 1 (EC, 5.7% \pm 0.5%; K, 4.4% \pm
390 0.3%) and episode 3 (EC, 5.3% \pm 0.2%; K, 3.0% \pm 0.2%). Because EC is the tracer of
391 incomplete combustion (Chow et al., 1996) and K is the indicator of biomass burning (Saarikoski
392 et al., 2007; Echalar et al., 1995), the higher percentages of EC and K in episodes 1 and 3 imply
393 the outstanding contribution of biomass burning. In contrast, the fraction of OC in PM_{2.5}
394 remained stable on both episode and non-episode days ($p > 0.05$), possibly because the high
395 temperatures in summer hindered the gas-to-particle partitioning of semivolatile organics
396 (Takekawa et al., 2003). Furthermore, the percentages of Ca (2.9% \pm 0.4%) and Fe (2.7% \pm 0.3%)
397 significantly increased during episode 2 ($p < 0.05$) compared to those in non-episode 1 (Ca, 1.1%
398 \pm 0.1%; Fe, 1.5% \pm 0.1%), which shows that fugitive dust made a considerable contribution to
399 PM_{2.5} in episode 2. In addition, biomass burning might also have contributed to PM_{2.5}, in view of
400 the increase in the percentage of K (non-episode 1, 2.0% \pm 0.1%; episode 2, 3.2% \pm 0.2%).
401 In autumn, the percentage of K significantly ($p < 0.05$) increased during episode 4 (3.1% \pm 0.1%
402 vs. 2.1% \pm 0.1% in non-episode 2), as did that of OC (27.3% \pm 0.7% vs. 20.9% \pm 0.8% in non-
403 episode 2), suggesting the dominant role of biomass burning in episode 4. Furthermore, the
404 fractions of OC in episode 5 (23.8% \pm 1.5%) and NO₃⁻ in episode 6 (26.1% \pm 1.0%) were
405 obviously higher than those in non-episode 2 (OC, 20.9% \pm 0.8%; NO₃⁻, 19.8% \pm 0.9%). Due to
406 the complexity of the sources of OC and NO₃⁻, the causes of episodes 5 and 6 are further
407 explored in the following sections.
408 In summary, episodes 1, 3, and 4 were greatly affected by biomass burning. This finding was
409 further confirmed by the significant increases in the gaseous tracers of biomass burning such as
410 ethyne (C₂H₂) and methyl chloride (CH₃Cl) (Guo et al., 2011b; Simoneit et al., 2002) during
411 these episodes ($p < 0.05$; see Figure S8 in the Supplement).

412 Table 3. Concentrations ($\mu\text{g}/\text{m}^3$) and percentages (in parentheses) of the main components of $\text{PM}_{2.5}$ during non-episodes and episodes.
 413 Bold font demonstrates significant increase in percentage of $\text{PM}_{2.5}$ components during episodes compared to non-episodes.

	Summer				Autumn			
	Episode 1	Episode 2	Episode 3	Non-episode 1	Episode 4	Episode 5	Episode 6	Non-episode 2
OC	18.5 \pm 1.3 (15.1% \pm 0.8%)	16.3 \pm 3.3 (14.0% \pm 1.9%)	19.8 \pm 2.5 (14.5% \pm 1.0%)	7.9 \pm 0.3 (15.4% \pm 0.7%)	35.1\pm1.7 (27.3%\pm0.7%)	24.9\pm1.9 (23.8%\pm1.5%)	22.7 \pm 1.5 (21.4% \pm 0.8%)	14.6 \pm 1.0 (20.9% \pm 0.8%)

414

415 3.3.3 Source apportionment

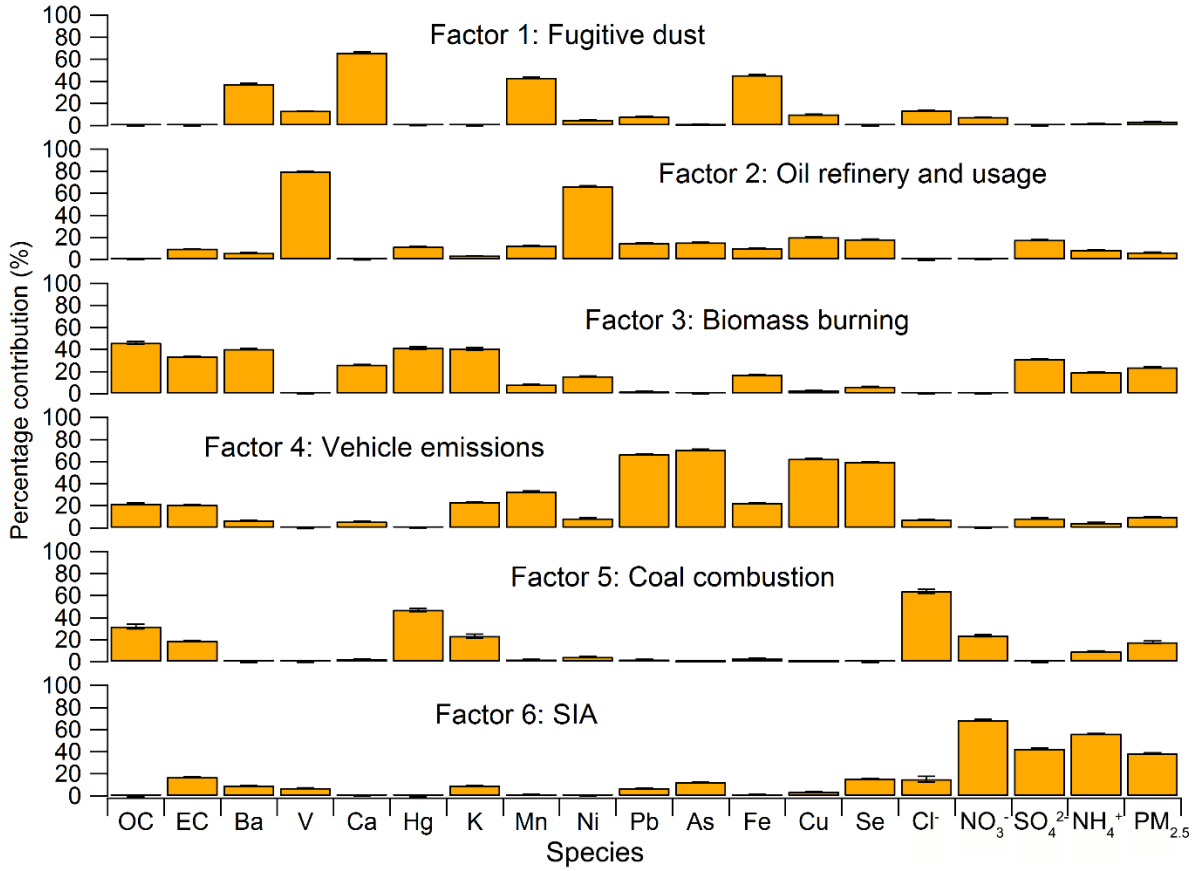

416 To clarify the sources of PM_{2.5} and quantify their contributions, the hourly data on PM_{2.5}
417 components were applied to PMF for source apportionment. Five and six sources were resolved
418 for summer and autumn, respectively, as shown in Figure 10 and Figure 11. The source of SIA
419 was missing in summer, due to the lack of WSI data. For other sources, the profile of each
420 corresponding source was similar in summer and autumn. Factor 1 had high loadings of crustal
421 elements (i.e., Ba, Ca, Mn, and Fe), indicating the source of fugitive dust. Factor 2 was likely
422 associated with oil refinery and usage, in view of the high percentages of V and Ni, which often
423 originate from the combustion of heavy oil (Barwise et al., 1990; Nriagu and Pacyna, 1988).
424 Factor 3 was distinguished by the high loadings of OC, EC, and K, indicating the biomass
425 burning source (Zhang et al., 2013; Friedli et al., 2003). Factor 4 seemed to represent vehicle
426 emissions, due to the dominance of Pb, As, Cu, and Se. Cu has been identified as one of the most
427 abundant metals in both brake linings and the brake wear particles with the concentration of up
428 to 210 mg/g in brake wear dust (Grigoratos and Martini, 2015). Although lead-containing
429 gasoline has been forbidden in China since 2000, high levels of Pb are often reported in traffic
430 sources (Yang et al., 2013; Song et al., 2012), which might be due to the use of Pb-containing
431 materials in car components, such as lead wheel weights, solder in electronics, and lead-acid
432 batteries (Song et al., 2012). Both biomass burning and vehicular emissions are important
433 sources of EC. The much lower EC apportioned to vehicular emissions in this study is explained
434 in Section 1 of the Supplement. OC and Hg dominated in factor 5, and Cl⁻ also showed high
435 loading in this factor in the autumn profile. It is well documented that Hg and Cl⁻ are largely
436 emitted from coal combustion (Wang et al., 2010; Ye et al., 2003). Hence, this factor was
437 assigned as coal combustion. Finally, a source of SIA with high loadings of NO₃⁻, SO₄²⁻, and
438 NH₄⁺ was resolved in autumn.

439 Figures S9 and S10 in the Supplement show the day-to-day variations of the source contributions
440 in summer and autumn, respectively. Overall, biomass burning was the largest contributor (45.0%
441 ±0.03%) to PM_{2.5} in summer. However, the contribution of biomass burning in autumn (23.7% ±
442 0.5%) was lower than that of SIA (38.6% ±0.7%). Bearing in mind the uncertainties caused by
443 the lack of WSIs, the greater contribution of biomass burning in summer might be associated
444 with the lower WSIs. For example, NO₃⁻ was expected to be much lower in summer due to its
445 thermal decomposition at high temperatures. Table 4 summarizes the source contributions during

446 episodes and non-episodes. Noticeably, the contributions of biomass burning were significantly
447 higher ($p < 0.05$) in episode 1 ($59.2 \pm 6.3 \mu\text{g}/\text{m}^3$; $46.6\% \pm 3.0\%$), episode 3 ($64.9 \pm 3.3 \mu\text{g}/\text{m}^3$;
448 $50.8\% \pm 1.2\%$), and episode 4 ($48.7 \pm 2.9 \mu\text{g}/\text{m}^3$; $44.8\% \pm 2.6\%$) than those in the corresponding
449 non-episodes, confirming that biomass burning was the main cause of these $\text{PM}_{2.5}$ episodes. In
450 addition, vehicle emissions made a greater contribution to episode 4 ($14.9 \pm 1.2 \mu\text{g}/\text{m}^3$; $13.7\% \pm$
451 1.1%) than to non-episode 2. In contrast, the contribution of fugitive dust ($6.5 \pm 1.3 \mu\text{g}/\text{m}^3$; 5.6%
452 $\pm 1.0\%$) in episode 2 was remarkably ($p < 0.05$) higher than in non-episode 1 ($1.1 \pm 0.1 \mu\text{g}/\text{m}^3$;
453 $1.8\% \pm 0.2\%$). This finding was consistent with the inference that episode 2 was attributable to
454 fugitive dust according to the low $\text{PM}_{2.5}/\text{PM}_{10}$ ratio ($45.9\% \pm 2.5\%$) and high levels of crustal
455 elements (Ca, $2.9\% \pm 0.4\%$; Fe, $2.7\% \pm 0.3\%$) in this episode. In addition, vehicle emissions and
456 SIA both experienced significant increases in episodes 5 and 6 ($p < 0.05$). In fact, the increase of
457 OC in episode 5 (see Table 3) was mainly caused by vehicle emissions and coal combustion
458 (Table S3 in the Supplement). For episode 6, in addition to the increase in OC, SIA was also an
459 important contributor, particularly for NO_3^- , which increased from $9.9 \pm 1.2 \mu\text{g}/\text{m}^3$ in non-
460 episode 2 to $21.4 \pm 3.3 \mu\text{g}/\text{m}^3$ in episode 6 (Table S3). In addition, we noted that the contribution
461 of coal combustion was much lower in non-episode 2 than that in non-episode1 ($p < 0.05$). The
462 explanation is provided in Section 2 of the Supplement.

463
 464 Figure 10. Profiles of PM_{2.5} sources in summer. Error bars represent 95% CI estimated by
 465 bootstrap method in PMF.

466

467 Figure 11. Profiles of PM_{2.5} sources in autumn. Error bars represent 95% CI estimated by

468 bootstrap method in PMF.

471

472 **3.3.4 Open fires and air mass trajectories**

473 To further confirm the biomass burning activities during the PM_{2.5} episodes, the wildfire
474 distribution (downloaded from NASA Firms Web Fire Mapper, and accessible at
475 <https://firms.modaps.eosdis.nasa.gov/firemap/>) and 72-h backward air mass trajectories
476 (simulated by Hysplit v4.9 model) are plotted in Figure 12. Because the concentrations,
477 compositions and source contributions of PM_{2.5} were averaged over the entire period of each
478 episode, the wildfire distribution and backward trajectories were also averaged for the entire
479 period of each episode. Consistent with the great contributions to PM_{2.5} of biomass burning, the
480 air masses arriving in Wuhan had passed over the areas where intensive open fires were detected
481 in episodes 1, 3, and 4. In episode 2, wildfires were widespread in northeast China. However, the
482 air mass trajectories were mainly from the south and northwest and evaded the burning areas,
483 which might explain why biomass burning was not a predominant factor in episode 2. The sparse
484 wildfires in episodes 5 and 6 coincided with the source apportionment result that biomass
485 burning did not significantly elevate the concentration of PM_{2.5}.

486

487
488 Figure 12. Wildfire distribution and 72-h backward air mass trajectories. Red squares
489 demonstrate potential areas where biomass burning aggravated particulate pollution in Wuhan.

490

491 3.4 Formation mechanisms

492 3.4.1 Model validation

493 In this study, the PBM-MCM model was used to help investigate the formation mechanisms of
494 NO_3^- and SOC. Before application, the model was validated via O_3 simulation. Figure S11
495 compares the daily averages and diurnal variations of O_3 between the simulation and the
496 observations. It was found that the model simulated O_3 variation well in both daily and diurnal
497 patterns. However, it generally overestimated the O_3 levels in November. The meteorological
498 parameters indicated that the frequency of foggy days was extremely high (36.7%) in November,
499 possibly resulting in a weakening of solar radiation and consequently of photochemical reactivity.
500 To quantitatively evaluate the performance of the model, the index of agreement (IOA) was
501 calculated using Equation 9.

$$502 \quad \text{IOA} = 1 - \frac{\sum_{i=1}^n (O_i - S_i)^2}{\sum_{i=1}^n (|O_i - \bar{O}| + |S_i - \bar{O}|)^2} \quad (\text{Eq.9})$$

503 where \bar{O} is the average of n samples and O_i and S_i represent the observed and simulated values,
504 respectively. Within the interval of [0, 1], higher IOA values indicated better agreement between
505 the simulation and observation.

506 By calculation, the IOA reached 0.86, indicating excellent performance of the model in the O_3
507 simulation. Because O_3 production is closely associated with oxidative radicals, intermediates,
508 and products, the robust O_3 simulation gave us full confidence to accept the simulated N_2O_5 ,
509 HO_2 , and SVOCs.

510

511 3.4.2 NO_3^- formation

512 The composition analysis indicated that the proportion of NO_3^- increased remarkably during
513 episode 6. To interpret this phenomenon, the formation mechanisms of NO_3^- were investigated.
514 Figure 14 shows the hourly variations of the calculated and observed NO_3^- and the contribution
515 of R3 (i.e., $\text{N}_2\text{O}_5 + \text{H}_2\text{O} \rightarrow 2\text{HNO}_3$), among which $\text{NO}_3^-_{\text{cal 1}}$, $\text{NO}_3^-_{\text{cal 2}}$, and $\text{NO}_3^-_{\text{obs}}$ referred to
516 homogeneous formation (R1 and R2), total formation (R1, R2, and R3), and field measurement
517 of NO_3^- , respectively. Although the particle-bound NO_3^- was influenced by many factors (i.e.,
518 formation, deposition, and dispersion), the calculations generally well reproduced the measured
519 NO_3^- in episode 6, with a high correlation coefficient ($R^2 = 0.63$) and an IOA of 0.78. However,
520 on November 23, 2014, the observed NO_3^- decreased rapidly from 09:00, which was not
521 captured by the calculations. This discrepancy was likely caused by the weather conditions on

522 that day, because (1) the average wind speed increased from 1.7 m/s before 09:00 to 2.7 m/s after
523 09:00 and even reached 4.0 m/s at 14:00; and (2) moderate rain began at 12:00 and continued
524 until 23:00, with total precipitation of 24 mm. Indeed, this was the beginning of a 7-day rainy
525 period, which ended episode 6 with a sharp decrease of the PM_{2.5} concentration (approximately
526 175 µg/m³; see Figure 2).

527 Because the values of NO₃⁻_{cal 1} were very close to those of NO₃⁻_{cal 2}, the variation of NO₃⁻ in
528 episode 6 could be well explained by the homogeneous formation (R1 and R2), whereas the
529 heterogeneous reaction of N₂O₅ on aerosol surfaces (R3) made only a minor contribution to the
530 total NO₃⁻ (i.e., nearly nil from 0:00 to 17:00 and 3.7% ± 0.6% from 18:00 to 23:00). Because
531 the homogeneous formation of NO₃⁻ was closely related to the concentrations of HNO₃ (g) and
532 NH₃ (g) and the temperature (see R1 and R2), Table 4 compares the temperature, HNO₃ (g), NH₃
533 (g), NO, NO₂, O₃, and the simulated OH and HO₂ (a measure of oxidative capacity [Cheng et al.,
534 2010]) between episode 6 and non-episode 2. It was found that the levels of HNO₃ (g) (0.65 ±
535 0.01 ppbv) and NH₃ (g) (13.48 ± 0.72 ppbv) in episode 6 were significantly higher than those
536 during the non-episode 2 (0.47 ± 0.03 and 9.54 ± 0.37 ppbv for HNO₃ and NH₃, respectively),
537 which might substantially favor the formation of NH₄NO₃. Because HNO₃ (g) is generally
538 formed by oxidation of NO_x, the production of HNO₃ (g) should be closely related to the
539 oxidative capacity of the air and the level of NO_x. In episode 6, the levels of O₃ (17.09 ± 2.04
540 ppbv), OH ([3.8 ± 1.3] × 10⁵ molecules/cm³), and HO₂ ([1.1 ± 0.3] × 10⁷ molecules/cm³) were
541 noticeably lower than those in non-episode 2 (O₃, 24.57 ± 1.64 ppbv; OH, [7.2 ± 0.9] × 10⁵
542 molecules/cm³; HO₂, [2.0 ± 0.2] × 10⁷ molecules/cm³), indicating a weaker oxidative capacity.
543 However, the levels of NO (43.55 ± 11.65 ppbv) and NO₂ (44.93 ± 2.29 ppbv) were much higher
544 than those in non-episode 2 (14.70 ± 2.40 and 29.46 ± 0.95 ppbv for NO and NO₂, respectively),
545 possibly leading to the enhancement of HNO₃ (g) in episode 6. Furthermore, the particle-bound
546 NO₃⁻ was of low thermal stability (Querol et al., 2004), and the temperature lowered ~2.3 C ° in
547 episode 6, which suppressed the decomposition and volatilization of NH₄NO₃. Therefore, the
548 high levels of NO_x and NH₃ and the low temperature were both responsible for the increase in
549 NO₃⁻ in episode 6.

550
 551 Figure 14. Comparison of NO₃⁻ between theoretical calculations and observation in episode 6.
 552
 553 Table 4. Comparison of temperature, HNO₃ (g), NH₃ (g), NO, NO₂, O₃, and simulated OH and
 554 HO₂ between episode 6 and non-episode 2.

	Episode 6	Non-episode 2
Temperature (°C)	14.9 ±0.5	17.2 ±0.3
HNO ₃ (ppbv)	0.65 ±0.01	0.47 ±0.03
NH ₃ (ppbv)	13.48 ±0.72	9.54 ±0.37
NO (ppbv)	43.55 ±11.65	14.70 ±2.40
NO ₂ (ppbv)	44.93 ±2.29	29.46 ±0.95
O ₃ (ppbv)	17.09 ±2.04	24.57 ±1.64
OH (molecules/cm ³)	(3.8 ±1.3) ×10 ⁵	(7.2 ±0.9) ×10 ⁵
HO ₂ (molecules/cm ³)	(1.1 ±0.3) ×10 ⁷	(2.0 ±0.2) ×10 ⁷

555
 556 **3.4.3 SOC formation**
 557 In addition to the high levels of NO₃⁻ in episode 6, the proportions of OC also increased during
 558 the autumn episodes. Because SOC is an important fraction in OC that often grows as an air
 559 mass ages, it could help to explain the increase of OC in the autumn episodes by exploring the
 560 possible formation mechanisms of SOC. It is well known that SOC formation is closely related

561 to SVOCs, which are formed from the reactions with oxidative radicals (i.e., RO_2 , NO_3 , and HO_2 ;
562 Kanakidou et al., 2005; Forstner et al., 1997). Hence, the relationship between SOC and SVOCs
563 was investigated. The SVOCs were simulated with the PBM-MCM model and SOC was
564 calculated with the EC-tracer method mentioned in section 3.2.1. The speciation of SVOCs and
565 their precursors can be found in the Table S4 in the Supplementary Material. Briefly, the
566 precursors of SVOCs include isoprene, aromatics, and C_7 - C_{12} n-alkanes.

567 Figure 15 presents the daily and diurnal variations in SOC and SVOCs. It was found that SOCs
568 correlated well with SVOCs in both daily ($R^2 = 0.52$) and diurnal ($R^2 = 0.63$) patterns in autumn,
569 indicating that the simulated SVOCs were responsible for the production of SOC. The oxidation
570 products of aromatics and isoprene were the main constituents of the SVOCs, with average
571 contributions of $42.5\% \pm 2.8\%$ and $39.4\% \pm 2.0\%$, respectively. Among the aromatics, xylenes
572 made the greatest contribution ($15.0\% \pm 0.7\%$) to the SVOCs, followed by trimethylbenzenes
573 ($11.5\% \pm 0.7\%$), ethylbenzene ($8.8\% \pm 0.5\%$), toluene ($5.1\% \pm 0.7\%$), and benzene ($2.2\% \pm$
574 0.2%). Compared to those in non-episode 2 (i.e., $40.7\% \pm 3.4\%$ and $41.1\% \pm 2.4\%$ contributed
575 by aromatics and isoprene, respectively), the contribution of aromatics to SVOCs increased to
576 $46.3\% \pm 4.1\%$ during the episodes, whereas the proportion of isoprene oxidation products
577 decreased to $36.1\% \pm 3.7\%$, suggesting that the increase in aromatics was the main cause of the
578 autumn episodes. To quantify the contribution of biomass burning to SOC, the observed VOCs
579 were apportioned to different sources, including biomass burning with CH_3CN as the tracer. The
580 source profiles are provided in Figure S12 in the Supplementary Material. According to the
581 SVOCs simulated on the basis of VOCs emitted from biomass burning, the SVOCs were
582 elevated by $15.4\% \pm 1.3\%$ due to biomass burning during the episodes.

583 In contrast, the correlations were much worse in summer ($R^2 = 0.01$ and 0.31 for daily and
584 diurnal variations, respectively). The high frequency (50.8%) of rainy days in summer was a
585 factor for the poor correlation; for example, the level of SOC was low during the late period of
586 June when the precipitation lasted for about 10 days, and the model overestimated the SVOCs
587 without considering the influence of precipitation. The correlations between SOC and SVOCs
588 ($R^2 = 0.14$ and 0.19 for the daily and diurnal variations, respectively) were still poor even after
589 the rainy days were excluded. Hence, the poor correlation should also be related to other factors,
590 such as incomplete consideration of the contribution of biogenic VOCs. Although isoprene was
591 included as a precursor of the SVOCs, other biogenic species (i.e., α -pinene, β -pinene, and

592 monoterpenes) that were proven to be important precursors of SOC (Kanakidou et al., 2005)
 593 were not monitored in this study. Moreover, the level of biogenic VOCs was much higher in
 594 summer than in autumn. Taking isoprene as an example, the mixing ratio of isoprene was $66.7 \pm$
 595 4.9 pptv in summer and only 37.2 ± 2.6 pptv in autumn. The higher missing level of biogenic
 596 VOCs in summer led to a higher deficit of SVOCs, perhaps causing the poorer correlation
 597 between SOC and SVOCs. Nevertheless, this notion needs requires validation with more
 598 comprehensive data on biogenic VOCs.

599

600

 602 variation and (b) diurnal pattern.

603

604 4. Conclusions

605 In summer and autumn 2014, the concentrations of $PM_{2.5}$ and its components were continuously
 606 monitored in Wuhan; six $PM_{2.5}$ episodes were captured. The analysis of $PM_{2.5}$ concentrations and
 607 compositions found that Wuhan suffered from relatively high levels of $PM_{2.5}$, even in the warm
 608 seasons. Secondary inorganic ions were the most predominant species in $PM_{2.5}$ in the form of
 609 NH_4NO_3 and $(NH_4)_2SO_4$. Comparable levels of SO_4^{2-} and NO_3^- indicate that stationary and
 610 mobile sources had equivalent importance in Wuhan. With the EC-tracer method, it was found
 611 that the POC level was slightly higher than that of SOC, and both increased significantly during
 612 the episodes. K was the most abundant element in $PM_{2.5}$, implying biomass burning in and

613 around Wuhan during the sampling campaign. Indeed, the source apportionment revealed that
614 biomass burning was the main cause of increases in PM_{2.5} in episodes 1, 3, and 4. Fugitive dust
615 was the leading factor in episode 2. However, episodes 5 and 6 were mainly attributable to
616 vehicle emissions and SIAs. Study of the formation mechanism of NO₃⁻ and SOC found that
617 NO₃⁻ was mainly generated from the homogeneous reactions in episode 6, and the high levels of
618 NO_x and NH₃ and the low temperature caused the increase in NO₃⁻. Furthermore, the daily and
619 diurnal variations of SOC correlated well with those of SVOCs in autumn. Aromatics and
620 isoprene were the main precursors of SOC, and the contribution of aromatics increased during
621 the episodes. However, the correlation between SOC and SVOCs was much worse in summer,
622 possibly as a result of the incompleteness of the biogenic VOC input in the simulation of SVOCs.
623 This study advances our understanding of the chemical characteristics of PM_{2.5} in warm seasons
624 in Wuhan and for the first time quantifies the contribution of biomass burning to PM_{2.5}. The
625 investigation of SOC formation will also inspire the application of the explicit chemical
626 mechanisms on the study of SOA.
