Abstract. The ability of a Bayesian atmospheric inversion to quantify the Paris region's fossil fuel CO₂ emissions on a monthly basis, based on a network of three surface stations operated during one year as part of the CO₂-MEGAPARIS experiment (August 2010–July 2011), is analysed. Differences in hourly CO₂ atmospheric mole fraction between the near-ground monitoring sites (CO₂ gradients), located at the north-eastern and south-western edges of the urban area, are used to estimate the 6-h mean fossil fuel CO₂ emission. The inversion relies on the CHIMERE transport model run at 2 km × 2 km horizontal resolution, on the spatial distribution of fossil fuel CO₂ emissions in 2008 from a local inventory established at 1 km × 1 km horizontal resolution by the AIRPARIF air quality agency, and on the spatial distribution of the biogenic CO₂ fluxes from the C-TESSSEL land surface model. It corrects a prior estimate of the 6-h mean budgets of the fossil fuel CO₂ emissions given by the AIRPARIF 2008 inventory. We found that a stringent selection of CO₂ gradients is necessary for reliable inversion results, due to large modelling uncertainties. In particular, the most robust data selection analysed in this study uses only mid-afternoon gradients if wind speeds are larger than 3 ms⁻¹ and if the modelled wind at the upwind site is within ±15° of the transect between downwind and upwind site. This stringent data selection removes 92 % of the hourly observations. Even though this leaves few remaining data to constrain the emissions, the inversion system diagnoses that their assimilation significantly reduces the uncertainty in monthly emissions, by 9 % in November 2010 to 50 % in October 2010. The inverted monthly mean emissions correlate well with independent monthly mean air temperature. Furthermore, the inverted annual mean emission is consistent with the independent revision of the AIRPARIF inventory for the year 2010, which better corresponds to the measurement period than the 2008 inventory. Several tests of the inversion's sensitivity to prior emission estimates, to the assumed spatial distribution of the emissions, and to the atmospheric transport modelling demonstrate the robustness of the measurement constraint on inverted fossil fuel CO₂ emissions. The results, however, show significant sensitivity to the description of the emissions' spatial distribution in the inversion system, demonstrating the need to rely on high-resolution local inventories such as that from AIRPARIF. Although the inversion constrains emissions through the assimilation of CO₂ gradients, the results

are hampered by the improperly-modelled influence of remote CO₂ fluxes when air masses originate from urbanised and industrialised areas north-east of Paris. The drastic data selection used in this study limits the ability to continuously monitor Paris fossil fuel CO₂ emissions: the inversion results for specific months like September 2010 or November 2010 are poorly constrained by too few CO₂ measurements. The high sensitivity of the inverted emissions to the prior emissions' day-to-day variations highlights the limitations induced by assimilating data during a limited number of suitable days. Therefore, even though the inversion improves the seasonal variation and the annual budget of the city's emissions, it does not necessarily yield robust estimates for individual months. These limitations, could be overcome through a refinement of the data processing for a wider data selection, and through the expansion of the observation network.

1 Introduction

There is a high political and scientific interest in developing methods for improving and verifying estimates of fossil fuel and cement CO₂ emissions. Consequently, there is an increasing deployment of urban CO₂ monitoring networks with the objective of quantifying city emissions through the atmospheric inversion approach (Duren and Miller, 2012; Lavaux et al., 2013; Kort et al., 2013; McKain et al., 2012; Strong et al., 2011; Turnbull et al., 2015). Bréon et al. (2015), upon which this study builds, recently reported first estimates of fossil fuel CO₂ emissions of the Paris urban area during a two-months period. They used three ground-based CO₂ measurement sites at the north-eastern and south-western edge of the area and an inversion system based on a 2 km × 2 km horizontal resolution transport model. The monitoring stations in Gonesse (GON), approximately 15 km north of Paris' city centre, and in Montgé-en-Goële (MON), 35 km north-east (NE) of Paris' city centre, were deployed by the CO₂-MEGAPARIS project and operated from August 2010 to July 2011. The monitoring station in Gif-sur-Yvette (GIF), 20 km south-west (SW) of Paris' city centre, is part of the Integrated Carbon Observation System-France long-term network. The principle of the atmospheric inversion proposed by Bréon et al. (2015) consists in constraining CO₂ emission budgets of the urban area by assimilating atmospheric CO₂ mole fraction gradients between pairs of sites located upwind and downwind of the city.

The use of cross-city gradients, rather than individual mole fractions, aims at eliminating the variability of CO₂ caused by the transport of remote fluxes outside the urban area. This signal cannot be sufficiently well controlled by the monitoring network and it can be as high as the signal caused by the emissions within the urban area (Bréon et al., 2015; Kort et al., 2013). The selected cross-city gradients correspond to an increase in the CO₂ mixing ratios of air parcels that pass through the city. This increase is assumed to represent the emissions from the entire city. Therefore, the inversion system of Bréon et al. (2015) only controls the temporal variations of the fossil fuel CO₂ emissions, but not their spatial distribution. It uses CO₂ gradients between downwind and upwind stations during the afternoon to correct prior estimates of 6-h fossil fuel CO₂ emissions budgets of the Paris metropolitan area (Île-de-France administrative region). These prior estimates are derived from the AIRPARIF inventory for the year 2008 (AIRPARIF, 2012). AIRPARIF is a non-profit agency that is accredited by the French Ministry of Environment to monitor the air quality in Île-de-France. The system of Bréon et al. (2015) also inverts biogenic fluxes in the region, since the urban area, while being dense, is surrounded by green areas which can cause variations in the selected

CO₂ gradients. It thus corrects prior estimates of the biogenic fluxes from C-TESSSEL, the land-surface component of the ECMWF (European Centre for Medium-Range Weather Forecasts) numerical weather forecasting system (Boussetta et al., 2013). In order to model the CO₂ gradients, the inversion uses an estimate of the fossil fuel CO₂ emission and biogenic flux distribution at 2 km×2 km and hourly resolution, coupled to a 2 km×2 km resolution configuration of the chemistry transport model CHIMERE (Menut et al., 2013).

Bréon et al. (2015) developed and tested this inversion set-up for two months in autumn 2010. The values of the AIRPARIF 2008 inventory were used to derive the prior estimates for the corresponding dates in 2010. Bréon et al. (2015) reported a significant improvement of the fit between modelled and measured CO₂ gradients by the inversion and reasonable patterns of corrections applied to prior emission values. The small number of monitoring sites and the stringent criteria for selecting gradients leads to a high number of periods, ranging from one to several days, during which the inversion does not assimilate any atmospheric CO₂ data. As a consequence, averages of the inverted emissions over one month were found to be more reliable than 1-day to 1-week mean results.

The aim of this study is to derive a full year of monthly mean emission estimates for the Paris area, based on the inversion system described by Bréon et al. (2015) and on the availability of measurements at MON, GON and GIF during the period mid-2010 to mid-2011. The 1-yr long inversion allows a better evaluation of the method by analysing the seasonal variation and the annual budget of the inverted emissions. In particular, the annual budget can be compared to the AIRPARIF emission assessment for 2010 (AIRPARIF, 2013). This assessment is based on an inventory model that has been improved since the release of the 2008 inventory. The 2010 inventory applies to a time period which better corresponds to the inversion period than the 2008 inventory used for the inversion. Therefore it provides some independent information to check the corrections applied by the inversion to the prior estimate of the annual budget derived from the 2008 inventory.

Preliminary tests of the inversion during the 1-yr period, however, revealed that the selection of gradients, as proposed by Bréon et al. (2015), do not conform fully with the underlying assumptions of having gradients dominantly influenced by urban emissions. Notably, negative measured CO₂ gradients between downwind and upwind sites were frequently found when using the gradient selection criteria of Bréon et al. (2015). This led us to revise the selection of CO₂ data to form gradients. Section 2 presents a summary description of the inversion configuration and the revision of gradient selection. Section 3 analyses the inversion results for different configurations. In particular, it assesses the impact of the stricter gradient selection, and the sensitivity of the results to the prior emission estimates, to the emissions' spatial distribution, and to the atmospheric transport modelling, so as to evaluate how robustly the emissions are constrained by atmospheric CO₂ data. These results are discussed in Sect. 4.

2 Inversion configuration

The inversion method described by Bréon et al. (2015) is based on the Bayesian approach. The control vector \mathbf{x} gathers the CO₂ flux budgets. \mathbf{x}_b is the vector of the prior estimates of these budgets, independent of atmospheric observations. The observed CO₂ mole fraction gradients selected for the inversion are assembled into \mathbf{y}_0 , which defines the observation space \mathbf{y} . The linear

observation operator $\mathcal{H} : \mathbf{x} \mapsto \mathbf{y} = \mathbf{H}\mathbf{x} + \mathbf{y}^f$ projects \mathbf{x} into the observation space through the linear operator \mathbf{H} (combining the description of the fluxes' spatial distribution and the atmospheric transport model) and the addition of CO_2 gradients \mathbf{y}^f caused by fluxes that are not controlled by the inversion, such as the remote fluxes characterized by the CO_2 boundary conditions of the regional transport model. The uncertainties in \mathbf{x}_b and the observation errors, i.e., errors in the measurements \mathbf{y}_0 and from the observation operator \mathcal{H} , are assumed to have unbiased Gaussian distributions and are characterized by the prior uncertainty covariance matrix \mathbf{B} and the observation error covariance matrix \mathbf{R} , respectively. \mathbf{x}_a , the optimal posterior estimate of \mathbf{x} , knowing \mathbf{x}_b and \mathbf{y}_0 , can be obtained from (e.g., Rodgers, 2000):

$$\mathbf{x}_a = \mathbf{x}_b + (\mathbf{B}^{-1} + \mathbf{H}^T \mathbf{R}^{-1} \mathbf{H})^{-1} \mathbf{H}^T \mathbf{R}^{-1} (\mathbf{y}_0 - \mathbf{y}^f - \mathbf{H}\mathbf{x}_b). \quad (1)$$

The uncertainty in \mathbf{x}_a has unbiased Gaussian distribution and is characterized by the posterior uncertainty covariance matrix \mathbf{A} :

$$\mathbf{A} = (\mathbf{B}^{-1} + \mathbf{H}^T \mathbf{R}^{-1} \mathbf{H})^{-1}. \quad (2)$$

The inversion uses measurements during a given 30-day period to derive fluxes during the same 30-day period. Independent inversions are made for twelve consecutive 30-days periods starting on 1 August 2010 to cover the entire observation period from August 2010 to July 2011. The 6-h mean inverted emissions during each period serve as the basis for the analysis of emissions in the Paris area at the monthly scale. Even though these 30 day periods do not correspond exactly to the month in the year, the names of months are used to label them.

We briefly recall descriptions of the components of Eq. (1)–(2) as laid out by Bréon et al. (2015) in the next Sections (Sect. 2.1–2.4). As detailed in Sect. 2.2, two modifications, however, are brought to the definition of \mathbf{y} and thus to \mathcal{H} . The modifications result in two new inversion configurations that are denominated *initial* (i.e., close to Bréon et al. (2015)) and *reference* configuration hereafter. Section 2.6 presents the set-up of the sensitivity tests, where \mathbf{x}_b and components of \mathcal{H} are modified with respect to the reference configuration.

2.1 Control vector \mathbf{x} and the prior estimate of the flux budgets \mathbf{x}_b

\mathbf{x} contains 6-h mean fossil fuel CO_2 emission budgets for windows 0–6 h, 6–12 h, 12–18 h, 18–24 h (local time is used hereafter) for each day for the whole Paris region. It also contains 30-day mean biogenic CO_2 fluxes for each of the four 6-hour windows of the day (0–6 h, 6–12 h, 12–18 h, 18–24 h) for 9 areas that make up the Northern France modelling domain, including one that encompasses the Paris region (see Fig. 1). The inversion optimises the diurnal cycle of both the fossil fuel CO_2 emissions and biogenic fluxes through resolving these fluxes for the different 6-hour windows of the day. However, it controls the day-to-day variability of the fossil fuel CO_2 emissions but not the one of the biogenic fluxes. The inversion controls scaling factors of the flux budgets provided by the emission inventories and the ecosystem model simulations through the operator \mathbf{H} (see below). For the sake of simplicity however, we state hereafter that it controls the flux budgets themselves.

The initial and reference inversion configurations use our best available knowledge on the flux budgets—the AIRPARIF 2008 inventory (since the AIRPARIF 2010 monthly mean budgets were not available for this study) and the C-TESSSEL simulation—to define the prior estimate x_b . The sensitivity tests, described in Sect. 2.6, investigate the impact of using different prior estimates for the Paris fossil fuel CO₂ emissions.

5 2.2 Configuration of the observation vector y and measurement vector y_0

The specific definition of y and of the corresponding measurement vector y_0 depends on the measurement availability, on the range of wind directions used to select gradients, and on the meteorological forcing of the CO₂ transport model. Two different meteorological products are used to define the wind direction for the gradient selection (see forward Sect, 2.3.1).

The three monitoring sites are located roughly along a NE-SW direction at edges of the urban area in mixed urban-rural environments (Fig. 1). The NE-SW direction corresponds to the dominant wind directions in Île-de-France. Technical details about the measurements are given in Bréon et al. (2015) and Lac et al. (2013). Here we briefly summarise the main aspects. The CO₂-MEGAPARIS sites GON and MON were equipped with a ring-down cavity analyser from Picarro (model G1302), while an automated gas chromatograph analyser (Agilent HP6890, see Gibert et al., 2007) has been used at GIF. All measurements are quality controlled and calibrated against the World Meteorological Organisation mole fraction scale WMO-X2007 (Zhao and Tans, 2006). The instrumental reproducibility of the Picarro 5 min averages is better than 0.17 ppm, while measurement accuracy is estimated at 0.38 ppm (Bréon et al., 2015). The precision of the chromatograph analyser in GIF is estimated at 0.05 ppm for 5 min averages (Lac et al., 2013). In our study, we binned measured CO₂ data into 1-h means.

Figure 2 and Fig. A1–A2 illustrate the temporal coverage of the measurements available during the CO₂-MEGAPARIS period (August 2010–July 2011) at each measurement site. They also show which data are finally used to form gradients. Some significant data gaps can be noticed, e.g., during June 2010 and 2011 at GON, September 2010 at MON, January, November and December 2010 at GIF. The regular 1-day gaps correspond to instrument calibrations.

CO₂ at the measurement sites is significantly influenced by both the Paris urban emissions and the remote fluxes (i.e., by fluxes outside the modeling domain, whose influence is simulated by the transport of the CO₂ conditions imposed at the model boundaries, and by biogenic and anthropogenic fluxes within the modelling domain but outside the Paris urban area). It is assumed, that, due to atmospheric diffusion, the signature of the remote fluxes upwind the city on the concentrations in our domain has horizontal and vertical spatial scales and a temporal scale of variability that are large enough so that it does not evolve during the transit of an air parcel above the city. In other words, it is assumed that the remote fluxes do not cause CO₂ gradients between downwind and upwind stations when the wind blows from the upwind to the downwind sites. This critical assumption is supported by the fact that the simulated CO₂ gradients, caused by remote fluxes, are negligible. However, this does not necessarily imply that the measured gradients are not influenced by the actual fluxes (Bréon et al., 2015). This assumption is also supported by the much better fit between observed and modelled CO₂, when observations are defined by cross-city gradients instead of CO₂ mixing ratios at individual sites (Bréon et al., 2015). By assimilating CO₂ gradients rather than individual CO₂ mole fractions, we thus expect to prevent the inversion from being sensitive to the uncertainties in the estimate of the remote fluxes.

Local sources in the vicinity of the measurement sites are difficult to represent in the model. In order to limit their impact, Bréon et al. (2015) selected gradients only if the wind speed is above a given threshold of 2 ms^{-1} . Similar to most inversion studies that used rural measurement sites (e.g., Broquet et al., 2011), Bréon et al. (2015) assimilated data during the afternoon only, since the model seemed to poorly represent vertical transport during other periods of the day. Specifically, Bréon et al. (2015) used differences in simultaneous hourly-averaged CO_2 measurements between the peri-urban stations during the afternoon (12-16h) to define the measurement vector \mathbf{y}_0 . When (at a given hour) the wind at GIF, given by the meteorological simulation (see below Sect. 2.3.1), is from SW, i.e. from 160° to 260° , and is above 2 ms^{-1} , GIF is the upwind site and Bréon et al. (2015) assimilate hourly CO_2 mole fraction differences between MON and GIF and between GON and GIF. When the simulated wind at MON is from NE, i.e. from 0° to 135° and exceeds 2 ms^{-1} , MON is the upwind site and Bréon et al. (2015) assimilate the CO_2 differences between GON and MON and between GON and GIF.

Using this configuration, Bréon et al. (2015) assimilated CO_2 gradients between GON and MON. GON and MON, however, are separated by a small portion of the North-Eastern suburbs of Paris. Gradients between these two sites do not relate to the whole Paris urban area. Furthermore, in order to retain a lot of data in the inversion, Bréon et al. (2015) used a loose range of wind directions to define upwind and downwind conditions. This loose range could allow the assimilation of gradients when air masses leaving the upwind site or reaching the downwind site hardly cross a significant portion of the Paris urban area, or, more generally, when air masses are not really transported from the upwind to the downwind site. This loose selection of gradients for constraining fluxes was not identified as a major source of systematic error. Through this configuration, they primarily aimed at decreasing the impact of remote fluxes on CO_2 mole fractions while keeping a large amount of data for the inversion. These choices, however, lead to estimates of spatially integrated emissions of the city constrained by measurements that are influenced only by emissions from a small fraction of the city. This would not be an issue if the spatial distribution of emissions provided by AIRPARIF was perfectly accurate. On the other hand, any significant error in the emissions' spatial distribution may induce a large error on the city-wide emission inversion. Indeed, if the assumed spatial distribution of the emission bears significant errors (which is likely the case), the inversion corrections, driven by model-data misfits due to errors in emissions from a small part of the city, will become inconsistent with the errors at the city-scale, raising large so-called aggregation errors (Kaminski et al., 2001).

As mentioned in the introduction, preliminary tests of inversions using the BR2105 configuration for the period August 2010–July 2011 demonstrated the need for an improved configuration where the selection of CO_2 conforms better with our assumptions on gradients. In this study, two critical changes are applied. They consist in assimilating GIF-GON and GIF-MON and in discarding GON-MON gradients when the wind is from NE. Furthermore, a stricter (narrower) range of wind directions to select CO_2 gradients is used. Discarding GON-MON gradients suppresses the large amount of negative gradients in the measurement vector \mathbf{y}_0 . The impact of discarding GON-MON gradients on the inversion results is not analysed deeper in the following. It relates to specific details of the Paris network configuration. Here, we focus on the impact of using a narrower range of wind directions for the gradient selection. The stricter selection of wind directions consists in assimilating a gradient between two sites only if the modelled wind at the upwind site is within $\pm 15^\circ$ of the transect between the downwind and upwind site. The specific choice of $\pm 15^\circ$ is somewhat arbitrary. On the one hand it ensures the selection of a significant number of

gradients. On the other hand it ensures that air masses leaving the upwind site or reaching the downwind site are transported over a large part of the urban area. Thus, the gradients GIF-GON, GIF-MON, MON-GIF and GON-GIF are assimilated only if the wind is from 20° to 50° , 35° to 65° , 215° to 245° , and 200° to 230° , respectively. We use the term *SW gradients* for the gradients GON-GIF and MON-GIF and *NE gradients* for the gradients GIF-MON and GIF-GON.

5 We apply other significant changes to the gradient selection criteria of Bréon et al. (2015). First, we increase here the minimum wind speed threshold at the upwind site from 2 to 3 ms^{-1} . This change is driven by the fact that, as noticed by Bréon et al. (2015), large model-data misfits persist after inversion for wind speeds close to 2 ms^{-1} . This suggests that a threshold of 2 ms^{-1} was not sufficient to avoid a large contamination of the measurements by poorly-modelled local sources. Furthermore, in this study, a single valid 1-h mean gradient during a given afternoon is not selected for the inversion. This avoids constraining
 10 the emissions of a given day based on a single observation that potentially bears a large transport model error. At last, the analysis of the impact of individual observations on the corrections applied by the inversion to the prior flux estimates (analysis not shown in this study) revealed that during two 30-day periods (November, December), one of the gradients had far more impact than the rest of the gradients. Again, in order to avoid giving too much weight to individual measurements, the two corresponding gradients have not been assimilated in any inversion experiment of this study.

15 Three configurations of \mathbf{y} are used in this study: \mathbf{y}_{ini} , \mathbf{y}_{ref} , and \mathbf{y}_{lag} . The first one, \mathbf{y}_{ini} , corresponds to the initial inversion configuration. It includes all the new options discussed above, except the narrowing of the wind direction ranges for the gradient selection. The selection of GIF-GON, GIF-MON, MON-GIF and GON-GIF gradients in \mathbf{y}_{ini} is based on the wind direction ranges at GIF and MON as proposed by Bréon et al. (2015). The second one, \mathbf{y}_{ref} , corresponds to the reference inversion configuration. It includes all the new options and selects gradients based on the new wind direction ranges at GIF,
 20 GON and MON defined in this section. The comparison between the initial and reference inversions is used to assess the impact of using tight wind direction ranges on retrieved emissions and to evaluate if the selected gradients now conform better with our assumptions (see Sect. 3.1-3.2). \mathbf{y}_{lag} is only used for a single experiment whose results are briefly discussed in Sect. 3.2. This Lagrangian experiment consists in spatio-temporal gradients between upwind and downwind sites, i.e., mole fraction differences between a downwind sites at a given time and upwind sites 1-h or 2-h before. The wind selection in this
 25 experiment is similar to that of the reference experiment. It uses simulated wind fields at the time of the upwind mole fraction measurement involved in the gradient. At a given site the assimilation window is also reduced so that a given gradient does not involve any measurement outside the 12-16 h window, despite the use of a time lag in the gradient. The typical time for air being transported from the upwind to the downside site is 2 h, justifying the time lag that have been tested. The use of spatio-temporal gradients instead of spatial gradients appears more in line with our approach to constrain emissions based on
 30 the mole fraction variations in air parcels that are transported above the Paris area. However, with such a configuration of the observation vector, the number of data that can be assimilated is further decreased.

2.3 Observation operator \mathcal{H}

This section describes the observation operator $\mathcal{H} : \mathbf{x} \mapsto \mathbf{y} = \mathbf{H}\mathbf{x} + \mathbf{y}^f$. The linear operator \mathbf{H} combines the fluxes' spatio-temporal distribution (\mathbf{H}^{map}), the atmospheric transport simulated using CHIMERE ($\mathbf{H}^{\text{trans}}$), and the sampling of simulated

4D-CO₂ field like the observations (\mathbf{H}^{samp}). \mathbf{y}^{f} gathers influences on the gradients which are not controlled by the inversion such as the signature of the model boundary conditions. In the following, we present the implementation of these operators and vectors used in Bréon et al. (2015) and the initial and reference inversions of this study, respectively, as well as alternative options used for sensitivity tests.

5 2.3.1 Atmospheric transport modelling and sampling

$\mathbf{H}^{\text{trans}}$ and \mathbf{y}^{f} are modelled using a Northern France configuration of CHIMERE. It has a $2\text{ km} \times 2\text{ km}$ spatial resolution for the Paris region, and a $2 \times 10\text{ km}$ and $10\text{ km} \times 10\text{ km}$ spatial resolution for the surroundings (see Fig. 1). It has 20 vertical hybrid pressure-sigma (terrain-following) layers that range between surface and the mid-troposphere, up to 500 hPa. In the initial and reference inversion of this study, as in Bréon et al. (2015), CHIMERE is driven by operational analyses of ECMWF's Integrated
 10 Forecasting System, available at approximately $15\text{ km} \times 15\text{ km}$ spatial resolution and 3 h temporal resolution. In this case we will denote $\mathbf{H}^{\text{trans}} = \mathbf{H}_{ECM}^{\text{trans}}$ and $\mathbf{y}^{\text{f}} = \mathbf{y}_{ini-ECM}^{\text{f}}, \mathbf{y}_{ref-ECM}^{\text{f}}$ or $\mathbf{y}_{lag-ECM}^{\text{f}}$, depending on the type of gradient selection used.

For sensitivity tests (see Sect. 3.3.3), CHIMERE is alternatively driven by the Meso-NH/TEB meteorological simulation at $2\text{ km} \times 2\text{ km}$ and 1-hour resolution (Lac et al., 2013). This Meso-NH/TEB simulation, originally conducted over a slightly different grid (see Lac et al., 2013, their Fig. 1a.), is interpolated onto the CHIMERE grid. When using Meso-NH/TEB $\mathbf{H}^{\text{trans}}$
 15 and \mathbf{y}^{f} are denoted by $\mathbf{H}_{MNH}^{\text{trans}}$ and $\mathbf{y}_{ref-MNH}^{\text{f}}$, respectively.

The non-hydrostatic mesoscale model Meso-NH, jointly developed by Météo-France and Laboratoire d'Aérodynamique (Lafore et al., 1998), is coupled to 3-hourly analysed meteorological fields from AROME (Application of Research to Operations at Mesoscale)-France (Seity et al., 2010) and to the land-surface-atmosphere interaction model SURFEX (Masson et al., 2013). SURFEX includes the urban and vegetation scheme TEB (Masson, 2000). Therefore, in contrast to the ECMWF meteorological forcing,
 20 Meso-NH/TEB includes some urban parametrisation, which may have a large impact on the transport through the city and thus on the inversions.

In order to build \mathbf{H} and \mathbf{y}^{f} , the operator \mathbf{H}^{samp} is applied. \mathbf{H}^{samp} extracts the selected gradients between the monitoring sites from the simulated 4-D CO₂ mole fraction fields as described in Sect. 2.2. The underlying selection of the horizontal and vertical positioning of the monitoring sites in the CHIMERE grid is the same as in Bréon et al. (2015). Because the gradient
 25 selection depends on modelled wind speed and direction, \mathbf{y} and thus \mathbf{y}^{f} and \mathbf{H}^{samp} depend on the meteorological simulations (ECMWF or Meso-NH/TEB). We denote \mathbf{H}^{samp} by $\mathbf{H}_{ini-ECM}^{\text{samp}}, \mathbf{H}_{ref-ECM}^{\text{samp}}, \mathbf{H}_{lag-ECM}^{\text{samp}}$ or $\mathbf{H}_{ref-MNH}^{\text{samp}}$, depending on the inversion cases.

2.3.2 Fluxes and boundary conditions

\mathbf{y}^{f} encompasses the signature of anthropogenic CO₂ emissions outside the Paris region, that of the modelling domain's CO₂
 30 boundary conditions and that of the 30-day simulations initial conditions. These signatures are simulated by CHIMERE using fossil fuel CO₂ emissions outside the Paris region from the EDGAR database (Janssens-Maenhout et al., 2012). Daily CO₂ mole fraction fields provided by the global inversion of Chevallier et al. (2010) are used as CO₂ boundary conditions at the lateral and top edges of the modelling domain and as initial conditions for the CO₂ mole fraction fields at the beginning of each

30-day period. The global inversion of Chevallier et al. (2010) is based on the simulation of the CO₂ transport by the LMDZ model (Hourdin et al., 2006) and on the assimilation of ground-based measurements from a global network.

2.3.3 Mapping of the Paris fossil fuel CO₂ emissions and biogenic fluxes

\mathbf{H}^{map} is built on hourly biogenic flux and emission maps at the horizontal resolution of the CHIMERE transport model. In both
5 the initial and reference inversions, as in Bréon et al. (2015), the description of the fossil fuel CO₂ Paris emissions at 1-h and
2 km×2 km resolution in \mathbf{H}^{map} is based on the hourly AIRPARIF 2008 inventory. The temporal profiles and spatial distributions
of this inventory are analysed in Bréon et al. (2015). We just recall that emissions are available at 1 h and 1 km×1 km resolution
for three typical days (weekday, Saturday, Sunday) of 5 typical months (January, April, July, August, October) of the year 2008.
In order to build hourly estimates for the 1-yr period August 2010-July 2011, we follow AIRPARIF's recommendation and
10 use January emissions for all five months from November to March, April data for all three months from April to June, and
October data for both September and October and, for a given day in 2010 or 2011, we use the values from the same day in
2008.

For sensitivity tests (see Sect. 3.3.2), the emission component of \mathbf{H}^{map} is alternatively built based on a national emission
inventory for 2005 compiled by the Institut Für Energiewirtschaft Und Rationelle Energieanwendung (IER) of the University
15 of Stuttgart, Germany. Latoska (2009) disaggregated reported emission totals for France for 2005 into a 1×1 arc minute grid
with the use of various proxies for the distribution of emitting activities such as population census, traffic intensity and land
cover. We used monthly, weekly and hourly temporal profiles for different emissions sectors from the IER inventory for Europe
as described by Vogel et al. (2010) to disaggregate annual emissions to hourly emissions. The IER and AIRPARIF emission
inventories are two largely independent datasets.

20 In all experiments, the component in \mathbf{H}^{map} that corresponds to the biogenic control variables is based on Net Ecosystem
Exchange simulated by C-TESSSEL at 3 hourly and 15 km×15 km resolution. The simulated Net Ecosystem Exchange is
interpolated hourly onto the CHIMERE grid (at 2 km to 10 km resolution). We denote \mathbf{H}^{map} by $\mathbf{H}_{AP}^{\text{map}}$ if the hourly fossil fuel
CO₂ flux maps are built using AIRPARIF 2008; by $\mathbf{H}_{IER}^{\text{map}}$ if the hourly fossil fuel CO₂ flux maps are built using IER.

2.4 Prior error covariance matrix \mathbf{B}

25 As in Bréon et al. (2015), we model the prior error covariance matrix \mathbf{B} by assuming a 50 % uncertainty (in terms of standard
deviation) in the prior estimates of individual 6-h fossil fuel CO₂ emission budgets. The temporal correlations of prior un-
certainties in the 6-h fossil fuel CO₂ emission budgets are calculated as the product of the correlations between the four 6-h
windows of a same day and correlations between different days. Positive correlations are used between the 6-h windows of
the day: 0.4 for two consecutive windows (for example, 0-6 and 6-12 h) and 0.2 for two non-consecutive ones (for example,
30 0-6 and 12-18 h). The day-to-day correlations of prior uncertainties in emission budgets are modelled using an exponentially
decaying function with a characteristic time of 7 days.

For a given area and 6-h window of the day, the standard deviation of the prior uncertainty in the 30-day budgets of Net
Ecosystem Exchange is assumed to be about 75 % of the prior estimate of this budget from C-TESSSEL. In practice, it appears

that the resulting value of this uncertainty decreases when the surface of the corresponding area increases. Spatial and temporal correlations between the uncertainties for the various 6-hour windows of the day and areas are assumed to be negligible due to the large size of the corresponding areas and due to the differences in the processes dominating the ecosystem exchanges between daytime and night-time. It is also assumed that there is no correlation between the uncertainties in the fossil fuel CO₂ emissions and uncertainties in the biogenic fluxes.

2.5 Matrix \mathbf{R}

The observation errors encompass instrumentation errors and errors in the observation operator \mathcal{H} (such as transport model errors, representation errors, aggregation errors, errors from the boundary conditions, errors from the emissions in the modelling domain but outside the Paris area). Bréon et al. (2015) used the diagnostics of Desroziers et al. (2005) to estimate the variances of the observation error. It is assumed that these errors have the same statistics for any hourly gradient and that there is no correlation between errors for different hourly gradients. Their corresponding estimate of the standard deviation of the observation error was 3 ppm. \mathbf{R} is thus modelled as a diagonal matrix with a (3 ppm)² variance for all elements in the diagonal.

2.6 Principles of the sensitivity tests

Several tests are conducted to check the reference inversion results' sensitivity to changes in different components: the prior estimate of the Paris fossil fuel CO₂ emissions, the spatio-temporal distribution of the fossil fuel CO₂ emissions within the Paris region and within a given 6-h window, the meteorological forcing driving both the atmospheric transport model and the selection of the observations. These tests are representative of typical uncertainties in these components.

Regarding the prior estimate of the Paris fossil fuel CO₂ emission budgets, as an alternative to the AIRPARIF 2008 budgets, we use what is called hereafter *flat priors*, i.e., prior fossil fuel CO₂ emission estimates that are not informed about month to month variations. Three sets of flat priors are built by rescaling the AIRPARIF 2008 budgets using monthly, daily or 6-h scaling factors. In the first case, the flat priors have constant monthly values, but retain the relative temporal variations of the 6-hour budgets within a month. In the second case the flat priors have constant daily values, but retain the relative temporal variations of the 6-h budgets within a day. In the third case, the flat priors have constant 6-h mean values. For each set, different flat priors are tested by taking different values for the monthly budgets. These values cover a case of relatively high emissions (5 MtCO₂month⁻¹), a case of relatively low emissions (3 MtCO₂month⁻¹), as well as an intermediate case corresponding to the annual budget from the AIRPARIF 2008 inventory (4.3 MtCO₂month⁻¹). a prior estimate based on the budgets from the IER inventory is also used for the sensitivity tests. As explained in Sect. 2.3.3, $\mathbf{H}_{IER}^{\text{map}}$ is used as alternative \mathbf{H}^{map} to $\mathbf{H}_{AP}^{\text{map}}$, while $\mathbf{H}_{ref-MNH}^{\text{trans}}$, $\mathbf{y}_{ref-MNH}^f$ and $\mathbf{H}_{ref-MNH}^{\text{samp}}$ are used as alternative $\mathbf{H}^{\text{trans}}$, \mathbf{y}^f and \mathbf{H}^{samp} to $\mathbf{H}_{ECM}^{\text{trans}}$, $\mathbf{y}_{ref-ECM}^f$, $\mathbf{H}_{ref-ECM}^{\text{samp}}$. Table 1 summarizes the acronyms and settings of the different sensitivity tests.

3 Results

Bréon et al. (2015) analysed the skill of the inversion by comparing the fit between measured and modelled CO₂ gradients, which is a first indicator of the reliability of the inverted emissions. In Tab. 2, statistical comparisons between the selected measurement gradients and results from the initial and reference inversion, respectively, are provided. It demonstrates that both
5 inversions strongly increase the consistency between model and measurements compared to the prior simulations (Tab. 2). Of note is that the statistics of both the prior and posterior model-data misfits are smaller for the initial inversion than for the reference inversion. This is explained by the fact that the initial inversion selects gradient for which the signal (mainly the impact of the city emissions) is smaller than for the gradients that both inversions select. However, we avoid a more detailed analysis of the model-data misfit.

10 Here, the presentation of the results rather focuses on the estimates of the monthly fossil fuel CO₂ emission budgets from mid-2010 to mid-2011, expressed in MtCO₂month⁻¹ (strictly speaking MtCO₂ per 30 days, see Sect. 2). AIRPARIF (2013) reports an estimate of 41.8 MtCO₂yr⁻¹ for the annual emission budget of Île-de-France in 2010. This number is used as an indicator for the evaluation of the 1-yr budget of the estimates from the inversion. According to AIRPARIF (2013), the residential and the service sector account for 43% of the Paris fossil fuel CO₂ emissions in 2010. These emissions are almost
15 entirely linked to heating. Heating in the industry sector contributes also significantly to Paris' emissions. The heating is mostly dedicated to ambient air in the buildings and to sanitary water. Therefore we expect a large increase of the emissions from summer to winter and a high correlation between these emissions and the temperature during the cold season. An independent analysis of both daily gas use and hourly electric consumption within Île-de-France indicate a heating energy use that is highly correlated to the daily-mean temperature when this temperature is below 19° C, and essentially independent of the
20 daily mean temperature when this temperature is above 19° C. For the evaluation of the results, our emission estimates are thus compared with monthly averages of an independent measure, which we call heating degrees hereafter. It is defined as the positive difference between the daily mean temperature and 19° C (set to 0 for days when the temperature is higher than 19° C). The ratio between January and July emission estimates from the AIRPARIF 2008 inventory seem surprisingly low given these considerations. Furthermore, the prior estimates based on this inventory make use of a single emission value from
25 November to March, which does not account for the large temperature variations during this period. Therefore, an amplified seasonal cycle of the emissions that better correlates with heating degrees is expected through the atmospheric inversion.

The uncertainties (in terms of standard deviation) in prior and posterior estimates of the monthly emissions are based on the modelling of the **B** matrix, described in Sect. 2.4, and on the derivation of the **A** matrix (Eq. (2)). This section provides these uncertainties estimates and the corresponding uncertainty reduction (i.e., the relative difference between the posterior and prior
30 uncertainties) but it does not analyse them. The reliability in these uncertainty estimates is actually commented in Sect. 4 in the light of the assessment of the robustness of the inversions based on comparisons to AIRPARIF 2010 and to the monthly mean heating degrees.

3.1 Initial inversion using loose wind direction criteria for the gradients selection

Figure 3a shows prior and posterior estimates of the Paris emissions from the initial inversion (experiment *ini*, Tab.1). Monthly mean heating degrees for the centre of Paris, derived from the temperature given by the ECMWF's operational analysis, are also shown on this figure. The posterior estimates are lower than the prior ones for all months. The inversion decreases the annual emissions from $51.9 \text{ MtCO}_2\text{yr}^{-1}$ to $37.4 \pm 2.1 \text{ MtCO}_2\text{yr}^{-1}$. This number is smaller but closer to the AIRPARIF inventory 2010 used for evaluation ($41.8 \text{ MtCO}_2\text{yr}^{-1}$, see Tab. 1).

Posterior fluxes are lowest for August ($1.6 \text{ MtCO}_2\text{month}^{-1}$), increase steadily until peaking in February ($4.6 \text{ MtCO}_2\text{month}^{-1}$), drop strongly in March ($2.8 \text{ MtCO}_2\text{month}^{-1}$), and vary between 2 and $3 \text{ MtCO}_2\text{month}^{-1}$ from April to July. Compared to the prior estimate, the inversion yields larger emissions in winter and increases the amplitude of the seasonal variations. For the period analysed, monthly mean heating degrees were highest in December (Fig. 3a). Hence, fossil fuel CO_2 emissions are expected to be the highest in December rather than in February. There is no clear correlation between monthly heating degrees and emission estimates during the November-March period.

The number of assimilated gradients varies considerably from one month to another, which influences the month-to-month variations of the inverted emissions. For instance, 163 observations are assimilated in March, compared with only 34 in November. Figure 3a also shows that, for most months, the numbers of selected gradients are not apportioned equally amongst the NE and SW wind directions. For instance, there are no NE gradients to constrain August emissions, while less than half of the gradients in March are SW gradients. The different upwind conditions for NE and SW gradients could play a role in the month-to-month variability of the inverted emissions, in case the gradient approach does not remove entirely the influence of remote fluxes.

We investigate the impact of assimilating these two different gradient types on monthly fossil fuel CO_2 flux estimates by conducting inversions based on NE gradients, SW gradients, or even GIF-MON, GIF-GON, MON-GIF or GON-GIF only (Fig. 3b). The difference in inverted December emissions when assimilating only SW gradients compared to assimilating only NE gradients is large, even though a large number of both types of gradients is available during this month. Compared to the prior estimate, the inversion of SW gradients increases the December emissions. The opposite, however, is true for the inversion of NE gradients. This behaviour seems to be driven by both the assimilation of GIF-MON and GIF-GON gradients. An analysis of the average temperature in Paris (not shown) shows lower temperatures for NE wind conditions than for SW wind conditions. The heating emissions in Paris should thus be higher for NE wind conditions. Therefore, the temperature variations cannot explain the differences in December emissions between assimilating SW gradients or assimilating NE gradients.

The differences between the results when using NE gradients or SW gradients are not as large for other months as in December. However, they can still be significant, e.g., April (Fig. 3b). These differences cannot be explained by a lack of data for a given type of gradient, except in August, when there are no NE gradients. For January and February, differences of 1 to 1.5 MtCO_2 (i.e., about 35 % relative differences) are obtained between inversions assimilating only MON-GIF compared to assimilating only GON-GIF, although both are SW gradients and gather more than 40 observations during each month. This large mismatch between the different inversions when using different data subsets undermines the reliability of the inversion

results, in particular in December. The seasonal profile of the retrieved emission when assimilating only SW gradients is far better correlated with heating degrees than when the inversion uses both SW and NE gradients, as emissions reach their maximum in December. Results seem nearly as sensible when using MON-GIF or GON-GIF as when using all SW gradients.

Figures 4a and 4c illustrate that, even if we discard GON-MON and increase the threshold of the wind speed, there are 5 episodes when measured gradients show negative values. They, however, should be positive owing to the city's emissions. Most of the negative gradients are found when the wind is from NE, such as in December (Fig. 4a), suggesting that such gradients may not represent the emissions of the entire city.

3.2 Reference inversion

The estimates of the monthly Paris fossil fuel CO₂ emissions by the reference inversion (experiment *ref*, Tab.1) are given in 10 Fig. 3c. All negative observed gradients outlined above were obtained at the limit of the wind direction range proposed by Bréon et al. (2015). As illustrated for December and May by comparing Fig. 4a to Fig. 4b and Fig. 4c to Fig. 4d, respectively, the reference inversion, which uses a stricter range of wind directions (Sect. 2.2), removes the negative gradients. Despite the loss of 65 % of the data compared to the initial inversion, the reference inversion still predicts a large uncertainty reduction for monthly fossil fuel CO₂ emission estimates, from 9 % in November to 50 % in October.

15 The Paris monthly fossil fuel CO₂ emission estimates from the reference inversion correlate well with monthly heating degrees ($R^2 = 0.67$ for the whole period, $R^2 = 0.45$ for November–February), which was not the case of the initial inversion ($R^2 = 0.54$ for the whole period, $R^2 = 0.07$ for November–February). In general, the reference inversion decreases the fossil fuel CO₂ budget from the prior estimate, except in December, which becomes the peak of emissions (Fig. 3c). The emissions decrease from February to March, which does not correspond to a relative change in heating degrees, is significantly smaller 20 in the reference than in the initial inversion. The seasonal variations of the reference inversion are strongly improved compared to initial inversions. The annual budget from the reference inversion (40.9 MtCO₂) is close to that from AIRPARIF 2010 (41.8 MtCO₂, see Tab. 1).

The stricter gradient selection further leads to a much better agreement between emission estimates when using different subsets of gradients (compare Fig. 3d with Fig. 3b). Although significant differences in December and April emissions are still 25 apparent between using NE gradients or using SW gradients, and in January and February emissions between using GON-GIF or MON-GIF, these differences are smaller than in the initial inversion. Now, even when assimilating only NE gradients, the four months with largest inverted emissions correspond to the four coldest ones with the highest heating degrees of the year (November to February), though the assimilation of NE gradients still leads to smaller emissions in December than in November, January and February. One may argue that the improvements of the reference over the initial inversion reflect the 30 assimilation of a smaller dataset, and therefore are due to smaller corrections. However, results from the reference and initial inversion are closer to each other if only SW gradients are assimilated than if only NE gradients are assimilated. Highest correlation with the heating degrees are obtained when only SW gradients are assimilated.

Results from the Lagrangian inversion using a 2- h lag between the upwind and the corresponding downwind measurement are shown in Fig.5. The further and large decrease of the number of assimilated gradients (only 4% of available measurement

data are used by reducing the time window of eligible upwind or downwind measurements; see Sec.2.2) compared to the reference configuration clearly limits the weight of the observational constraint. The results of this inversion is between that from the reference inversion and the prior estimates from AIRPARIF 2008 (often closer to AIRPARIF 2008 than to the reference inversion), without any qualitative improvement.

5 3.3 Sensitivity Tests

3.3.1 Sensitivity to x_b

Monthly fossil fuel CO₂ emissions estimates using flat priors for x_b (all experiments *FLAT_* in Tab. 1) are reported in Fig. 6. Although differences in prior monthly budgets between the *FLAT_3.0*, *FLAT_4.3* and *FLAT_5.0* experiments amount to 2 MtCO₂month⁻¹, posterior differences between their monthly budgets are generally much lower. In addition, the posterior monthly emissions when using flat priors are comparable to those from the reference inversion—with a very similar month-to-month variation. The differences between posterior monthly emissions from the *FLAT_mM* ($m=3.0, 4.3$ or 5.0) inversions and the reference inversion are generally smaller than 1 MtCO₂month⁻¹, except during September, November, May and July when very few (4 to 24) gradients are assimilated (Fig. 6a). Larger differences are obtained between the reference inversion and *FLAT_mD* and *FLAT_mH* ($m=3.0, 4.3$ or 5.0) inversions, which use prior estimates that are flat at the daily or 6-hour scale (Fig. 6b and Fig. 6c). The *FLAT_mM* experiments yield larger posterior monthly budgets than the *FLAT_mD* and *FLAT_mH* experiments.

Posterior annual budgets from *FLAT_mM* inversions range between 33 and 45.3 MtCO₂yr⁻¹, encompassing the budgets from the reference inversion and AIRPARIF 2010 (Tab. 1). In particular, the inverted annual budget from *FLAT_4.3M*, whose prior estimate has the same annual budget as the prior estimate from the reference inversion, is equal to 41.1 MtCO₂. This is very close to the annual budgets from the reference inversion and AIRPARIF 2010. However, the annual emissions budgets from the *FLAT_mD* and *FLAT_mH* inversions range from 36.9 to 52.2 MtCO₂, which is biased compared to both the reference inversion and AIRPARIF 2010.

3.3.2 Sensitivity to \mathbf{H}^{map}

Figure 7 compares the estimates from the reference inversion, which uses $\mathbf{H}^{\text{map}} = \mathbf{H}_{AP}^{\text{map}}$, to the estimates from the sensitivity test with $\mathbf{H}^{\text{map}} = \mathbf{H}_{IER}^{\text{map}}$ (*INV_mapIER* and *INV_IER*, see Tab. 1). Thus, this experiment also includes results when using the IER inventory to build both the 6-h mean budgets in x_b and $\mathbf{H}^{\text{map}} = \mathbf{H}_{IER}^{\text{map}}$ (*INV_IER*). It provides estimates when the inversion relies entirely on the IER inventory to define these parameters and ignores the existence of the AIRPARIF inventory. This situation is similar to that in cities, where no local inventory is available. We have less confidence in the posterior estimates from such an inversion, since the IER inventory does not rely on the same amount of local data as the AIRPARIF inventory.

INV_mapIER regularly predicts lower monthly budgets than the reference inversion, except in June, July, September and November. The corresponding differences are relatively small and do not exceed 0.5 MtCO₂month⁻¹, except in January and February. Similar to the reference inversion, *INV_mapIER* predicts highest emissions in December. However, its estimates for

January and February fluxes are particularly low, e.g., January estimates ($3.9 \text{ MtCO}_2\text{month}^{-1}$) roughly equal that for May ($3.9 \text{ MtCO}_2\text{month}^{-1}$) or October ($3.8 \text{ MtCO}_2\text{month}^{-1}$), and are smaller than that for September ($4.1 \text{ MtCO}_2\text{month}^{-1}$). This results in an annual budget of $39 \text{ MtCO}_2\text{yr}^{-1}$ that is still closer to the one from AIRPARIF 2010 than to the one from AIRPARIF 2008 (Tab. 1).

5 The monthly prior emissions from AIRPARIF 2008 and IER differ substantially. In particular, from November to May, the IER inventory estimates up to $3 \text{ MtCO}_2\text{month}^{-1}$, (approximately 40%) higher fossil fuel CO_2 emissions for the Paris region than AIRPARIF 2008. At the annual scale, estimates differ by $8.2 \text{ MtCO}_2\text{yr}^{-1}$ (Tab. 1). The differences between the two inventories are due to both the differences in the emission model and the driving activity data used. The two inventories correspond to two different years (2008 versus 2005). However, this hardly explains the amplitude of the difference between
10 the two inventories by itself. The decrease of the total emission in France between 2005 and 2008 was approximately 5 % (see, e.g., CITEPA, 2015). Here, the difference in total emissions in Île-de-France between the IER and AIRPARIF 2008 inventory, however, is about 14%. Results of the inversion using IER for both the prior emission budgets and the emissions' spatial distribution (INV_IER) reflect these large prior discrepancies. Indeed, monthly and annual budgets of Paris' fossil fuel CO_2 emissions estimated by INV_IER are larger than that from the reference inversion and from INV_mapIER (Fig. 7).
15 The differences in posterior February emissions from IER_INV and the reference inversion exceed $2 \text{ MtCO}_2\text{month}^{-1}$. The discrepancies are even larger, when comparing the monthly emission estimates from INV_mapIER and IER_INV, since the change of \mathbf{H}^{map} from $\mathbf{H}_{AP}^{\text{map}}$ to $\mathbf{H}_{IER}^{\text{map}}$ has a tendency to decrease the posterior emission estimates.

The IER inventory indicates higher emissions in March than in November. Posterior estimates from INV_IER still indicate that the highest emissions are in November-February. Due to a residual influence from the IER prior estimate, INV_IER
20 predicts highest emissions in February. The December emission estimate is close to February emission estimate, and is the second highest 1-month mean estimate from INV_IER. Finally, the annual posterior emission from INV_IER is closer to that from AIRPARIF 2010 than to that from the 2008 inventory, despite the far higher prior annual estimate from the IER inventory (Tab. 1).

3.3.3 Sensitivity to \mathbf{H}^{samp} , $\mathbf{H}^{\text{trans}}$ and \mathbf{y}^f

25 INV_MNH is compared to the reference inversion to analyse the impact of using Meso-NH/TEB instead of ECMWF as meteorological simulation for both the gradient selection in the observation vector ($\mathbf{H}^{\text{samp}} = \mathbf{H}_{ref-MNH}^{\text{samp}}$ versus $\mathbf{H}^{\text{samp}} = \mathbf{H}_{ref-ECM}^{\text{samp}}$) and the forcing of CHIMERE ($\mathbf{H}^{\text{trans}} = \mathbf{H}_{MNH}^{\text{trans}}$ versus $\mathbf{H}^{\text{trans}} = \mathbf{H}_{ECM}^{\text{trans}}$ and $\mathbf{y}^f = \mathbf{y}_{ref-MNH}^f$ versus $\mathbf{y}^f = \mathbf{y}_{ref-ECM}^f$). Meso-NH/TEB data are available up to June only which explains that the analyses here are restrained to the period August 2010 to June 2011.

30 The time series of the gradients that are selected for the assimilation using $\mathbf{H}_{ref-MNH}^{\text{samp}}$ and $\mathbf{H}_{ref-ECM}^{\text{samp}}$, respectively, are shown in Fig. 2 (and Fig. A1–A2). The significant differences in selected gradients apparent in Fig. 2 (and Fig. A1–A2)) are driven by small differences in simulated wind fields between ECMWF and Meso-NH/TEB. Small differences in wind direction and speed are often sufficient to cross the thresholds defining the gradient selection (Fig. A1–A2). This differences result in

a significantly different set of assimilated gradients and in a different apportionment according to prevailing NE or SW wind directions (Fig. 8).

Despite this, Fig. 8 reports similarities in inverted monthly emissions from INV_MNH and the reference inversion. Differences in monthly posterior emission estimates are less than $0.5 \text{ MtCO}_2\text{month}^{-1}$ when assimilating all selected gradients (Fig. 8). The four highest emitting months are still November to February for INV_MNH. However, larger differences to the reference inversion estimates are found for December and May, resulting in the loss of the peak in December and in an unexpected peak in May in INV_MNH (Fig. 8a). This disagreement is related to the assimilation of NE gradients. As shown in Fig. 8b, emissions estimates from INV_MNH and the reference inversion are very similar when only SW gradients are assimilated. By contrast, large differences are obtained in December and May when only NE gradients are assimilated (Fig. 8c). The larger fraction of selected NE gradients compared to selected SW gradients when using Meso-NH/TEB instead of ECMWF could explain the loss of the emission peak in December. There is no peak in December when using either Meso-NH/TEB, or ECMWF and NE gradients only. Nevertheless, when assimilating SW gradients, the consistency between INV_MNH and the reference inversion is surprising, given the significantly different SW gradient selection.

4 Discussion and Conclusions

4.1 Summary and general analysis of the results

We have analysed estimates of monthly mean anthropogenic CO_2 emissions from the Paris urban area from August 2010 to July 2011 using continuous CO_2 measurements from three stations and a city-scale atmospheric inverse modelling framework derived from Bréon et al. (2015). The inversion modeling is based on a mesoscale configuration of CHIMERE, on the AIR-PARIF high-resolution CO_2 emission inventory for 2008, on the C-TESSSEL simulation for the biogenic fluxes in Northern France, and on the principle of constraining the 6-hour mean city-scale budget of the emissions using cross-city CO_2 gradients. This study has critically improved configuration of Bréon et al. (2015) by (i) discarding GON-MON gradients since that are not evidently related to the whole city emissions, and (ii) by using stricter criteria on the wind direction and wind speed for the selection of gradients.

The analysis suggests an improvement of the city's seasonal to annual emission budget from the reference inversion compared to the prior estimate that is based on the AIRPARIF 2008 inventory. The inversion derives an annual emission budget (for August 2010–July 2011) of $40.9 \text{ MtCO}_2\text{yr}^{-1}$, which is closer to the independent estimate from the AIRPARIF 2010 inventory ($41.8 \text{ MtCO}_2\text{yr}^{-1}$) than to the prior estimate ($51.9 \text{ MtCO}_2\text{yr}^{-1}$). Although the reported estimate from the AIRPARIF 2010 inventory does not exactly correspond to the mid-2010 to mid-2011 period, changes between the 2008 and 2010 inventories reflect improvements in the inventory model and actual changes of the Paris emissions. Therefore, the fact that the corrections applied by the inversion to the prior estimate from AIRPARIF 2008 are consistent with the differences between the AIRPARIF 2008 and 2010 inventories gives confidence in the inversion.

The seasonal variations of the monthly inverted emissions also appear more realistic than that of the prior emission estimates. The seasonal amplitude of the emissions revealed by the reference inversion is higher than that of the prior estimate of the

emission, derived from the 5 typical months of the AIRPARIF 2008 inventory. This increase in amplitude makes sense, given that a large fraction (43 %) of the Paris emissions are due to domestic and commercial heating. It is supported by the fact that the seasonal variations in the AIRPARIF 2010 inventory are higher than that derived from the AIRPARIF 2008 inventory. The inverted seasonal cycle of the emissions correlates well ($R^2 = 0.45$) with the heating degrees in fall-winter (November–
5 February). The four months with highest inverted emissions correspond to the four coldest months (November to February)–with a peak in both the emissions and the heating degrees in December. By contrast, the prior estimate of the emissions derived from AIRPARIF 2008 does not differentiate monthly budgets from November to March.

The sensitivity tests indicate that the uncertainties assigned to the prior estimates of the 6-h mean emissions, to the spatio-temporal distribution of the emissions within the Paris area and 6-h windows, and to the meteorological simulations (for
10 the cross-city gradient selection and for the forcing of CHIMERE) have a moderate impact on the monthly mean emission estimates once the inversion is driven by the most stringent selection of the measurements. This weak sensitivity of the inverted emissions to the uncertainties assigned to the inverse modeling components is important for the credibility of the inversion approach in view to apply this approach as an independent method to verify inventories. Here, the inverted emission budgets are sensitive to each of the above-mentioned components. However, even though we assimilate a relatively small number of
15 data, this sensitivity is generally much smaller than the differences between inverted and prior estimates at monthly to annual scale. Furthermore, the plausible seasonal variations of the emissions revealed by the reference inversion is robust to most sensitivity tests.

The inversions generally return smaller emissions than the prior estimates. This is even the case when using a prior estimate that is flat at the monthly scale only, and that has an annual emission budget of $36 \text{ MtCO}_2\text{yr}^{-1}$, i.e., a budget that is smaller
20 than that from AIRPARIF 2010. Moreover, we define the uncertainties in the prior emission estimates in terms of relative rather than absolute uncertainty. Consequently, using higher (smaller) prior emissions at monthly to annual scale leads to higher (smaller) prior uncertainties, and thus to a stronger (weaker) constraint from the atmospheric measurements, resulting in a stronger (weaker) decrease of the emissions. One could argue that this artificially helps getting a robust convergence of the sensitivity tests using different prior estimates and it likely plays a role at the annual scale. This could be problematic, since
25 having a fixed value for the relative uncertainty in the prior estimates is not suitable when these estimates become very small. However, for some months, the convergence between inversions utilising different flat priors is obtained by both positive and negative corrections. This is the case in January and February 2011 for FLAT_mM experiments (Fig.6a). The convergence can also be obtained with positive corrections that are larger when prior uncertainties are smaller, e.g., in December 2010 for FLAT_mM experiments (Fig.6a). Tests with prior estimates that are flat at the daily and 6-h scale (Fig. 6b,c) give a lot
30 of examples when the sign of the corrections to the monthly estimates depends on the value of the flat prior and where the amplitude of this correction is not obviously driven by the prior uncertainty. Furthermore, the fact that higher prior emission estimates are assigned higher prior uncertainties cannot explain the level of convergence of the sensitivity tests. In particular, it can not explain the robustness of the retrieved seasonal cycle of emissions when using flat priors. It neither explains the fact that the annual budget from INV_IER is closer to AIRPARIF 2010 than to AIRPARIF 2008. INV_MNH selected a significantly

different set of gradients. However, it still constrains the inverted emissions towards the same levels of emissions as in the reference inversion (typically differences in monthly emissions are $<5\%$).

The improvement of the reference inversion compared to the initial inversion demonstrates the need for a narrow definition of the wind direction ranges, and more generally the need for a very careful selection of CO_2 data. This reveals the asset of following as much as possible the concept of assimilating cross-city CO_2 gradients to control the emissions at the whole city scale, and to filter out the poorly modelled influence of fluxes outside the Paris urban area. The positive insights from the evaluation of our results also strengthens the confidence in this relatively simple concept to estimate monthly budgets of the city emissions, even if it relies on the assimilation of a relatively small amount of data.

4.2 Problems to be solved

The different inversion tests still raise concerns for the inversion of the cities' monthly emission budgets. We expected that cross-city gradients would be weakly sensitive to the uncertainties in the distribution of the emissions within the Paris region and 6-h windows. The inversion results, however, are significantly affected by changes in the emission distribution. It reveals the need to rely on robust, high resolution emission maps such as those produced by local agencies like AIRPARIF. However, many cities do not have such local inventories.

Bréon et al. (2015) have shown that the selection of afternoon data provide little constraint on night-time emissions. This is problematic since the diurnal cycle is highly uncertain in inventories. However, the similarity between FLAT_{mD} and FLAT_{mH} results seems to indicate that the poor representation of the diurnal cycle in FLAT_{mD} does not much impact the inverted monthly emissions. The poor representation of the day-to-day variations in both flat priors is the main explanation for the positive bias in the annual estimates between these tests and the reference inversion. The dependence of the inversion to the prior day-to-day variations within the months can be explained by the large number of days, even sometimes weeks, during which no gradients are selected for the inversion. This is primarily due to the small number of sites available for this study, and thus to the relatively small wind sectors by which we select cross-city gradients. Therefore, one can hope that this limitation could be overcome by an expansion of the observation network with stations all around the Paris urban area. This could ensure a continuous monitoring of the cross-city CO_2 gradients. The lack of data hinders the results of all inversions for specific months such as September, November, April, May and July, when less than 30 1-hour mean gradients are assimilated. The month-to-month variability is thus often driven by the variability of the data availability. Results at the monthly scale are thus not systematically consistent with the different sensitivity tests. Monthly estimates can be weakened by missing or over-weighting high variations in the emissions over short time periods (e.g., due to a cold event).

In December, the number of assimilated data is relatively high for both the reference inversion and INV_{MNH} . However, while the inversions increase the emissions compared to AIRPARIF 2008 during December when using ECMWF data and all gradients (SW and NE gradients), this is not the case when assimilating subsets of the cross-city gradients only, or when using Meso-NH/TB. Consequently, there is no peak of inverted emission estimates in December. Neither is this a robust feature of the reference inversion. The absence of an emission peak in December is associated with the assimilation of NE gradients (i.e.,

due to the assimilation of NE gradients only, or, to the use of the Meso-NH/TEB meteorology which selects a larger fraction of NE gradients than its ECMWF counterpart).

More generally, the assimilation of NE gradients seems to raise concerns while more satisfying results are obtained when using SW gradients. This applies also to the initial inversion, for which the NE direction corresponds to wider wind direction ranges. Thus, the problem cannot be related to a very specific source NE of Paris. When the wind blows from NE, the signature of emissions from remote, highly urbanised and industrialised areas (North-Eastern France, Benelux and Western Germany) should impact the CO₂ fields in the Paris area. On the opposite, the regions between the Atlantic Ocean and Paris are mostly rural. While the computation of gradients is an efficient way of limiting the signatures of the fluxes outside the Paris area on assimilated data, it does not ensure a total removal of such signatures. The large-scale signature of the remote natural fluxes from SW may be more easily modelled or filtered out by the computation of gradients in the Paris area than the one from NE. This could explain why the assimilation of NE gradients is more problematic than that of SW gradients. This could reveal another limitation in assimilating cross-city gradients. The high temporal variability of the ratio of assimilated NE gradients to SW gradients may be problematic for the monitoring of the month-to-month variability of the city emissions.

The last major issue is the limited confidence in the posterior uncertainties computed by the inversion system. We purposely avoided analysing them in details in Sect. 3. They provide qualitative insights on the behaviour of the inversion, i.e., posterior uncertainties remain close to the prior ones for night-time emissions, which are not strongly constrained by using only afternoon CO₂ data (Bréon et al., 2015). The posterior uncertainties also vary as a function of the number of assimilated data. The different estimates from the sensitivity tests generally lie in the 68 % confidence (1- σ) interval of the reference inversion. However, the posterior uncertainties look generally very low for specific months, despite the lack of confidence in the specific monthly estimates as discussed above, and despite the very limited number of assimilated data. During February and March, the posterior uncertainties from the reference inversion are lower than 0.69 MtCO₂month⁻¹. The large emission decrease of 1.32 MtCO₂month⁻¹ from February to March seems surprising. The relative difference between the posterior and prior uncertainties when moving from the initial inversion to the more reliable reference inversion demonstrates how misleading the interpretation of theoretical uncertainties can be when the configuration of the inversion is not perfect. However, even though the configuration is not perfect, the misfits between posterior estimates and observations are still smaller than between prior estimates and observations. This gives a stronger confidence in posterior emission estimates than in the posterior uncertainties of these emissions. Sensitivity tests with the analysis of the posterior estimates only were conducted to give a better picture of the strength of the measurement constraint.

4.3 Perspectives

Despite these concerns, the results from this study are promising and several methodological improvements were found. The Lagrangian inversion test accounts for the time air parcels need to pass from the upwind site over the urban area to the downwind site. The lack of data, however, prevented this inversion from significantly departing from its prior emission estimate. Such a strategy would be more appropriate if a larger amount of data was available, but it is impractical for our limited network:

it exacerbates the loss of data from already strict gradient selection criteria and degrades the overall emission retrieval compared to this reference inversion.

The expansion of the network, and in particular a full encirclement of the city with at least 8 sites (given that the wind ranges for the selection of gradients between one upwind site and one downwind site cover 30 degrees in this study) should strengthen the results and could allow applying such new techniques that result in a stricter gradient selection. However, relying on such an increase of the measurement network may not be sufficient. Exploiting more information from the available dataset without violating or undermining our assumptions on the selection of cross-city upwind-downwind gradients is a requirement to strengthen the observational constraint of the inversion. The Paris observation network has been set back since September 2014 in the framework of the CARBOCOUNT-CITY and LE CO₂ PARISIEN projects. Both projects aim to deploy more measurement sites than the CO₂-MEGAPARIS project. However, relying on such a measurement network expansion may not be sufficient. New methods should be developed to exploit urban measurements (Bréon et al., 2015) which also solve for the spatial distribution of the emissions. This in turn, could help assimilating data that do not necessarily bear the signature of the emissions from a large part of the city. Finally, developing methods to exploit late morning or evening measurements would be necessary to constrain night-time fluxes. This is not necessary to improve the knowledge on the emissions based on atmospheric inversion, but this is necessary to develop accurate tools for the operational monitoring and verification of the emissions based on this approach.

Even though it applies to the specific case of monitoring the CO₂ emissions from Paris, this study demonstrates the potential of an approach which can be adapted to a wide range of cities. It is currently tested in the city of Recife in Brazil. The urban surrounding, spread, size, topography and meteorology of some cities increase the difficulty for catching cross-city downwind-upwind gradients, and different strategies may be more adapted for such cases. The atmospheric inversion of the city emissions is still an emerging activity, but the present results already raise some confidence in this concept, especially since many other resources (combining CO₂ atmospheric inversions with air quality monitoring, the development of new measurement types) could help overcoming the remaining challenges.

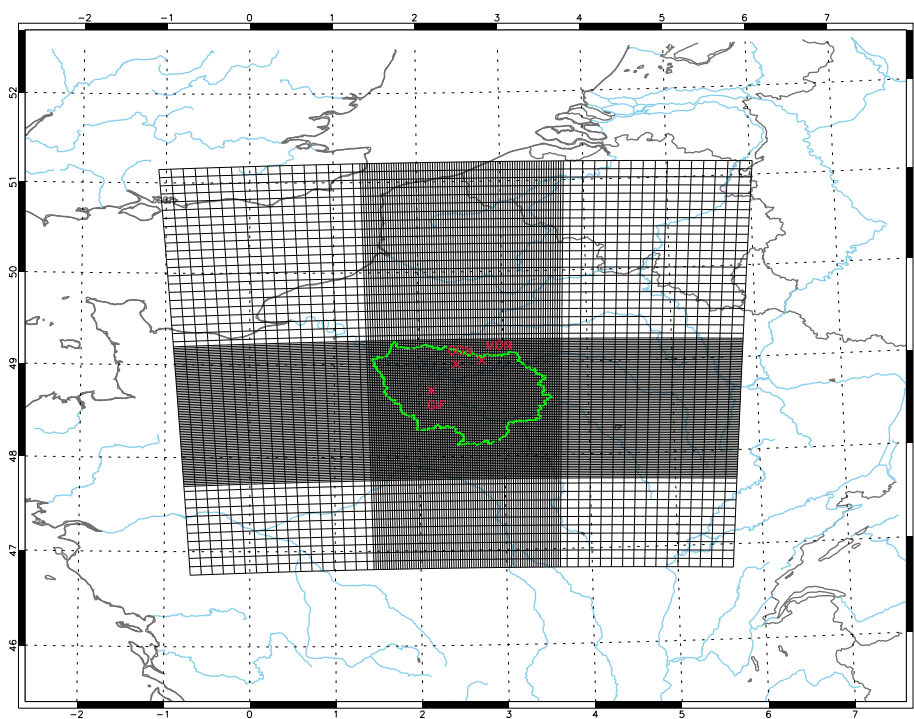

Figure 1. Map of the Northern France modelling domain. The monitoring sites are depicted as red crosses, while the green line denotes the boundaries of the Île-de-France region. Black lines show the model grid: 2 km × 2 km spatial resolution in the centre, 2 km × 10 km and 10 km × 10 km spatial resolution for the surroundings, respectively.

Figure 2. Afternoon (12–16 h) CO₂ data availability during the CO₂-MEGAPARIS project (August 2010–July 2011) for the different monitoring sites used in this study. Available hourly observed data are displayed as grey vertical lines. Red and blue: observations that are actually assimilated when using the reference (stringent) gradient selection criteria. Red: Selection when using ECMWF wind fields for the wind estimation. Blue: Selection when using Meso-NH/TEB wind fields for the wind estimation.

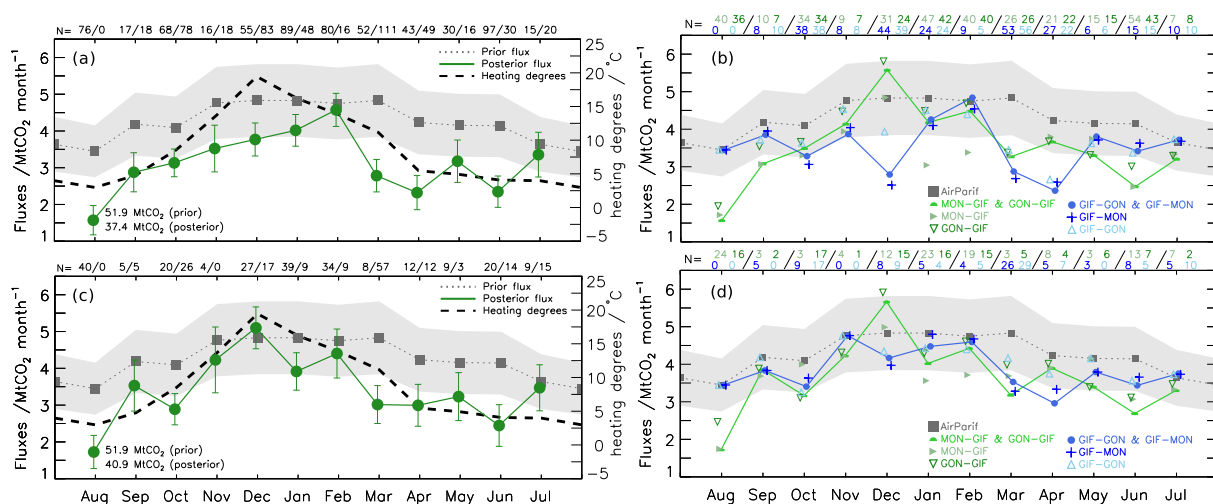

Figure 3. Monthly fossil fuel CO₂ emissions prior and posterior estimates from inversions in MtCO₂. Left column: Prior estimates (line) ± the standard deviation of uncertainties (shade) are displayed in grey while posterior estimates (line) ± the standard deviation (bars) are displayed in green. (a): Results using the initial inversion configuration. (b): Results using the reference inversion configuration. Monthly mean heating degrees for the centre of Paris, obtained from ECMWF’s operational analysis, are displayed in black. Numbers at the top are those of the CO₂ mole fraction gradients assimilated for SW- or NE winds, respectively. Prior and posterior annual emission estimates are displayed in the left bottom corner. Right column: Results using the initial (c) and reference (d) configuration of the inversions but assimilate only subsets of selected gradients (see Sect. 2.2.) Colour-coded numbers at the top are those of the assimilated gradient by each subset. Prior estimates (line) ± the standard deviation of uncertainties (shade) are displayed in grey. Symbols are slightly shifted to prevent overlap.

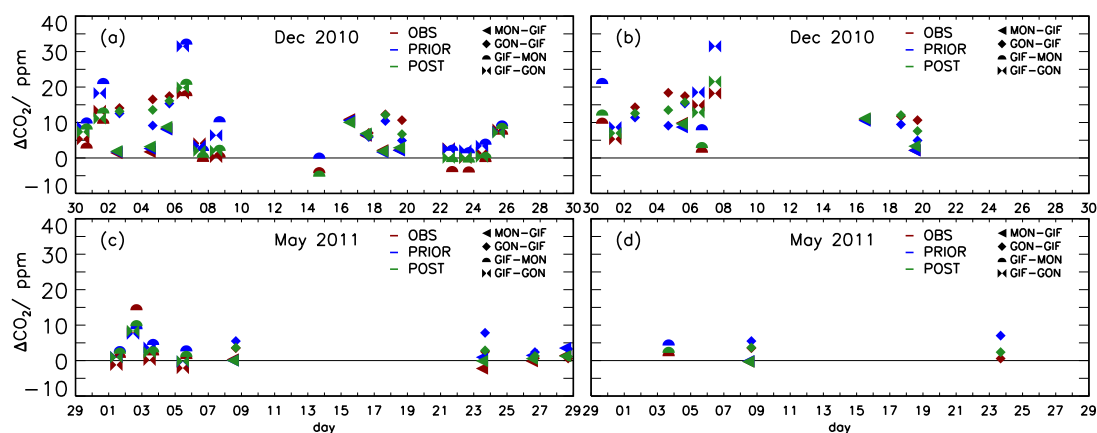

Figure 4. Time series of mean afternoon (12–16 h) CO_2 mole fraction differences (ΔCO_2) between downwind and upwind sites for December 2010 (upper panel) and May 2011 (lower panel). Measured CO_2 mole fraction differences are shown in red; prior and posterior CO_2 mole fraction differences in blue and green, respectively. (a) and (c): Selection of gradients relies on wind direction ranges of the initial inversion configuration. (b) and (d): Wind direction ranges are limited to a narrow SW/NE wind corridor across the city following the reference inversion configuration (see Sect. 2.2).

Figure 5. Results for the Lagrangian experiment (see Sect. 2.2 and Tab. 1). As for Fig. 3c, but a 2-hour time lag between downwind and upwind measurements is introduced.

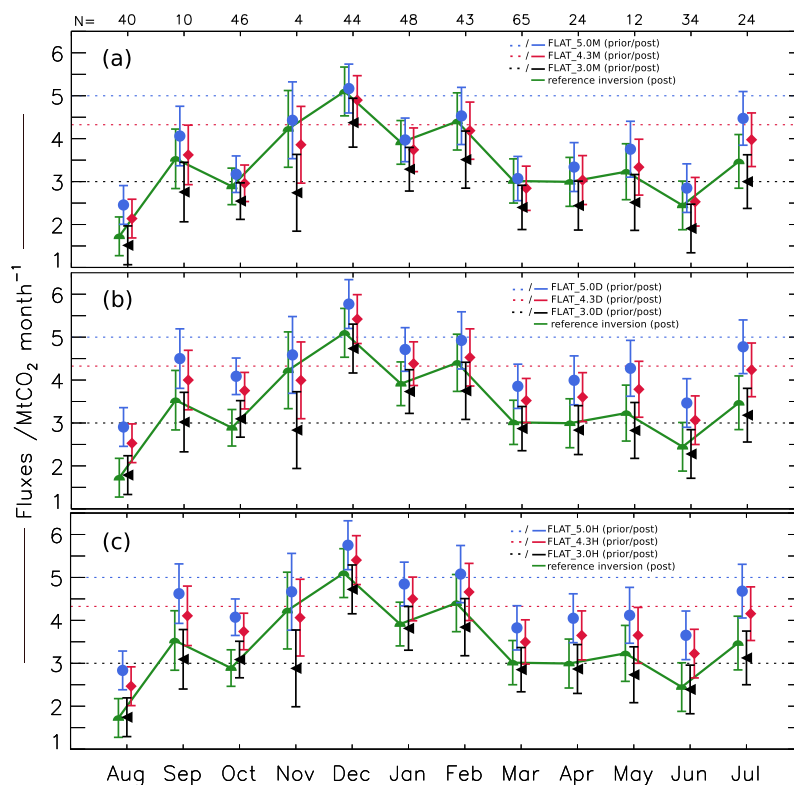

Figure 6. Sensitivity of monthly fossil fuel CO₂ emissions upon x_b . Monthly fossil fuel CO₂ estimates \pm the standard deviation of their uncertainties are shown for inversions that use 3 MtCO₂month⁻¹ (black), 4.3 MtCO₂month⁻¹ (red), and 5 MtCO₂month⁻¹ (blue) monthly prior emissions. (a) Priors are flat at monthly scale. (b) Priors are flat at daily scale. (c) Priors are flat at 6-h scale (see Sect. 2.6 for details). Fluxes obtained by the reference inversion are displayed in green. Numbers at the top denote the number of assimilated CO₂ mole fraction gradients. Symbols are slightly displaced to prevent overlap.

Figure 7. Sensitivity of monthly fossil fuel CO₂ emissions upon H^{map} . Red: Monthly fossil fuel CO₂ emissions estimates \pm the standard deviation of their uncertainties obtained from the reference inversion (green), INV_mapIER (red), and INV_IER (blue), respectively. Monthly fossil fuel CO₂ emissions prior estimates by AIRPARIF are depicted in black while IER's monthly estimates \pm the standard deviation of uncertainties are depicted in sky blue and grey, respectively. Note the different scale of the ordinate compared to Fig. 3, 5 and 6.

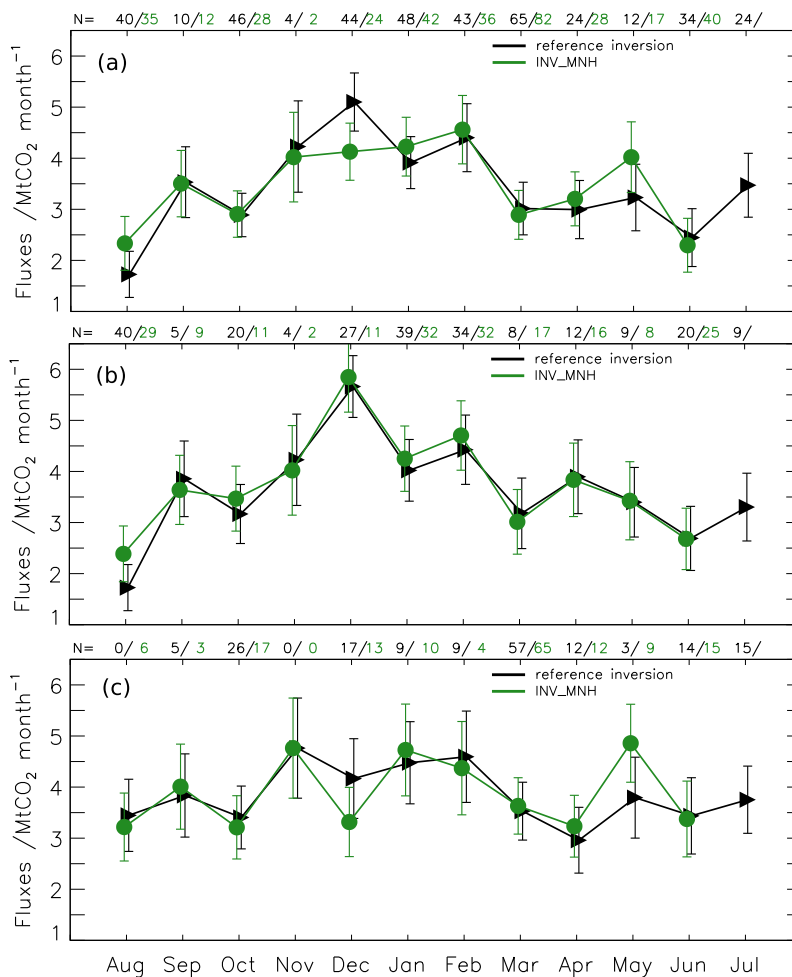

Figure 8. Sensitivity of monthly fossil fuel CO₂ budgets upon meteorological data. Displayed are the estimates \pm the standard deviation of their uncertainties obtained from the reference inversion (green) and INV_MNH (black), respectively. Numbers at the top denote color-coded the number of assimilated gradients. (a) Assimilation of both SW and NE gradients. (b) Assimilation of SW gradients. (c) Assimilation of NE gradients.

Figure A1. Time series of mean wind directions during afternoon (12–16 h) at the different monitoring sites used in this study. Solid horizontal lines denote the range of wind directions used by the reference (stringent) gradient selection (see Sect. 2.2). Red: Wind directions as simulated by ECMWF. Blue: Wind directions as simulated by Meso-NH/TEB. Yellow vertical lines indicate wind speed $> 3 \text{ ms}^{-1}$. Green vertical lines: Data are actually assimilated when using the reference (stringent) gradient selection criteria.

Figure A2. Time series of mean wind speed during afternoon (12–16 h) at the different monitoring sites used in this study. Solid horizontal lines denote a 3 m s^{-1} wind speed threshold. Red: Wind speed as simulated by ECMWF. Blue: Wind speed as simulated by Meso-NH/TEB. Yellow vertical lines indicate wind directions are within the range of wind direction used by the reference (stringent) gradient selection. Green vertical lines: Data are actually assimilated when using the reference (stringent) gradient selection criteria.

Table 1. Summary of the different inversion configuration and Île-de-France (IdF) annual fossil fuel CO₂ emissions from different inventories and inversion results. Priors that are flat at the monthly, daily and 6-hourly scale are denoted M, D and H, respectively (see section 2.6 for the details). Posterior estimates are derived from inversions using the operator and prior estimate indicated in the corresponding line of the table.
