Abstract. Aqueous multiphase chemistry in the atmosphere can lead to rapid transformation of organic compounds, forming highly oxidized low-volatility organic aerosol and, in some cases, light-absorbing (brown) carbon. Because liquid water is globally abundant, this chemistry could substantially impact climate, air quality, and health. Gas-phase precursors released from biogenic and anthropogenic sources are oxidized and fragmented, forming water-soluble gases that can undergo reactions in the aqueous-phase (in clouds, fogs, and wet aerosols) leading to the formation of secondary organic aerosol (SOA_{AQ}). Recent studies have highlighted the role of certain precursors

25

like glyoxal, methylglyoxal, glycolaldehyde, acetic acid, acetone, and epoxides in the
30 formation of SOA_{AQ}. The goal of this work is to identify additional precursors and
products that may be atmospherically important. In this study, ambient mixtures of water-
soluble gases were scrubbed from the atmosphere into water at Brent, Alabama during
the 2013 Southern Oxidant and Aerosol Study (SOAS). Hydroxyl (OH•) radical
oxidation experiments were conducted with the aqueous mixtures collected from SOAS
35 to better understand the formation of SOA through gas-phase followed by aqueous-phase
chemistry. Total aqueous-phase organic carbon concentrations for these mixtures ranged
from 92-179 $\mu\text{M-C}$, relevant for cloud and fog waters. Aqueous OH-reactive compounds
were primarily observed as odd ions in the positive ion mode by electrospray ionization
mass spectrometry (ESI-MS). Ultra high-resolution Fourier-transform ion cyclotron
40 resonance mass spectrometry (FT-ICR-MS) spectra and tandem MS (MS/MS)
fragmentation of these ions were consistent with the presence of carbonyls and tetrols.
Products were observed in the negative ion mode and included pyruvate and oxalate,
which were confirmed by ion chromatography. Pyruvate and oxalate have been found in
the particle phase in many locations (as salts and complexes). Thus, formation of
45 pyruvate/oxalate suggests the potential for aqueous processing of these ambient mixtures
to form SOA_{AQ}.

1 Introduction

Aqueous multiphase chemistry has the potential to alter the climate-relevant
50 properties and behavior of atmospheric aerosols. It is well-established that a major
pathway for secondary organic aerosol (SOA) formation is via the partitioning of semi-
volatile products of gas-phase photochemical reactions into preexisting organic
particulate matter (Seinfeld and Pankow, 2003). Semi-volatile partitioning theory is
widely used to model SOA (Odum et al., 1996; Seinfeld and Pankow, 2003; Donahue et
55 al., 2006). However differences between organic aerosol mass/properties predicted via
this formation mechanism and those measured in the atmosphere suggest that other

processes (e.g., aqueous chemistry) may also contribute (Foley et al., 2010; Hallquist et al., 2009).

Recent studies have highlighted the importance of water-soluble organic gases (WSOGs), liquid water, and condensed-phase reactions to SOA formation and properties (Ervens et al., 2011; Monge et al., 2012; Carlton and Turpin, 2013). Biogenic and anthropogenic gas-phase precursors are oxidized to form WSOGs such as glyoxal, methylglyoxal, glycolaldehyde, and acetone (Spaulding et al., 2003). These WSOGs are too volatile to form SOA through absorptive partitioning, but they can undergo aqueous reactions in clouds, fogs, and wet aerosols to form low-volatility products and “aqueous” SOA (SOA_{AQ}) (Blando and Turpin, 2000; Ervens et al., 2004; Kroll et al., 2005; Liggio et al., 2005; Lim et al., 2005; Heald et al., 2006; Loeffler et al., 2006; Sorooshian et al., 2006; Volkamer et al., 2006; Volkamer et al., 2007; Ervens et al., 2008; De Haan et al., 2009a; El Haddad et al., 2009; Ervens et al., 2011; Rossignol et al., 2014). Inclusion of aqueous chemistry of clouds, fogs, and wet aerosols in models and experiments helps to explain discrepancies in atmospheric observations of SOA that are not explained by semi-volatile partitioning theory, particularly high atmospheric O/C ratios, enrichment of organic aerosol aloft, and formation of oxalate, sulfur- and nitrogen-containing organics and high molecular weight compounds (Kawamura and Ikushima, 1993; Kawamura et al., 1996; Crahan et al., 2004; Kalberer et al., 2004; Herrmann et al., 2005; Altieri et al., 2006; Carlton et al., 2006; Heald et al., 2006; Volkamer et al., 2007; Nozière and Cordova, 2008; De Haan et al., 2009b; El Haddad et al., 2009; Galloway et al., 2009; Shapiro et al., 2009; Volkamer et al., 2009; Lim et al., 2010; Lin et al., 2010; Nozière et al., 2010; Perri et al., 2010; Sareen et al., 2010; Schwier et al., 2010; Sorooshian et al.,

80 2010; Sun et al., 2010; Ervens et al., 2011; Lee et al., 2011; Tan et al., 2012; Ervens et
al., 2013; He et al., 2013; Gaston et al., 2014; Ortiz-Montalvo et al., 2014). Although
uncertainties are large, modeling studies show that SOA_{AQ} is comparable in magnitude to
“traditional” SOA (Carlton et al., 2008; Fu et al., 2008; Fu et al., 2009; Gong et al., 2011;
Myriokefalitakis et al., 2011; Liu et al., 2012; Lin et al., 2014). However, SOA_{AQ}
85 precursors and their chemical evolution remain poorly understood.

Much of what we know about aqueous chemistry leading to SOA_{AQ} formation is
derived from laboratory studies with single precursors hypothesized to be important;
however, the most important precursors for SOA_{AQ} formation in the ambient
environment may remain unidentified. A small number of studies conducted with
90 ambient mixtures have provided insights into the pathways of SOA_{AQ} formation. For
example, photochemical oxidation of aerosol filter samples and cloud water from
Whistler, British Columbia suggest that water-soluble organic compounds of intermediate
volatility (e.g. *cis*-pinonic acid) can be important precursors for SOA_{AQ} (Lee et al., 2012).
Pyruvic acid oxidation experiments in Mt. Tai, China cloud water suggested a slowing of
95 pyruvic acid oxidation presumably due to competition for OH radicals with the complex
dissolved cloud water organics (Boris et al., 2014). However, further ambient
measurements are needed to identify precursors important for ambient SOA_{AQ} formation
in atmospheric waters.

This work reports, for the first time, results of aqueous OH radical oxidation
100 experiments conducted in ambient mixtures of water-soluble gases. Ambient mixtures
were collected in the southeast US during the Southern Oxidant and Aerosol Study
(SOAS) in the summer of 2013; experiments were used to identify water-soluble gases

that may serve as precursors of atmospheric aqueous SOA. This region has experienced an overall cooling trend in surface temperature over the second half of the twentieth century, compared to the warming trend observed elsewhere in the US (Robinson et al., 2002; Goldstein et al., 2009; Portmann et al., 2009). Biogenic sources dominate emissions in this region with varying degrees of impact from anthropogenic sources. Measurements by Nguyen et al. (2014) and model results by (Carlton and Turpin, 2013) indicate the significance of anthropogenic aerosol liquid water (ALW) in this region and support a role for ALW in SOA_{AQ} formation. In the southeast US, photochemistry and abundant liquid water coexist, making it an ideal location to study SOA_{AQ} formation through gas-phase followed by aqueous-phase chemistry. The objective of this work is to identify WSOGs important to SOA_{AQ} formation. Since OH oxidation experiments were conducted in dilute solution, we will also identify products expected through cloud/fog processing of ambient WSOG mixtures. Products may differ in aerosols, where solute concentrations are higher, and radical-radical chemistry and acid-catalyzed reactions (e.g. epoxide ring-opening reactions yielding tetrols and organosulfates from isoprene epoxydiol, IEPOX) are important. We expect that aqueous chemistry in clouds, fogs, and wet aerosols is a sink for reactants identified herein, and that this work will motivate laboratory studies and chemical modeling of newly identified aerosol/cloud precursors.

2 Methods

Samples of ambient water-soluble mixtures collected in mist chambers during the SOAS field study were used to conduct controlled aqueous OH radical oxidation experiments. Mass spectral techniques were used to tentatively identify compounds with

decreasing abundance in aqueous OH oxidation experiments, but not control experiments with the aim of identifying new aqueous chemistry precursors for further study. Ion chromatography was used to identify selected products.

130 **2.1 Mist chamber field sampling at SOAS (in Brent, AL)**

Water-soluble gases were scrubbed from filtered ambient air at the Centerville ground site in Brent, AL during SOAS. Samples were collected from June 1 – July 14, 2013 from 1 m above the sampling station roof through a 1.3 cm OD Teflon inlet (approximately 1.7 m in length). Four mist chambers (Anderson et al., 2008a; Anderson
135 et al., 2008b; Dibb et al., 1994; Hennigan et al., 2009) were operated in an air-conditioned trailer (indoor temperature, 25°C) at 25 L min⁻¹ in parallel for 4 hours, typically 2-3 times each day between 7 AM and 7 PM CDT. Particles were removed by passing the ambient air through a pre-baked quartz fiber filter (QFF) (Pall, 47mm) prior to introduction into the mist chamber.

140 The mist chambers were operated with 25 mL of 17.5 ± 0.5 MΩ ultra-pure water; additional water was added during the run to replace water lost by evaporation. Samples from all four mist chambers were composited daily and frozen in 35 – 40 mL (experiment-sized) aliquots. Total organic carbon (TOC) concentrations ranged from 45 – 180 μM-C (Supplementary Table S1). Prior to and at the end of a sampling day, each
145 mist chamber was cleaned using a 5-minute DI water wash step.

Based on daily forecast predictions, certain days were selected for intensive sampling (Supplementary Table S1). Intensive sampling during SOAS was conducted on days when high levels of isoprene, sulfate, and NO_x were predicted by the National

Center for Atmospheric Research (NCAR) using the Flexible Particle dispersion model
150 (FLEXPART) (Stohl et al., 2005) and the Model for Ozone and Related Chemical
Tracers (MOZART) (Emmons et al., 2010). In general, mist chamber samples on
intensive sampling days had higher organic content (TOC = 92-179 $\mu\text{M-C}$), and hence
we focused our experiments on those days and included two additional days from the
non-intensive period that had high TOC values (Table 1).

155

2.2 Aqueous OH radical oxidation in a cuvette chamber

Ambient SOAS field samples were exposed to OH radicals in a custom built
photochemical temperature-controlled (25°C) quartz cuvette reaction chamber. Ten
screw-capped quartz cuvettes (Spectrocell Inc., Orelan, PA) containing 3 mL of sample
160 were placed equidistant around a 254 nm mercury lamp (Heraeus Noblelight, Inc. Duluth,
GA) housed in a quartz sheath (Ace Glass Inc., Vineland, NJ). A solar spectrum lamp
was not used because the objective was to produce OH radicals by H_2O_2 photolysis,
rather than to mimic tropospheric photolysis. The chamber was protected from ambient
light by covering in aluminum foil. OH radicals ($1.25 \times 10^{-2} \mu\text{M} [\text{OH}] \text{ s}^{-1}$) were generated
165 *in situ* by photolysis of 125 $\mu\text{M} \text{H}_2\text{O}_2$, added to each cuvette prior to inserting the lamp.
While we can calculate the OH production rate from hydrogen peroxide photolysis
($1.25 \times 10^{-2} \mu\text{M} [\text{OH}] \text{ s}^{-1}$), the concentration of OH in the reaction vessel depends also on
the reactivity of the organics. If the WSOG mix behaves similarly to glyoxal, OH
concentrations would be on the order of 10^{-12} M (similar to Tan et al., 2009). Cuvettes
170 were removed at $t = 10, 20, 30, 40, 60, 80, 100, 120, 150$ min and any remaining H_2O_2
was destroyed by addition of 36 μL of 1% catalase (Sigma; 40,200 units/mg). A duplicate

cuvette was removed at $t = 40$ min to calculate method precision. The following control experiments were performed: 1) sample + H_2O_2 , 2) sample + UV, 3) H_2O_2 + UV, and 4) field water blank + OH. Replicate experiments were performed on selected samples.

175 Ambient conditions for sample collection are given in Table 1 for samples used in experiments.

2.3 Analytical methods

Samples and field water blanks from all collection days were characterized by
180 total organic carbon analysis (TOC; Shimadzu 5000A) and electrospray ionization mass spectrometry (ESI-MS; HP – Agilent 1100). Ion Chromatography (IC; Dionex ICS 3000) was used to analyze organic anions and track the formation of products and intermediates. Samples at each reaction time were analyzed by ESI-MS in positive and negative ion modes to identify precursors and products. Selected samples were also
185 analyzed by ultra-high resolution electrospray ionization Fourier-transform ion cyclotron resonance mass spectrometry (ESI-FT-ICR-MS) and tandem MS (MS-MS) on a Thermo-Finnigan LTQ-XL at Woods Hole Oceanographic Institute, MA to determine elemental composition and extract structural information on precursors. Analytical details and quality control measures have been described previously (Perri et al., 2009). Briefly, the
190 ESI quadrupole mass spectrometer was operated in positive and negative ion modes over a mass range of 50-1000 amu. In the negative ion mode, the mobile phase consisted of 1:1 methanol/0.05% formic acid in water; and in the positive ion mode, 0.05% formic acid in water. The fragmentor and capillary voltages for the ESI-MS were set at 40 V and 3000 V (nitrogen drying gas; 10 L min^{-1} ; $350\text{ }^\circ\text{C}$), respectively. Nitrobenzoic acid in the

195 negative ion mode and caffeine in the positive ion mode were used as mass calibrants. Standard mixtures were analyzed with each experimental sequence: acetic acid, pyruvic acid, nitric acid, succinic acid, tartaric acid, ammonium sulfate, and oxalic acid in the negative ion mode and glyoxal, methylglyoxal, and glycolaldehyde in the positive ion mode.

200 ESI ionization efficiency varies with sample mix and over time. However, the mass spectra of the mist chamber samples were similar across experimental days and the variability in the glyoxal, methylglyoxal, and glycolaldehyde standard ESI signals were 4-7% across analysis days, suggesting that ion abundance trends (Figure S1-S2) will reflect concentration trends. Six injections were averaged for each sample and data
205 retained for each ion abundance greater than zero within 95% confidence intervals. Ions were considered to be above detection limits if peaks were greater than the average plus three standard deviations of the water blank.

Organic acids were measured by IC (IonPac AS11-HC column; 30 °C, AG11-HC guard column) with conductivity detection (35 °C), using a Milli-Q water eluent and
210 KOH gradient method. For oxalate, the method precision is 22%, calculated as a pooled coefficient of variation (CV) from pairs of cuvettes removed at t=40 min. The analytical precision for oxalate is 19% (pooled CV) based on replicate analysis of 30% of samples. Analytical accuracy for oxalate is 7%. The limit of detection (LOD) for oxalate by this protocol has been previously determined to be 0.1 μM (Perri et al., 2009).

215 Samples from June 15 and June 30, 2013 were analyzed using ultra-high resolution FT-ICR-MS in the positive ion mode using 1:1 methanol/water as the mobile phase at 4 $\mu\text{L min}^{-1}$, capillary temperature of 260 °C and spray voltage 3.8-4.2 kV.

Weekly analysis of standards (caffeine, peptide-MRFA, ultramark, SDS, and sodium taurocholate) verified the mass accuracy < 2 ppm. Previously pyruvic acid and
220 peroxyhemiacetal standards analyzed with the same protocol were within 2 - 10 ppm. Five precursor masses were isolated (isolation width: $m/z = 2$) and fragmented by collision-induced dissociation (CID) (normalized collision energy: 26-33%) with helium in the ion trap (IT) and infrared multi photon dissociation (IRMPD) with a CO₂ laser. Elemental composition (within ± 1 ppm) and double bond equivalents of ions were
225 calculated by Midas Molecular Formula Calculator (v1.1). No restrictions were placed on the number of carbon, hydrogen, oxygen, nitrogen, sodium, and sulfur atoms included in the molecular formula calculations.

Compounds are detected in the ESI-MS by forming cluster ions with hydrogen, sodium, or ammonium in the positive ion mode; compounds are sometimes hydrated with
230 water or methanol. In the negative ion mode, ions are deprotonated.

3 Results & Discussion

OH oxidation experiments at concentrations relevant to cloud/fog water were conducted on samples collected June 11, 12, 15, 16, 20, 21, 29, and 30 of 2013, days on
235 which total organic carbon (TOC) was highest, ranging from 92-179 $\mu\text{M-C}$ in samples.

3.1 Precursors in SOAS samples

The concentration dynamics in experiments conducted with the 8 daily composites were similar. Positive ions at m/z 125, 129, 143, 173, and 187 exhibited
240 reactant-like trends (Figure 1; June 30 sample + OH), showing decreasing signal intensity

with increasing exposure to OH. These ions disappeared after 40 minutes of oxidation. Together, these ions account for roughly 30% of the total ion current in the positive mode in the experiment samples. In control experiments, the abundance of these ions did not change over time, as illustrated in Figure 1 (sample + UV and sample + H₂O₂) for the positive ion at m/z 187 in samples collected on June 15 and 30. Hence, reaction with UV or H₂O₂ alone does not explain the decreasing signals in the presence of OH radical. In control experiments where we generated OH radicals in field water blanks, these ions were not observed, confirming that they are not contaminants. Experiments conducted on all sample days showed the same reactants decreasing with exposure to OH, indicating that the water-soluble organics captured from the ambient daytime air in the mist chambers varied little across the study.

Elemental formulae assigned to precursor ions by Midas with corresponding MS-MS fragmentation data for the ions from June 15 and 30 samples are shown in Table 2. Both sampling days showed similar fragmentation spectra, consistent with the presence of the same parent compounds on both days, despite potential differences in the air mass on these days. MS-MS spectra were not obtained under the acquisition conditions of this work for positive ions at m/z 143, 129 and 125. Proposed structures for the positive ions at m/z 187 and 173 based on MS-MS data are shown in Figures 2 and 3. The O:C ratio for the reactant masses range from 0.1 - 0.8. In the following sections, we discuss individual reactants observed by ESI-MS. The discussion below is focused on the molecular formulas, rather than the detected ions, i.e. Na⁺ or H⁺.

m/z 187: This is the ion with the highest m/z observed by ESI-MS in the positive ion mode that follows a precursor-like trend (Figures 1 and 2). The composition

C₇H₁₆O₄Na is assigned by the Midas molecular formula calculator based on the exact
265 mass 187.0942 from FT-ICR MS, corresponding to the composition C₇H₁₆O₄ for the
neutral compound. The MS-MS shows loss of methanol, to give a product ion at *m/z*
155.0680 corresponding to the neutral molecular formula, C₆H₁₂O₃, consistent with
expectations for a sodium ion complex of a dihydroxy hemiacetal in methanol solution,
shown in Figure 2. In the absence of methanol, this compound would appear hydrated
270 with water as the C₆H₁₄O₄ tetrol, as shown in the blue box in Figure 2. The corresponding
gas-phase compound is shown in the tan box in Figure 2.

E-2-hexenal and *Z*-3-hexenal are unsaturated aldehydes that have frequently been
detected during field studies and are emitted to the atmosphere from vegetation due to
leaf wounding (O'Connor et al., 2006). The gas-phase oxidation of these two green leaf
275 volatiles, as shown in Figure 4a and 4b, could explain the presence of C₆H₁₂O₃ in the gas-
phase and C₆H₁₄O₄ in the aqueous-phase (Figure 2).

***m/z* 173:** On most sampling days this reactant mass has the highest abundance in
the positive mode ESI mass spectra (Supplementary Figure S1). Similar to other reactant
peaks, it reacts away within the first 40 minutes of exposure to OH in the cuvette
280 chamber (Figure 1). The Midas-suggested molecular formula for this parent ion (*m/z*
173.0782) and its two fragment ions at *m/z* 141.0523 and 129.0524 are C₆H₁₄O₄,
C₅H₁₀O₃, and C₄H₁₀O₃, respectively (a reactive parent ion with the formula C₄H₁₀O₃ was
also observed, and is discussed below).

A likely structure for positive mode *m/z* 173 is shown in Figure 3. In this case the
285 compound is proposed to be a C₅H₁₀O₃ aldehyde in the gas-phase (tan box in Figure 3)
and a C₅H₁₂O₄ tetrol in water (blue box in Figure 3). In the FT-ICR-MS it is seen

hydrated with methanol. The parent ion at m/z 173 loses methanol to form $C_5H_{10}O_3$ (m/z 141.0523), and it also loses C_2H_4O to form $C_4H_{10}O_3$ (m/z 129.0524). The aqueous oxidation precursor observed as $m/z+ 173$ and tentatively identified as the $C_5H_{10}O_3$ aldehyde shown in tan in Figure 3, could be derived from another green leaf volatile. Specifically, $C_5H_{10}O_3$ is consistent with the gas-phase oxidation product of (*E*)-2-methyl-2-butenal, another green leaf volatile (Figure 4c) (Jiménez et al., 2009; Lanza et al., 2008).

Positive ions at m/z 143, 129, and 125: No fragments were observed for these reactants under conditions of MS-MS acquisition in this work. The Midas-predicted molecular formulae for the ions at m/z 143.0676, 129.0520, and 125.096 are $C_5H_{12}O_3$, $C_4H_{10}O_3$, and $C_8H_{12}O$, respectively. Interestingly, the reactant detected at m/z 129 has the same mass as a fragment of the parent ion at m/z 173 discussed earlier (and the structure of the $C_4H_{10}O_3$ fragment shown in Figure 3 is a possible structure for m/z 129).

Methodological Limitations: In this work, we aim to collect the ambient mix of water-soluble gases into water at concentrations comparable to those found in clouds and fogs with the purpose of simulating cloud/fog-relevant OH oxidation chemistry and identifying previously unrecognized precursors of aqueous chemistry. Below we discuss limitations with respect to our ability to collect and store these aqueous mixtures and with respect to our ability to identify the OH-reactive compounds collected.

Mist chamber collection times (4 hr) were selected with the aim of collecting ambient mixtures of water-soluble gases near Henry's law equilibrium. Two pieces of evidence suggest that gas-aqueous partitioning of the WSOGs is close to Henry's Law equilibrium in our samples. In previous testing conducted in a different East Coast

310 location that is a recipient of long-range transport (i.e., central New Jersey), we found
that WSOG concentrations in the mist chamber leveled off after 1-3 hours of ambient
sampling, suggesting that the collected WSOG mixture approaches Henry's Law
equilibrium over these collection times. This is consistent with the one measurement we
have of breakthrough at SOAS, where we ran two mist chambers in series and found
315 TOC concentrations within +/- 11% of each other. These measurements suggest that a
representative mixture of the water-soluble gases entering the mist chambers were
collected.

However, WSOGs can be lost during sampling and storage through: 1) losses in
tubing and by adsorption to the QFF during collection, 2) reactions in the mist chamber
320 during collection with water-soluble ambient oxidants capable of penetrating the inlet
(e.g., ozone), and 3) losses during storage post collection. The QFF removes particles
upstream of the mist chambers. In the early stages of sampling, on the clean filter,
adsorption of gases on the filter will reduce the concentrations of gases sampled by the
mist chamber until these gases reach gas-phase – adsorbed-phase equilibrium. Using
325 glyoxal as a WSOG-surrogate and the work of (Mader and Pankow, 2001) we predict
that the measured WSOG in the mist chamber will be depleted for less than 2% of our
sampling time (after $<0.1 \text{ m}^3$) due to loss to the filter. Thus, we expect water-soluble
gases to penetrate through the QFF very efficiently for collection in the mist chamber
water. Losses to Teflon inlets and chamber walls (Krechmer et al., 2016) can be
330 significant and variable and may reduce the number of species we are able to collect and
identify in this work. While OH radicals are unlikely to penetrate the inlet, ozone might.

Thus some ozone could be scrubbed by the mist chambers and could result in oxidation of some unsaturated WSOGs during collection.

335 Though many organics are stable when stored frozen in water, IEPOX does not survive extended storage in water (confirmed with our organic synthesis collaborator). We expect this to be the case for isoprene hydroxyhydroperoxide (ISOPOOH) also. ISOPOOH is an OH oxidation product of isoprene, which is further oxidized by OH under low-NO conditions to form isomeric IEPOX (Paulot et al., 2009). IEPOX and ISOPOOH were present in the gas-phase during the SOAS campaign (Nguyen et al., 340 2015). They have relatively high Henry's Law constants (i.e., $(H_{L,IEPOX}=2.7 \times 10^6 \text{ M atm}^{-1})$). IEPOX was readily detected in ambient samples spiked with 3000 μM , 300 μM , and 30 μM of IEPOX, indicating that it can be ionized in our sample matrix. (Authentic *trans*- β -IEPOX, which is the predominant isomer of IEPOX, was synthesized for this purpose (Zhang et al., 2012).) However, it was not found in our ambient samples since it 345 is not stable when stored in water.

Together, the ions discussed herein account for 30% of the total ion abundance. The remaining 70% did not exhibit a clearly decreasing trend during OH oxidation experiments. It should be recognized that some water-soluble OH-reactive compounds might not have decreased during experiments because they were intermediates of 350 multiple precursors. Together, these methodological limitations suggest that additional OH-reactive water-soluble gases were likely present that we were unable to identify.

3.2 Product formation during aqueous oxidation experiments

355 Figure 5 shows significant formation of oxalate and pyruvate in OH radical
experiments conducted with all samples but not during the control experiments (Sample +
UV; Sample + H₂O₂). Pyruvate peaks around 60-80 min, which is earlier than the oxalate
peak at 100-120 min (Figure 5). Acetate + glycolate (which co-elute in the IC) also forms
in at least some samples and reacts away in the presence of OH (Supplementary Figure
360 S3). Sulfate and nitrate concentrations remained constant throughout the experiment as
measured by the IC. While there may be many sources of oxalate, aqueous OH radical
oxidation of pyruvate in the aqueous-phase is known to form oxalate at dilute (cloud-
relevant) concentrations (Carlton et al., 2006). Aqueous acetate oxidation is also a source
of oxalate (Tan et al., 2012). The concentration dynamics are consistent with a role for
365 these compounds in the formation of oxalate in the ambient mixtures although the
mechanisms by which pyruvate and acetate formed are not well constrained in these
experiments. These observations suggest that oxalate, pyruvate, and acetate/glycolate can
form in ambient mixtures of water-soluble gases in the southeast US in the presence of
clouds/fogs and oxidants. Pyruvate and oxalate have been observed primarily in the
370 particle phase in the atmosphere (Saxena and Hildemann, 1996; Limbeck et al., 2001;
Yao et al., 2002; Kawamura et al., 2003; Martinelango et al., 2007). Moreover, modeling
studies of oxalate, the most abundant dicarboxylic acid in the atmosphere, suggest that
aqueous chemistry is a large contributor of oxalate formation globally, making it a good
tracer for SOA_{AQ} formed in clouds and fogs (Myriokefalitakis et al., 2011). Above versus
375 below cloud measurements also support this (Sorooshian et al., 2010). Thus, the
experiments suggest that aqueous oxidation of ambient (southeastern US) water-soluble
mixtures at cloud/fog relevant concentrations has the potential to form material that

remains in the particle-phase species after droplet evaporation, i.e. SOA_{AQ}. However, the atmospheric prevalence of *particle-phase* oxalate can only be explained by the formation of salts and complexes, since oxalic acid is volatile and the volatility of oxalate salts is orders of magnitude lower than that of oxalic acid (Ortiz-Montalvo et al., 2014; Paciga et al., 2014). The aerosol at the SOAS ground site was acidic (campaign average pH~0.94) (Guo et al., 2015) and as a consequence oxalic acid may remain largely in the gas-phase in this environment, but may eventually react on more basic surfaces, e.g., coarse particles. Note that we expect the products of aqueous chemistry in wet aerosols to be different from those in clouds and fogs because of the extremely high (molar) solute concentrations in wet aerosols (Surratt et al., 2007; Noziere et al., 2008; Galloway et al., 2009; Lim et al., 2010; Sareen et al., 2010; Nguyen et al., 2012).

3.3 Atmospheric implications

We have tentatively characterized several water-soluble OH-reactive species collected at an isoprene-rich photochemically-active location in the southeastern U.S. In several cases compounds with the same elemental composition were measured in the gas-phase by HRToF-CIMS. The tentative structures for the proposed reactants are consistent with formation from green leaf volatiles and isoprene oxidation. Aqueous OH oxidation under dilute conditions (TOC approx. 100 μ M) relevant to fogs and clouds produced oxalate and pyruvate suggesting that cloud/fog processing of these compounds (and subsequent neutralization or complexation) is a potential source of SOA. The reactants characterized in this work are precursors for aqueous chemistry and are potentially important SOA_{AQ} precursors in all atmospheric waters, i.e. clouds, fogs, and wet aerosols.

The aqueous chemistry of these precursors is poorly understood and warrants further study.

4 Conclusions

405 We observed formation of pyruvate, oxalate, and acetate/glycolate during OH oxidation experiments conducted with ambient mixtures of WSOG from the southeastern US. The formation of these highly oxygenated organic acids indicates a potential for SOA_{aq} formation (e.g., upon neutralization with NH₃, metal complexation or heterogeneous reaction on coarse dust/salt particles). Given the acidity of SOAS fine
410 particles, we think it is unlikely that oxalate will be found in substantial quantities in the fine aerosol at the SOAS ground site.

We tentatively characterized several water-soluble reactive precursors which undergo aqueous chemistry and SOA_{aq} formation in wet aerosols, clouds and fogs at this location. High resolution mass spectrometric analyses suggest precursors had O:C
415 ranging from 0.125-0.80 and some are tentatively gas-phase oxidation products of green leaf volatiles. No distinct difference was seen in the aqueous oxidation of ambient samples collected across days during the SOAS field campaign. Further work involving organic synthesis, aqueous OH oxidation of authentic standards, and mass spectral analyses with pre-separation are likely to yield further insights into the aqueous chemistry
420 of these compounds in the future.

5 Acknowledgements

This research was funded by the EPA STAR grant 835412. The views expressed in this

manuscript are those of the authors and do not necessarily reflect the views or policies of
425 the U.S. Environmental Protection Agency. The authors acknowledge Melissa Soule and
funding sources of the WHOI FT-MS User's Facility (NSF OCE-0619608 and the
Gordon and Betty Moore Foundation). We also thank Jeffrey Kirland, Ronald Lauck, and
Nancy Sazo for their invaluable assistance in the laboratory and field, and Louisa
Emmons for the air quality forecasting during SOAS.

Tables & Figures

Table 1: Sample collection dates for which experiments were run and their sampling conditions. Temperature, relative humidity, and ozone ranges are shown both for the entire day and collection time period. Total organic carbon (TOC) accuracy and precision are verified with potassium hydrogen phthalate (KHP) standards to be better than 5% (Perri et al., 2009).

Collection date	Collection time	$\mu\text{M TOC}$	T ($^{\circ}\text{C}$) all day (coll. time)	RH (%) all day (coll. time)	O ₃ (ppbv) all day (coll. time)
11-Jun-2013	7am-7pm	139.5	22-32 (23-32)	53-99 (53-98)	9.9-38.2 (11.3-38.2)
12-Jun-2013	7am-7pm	179.7	23-33 (23-33)	48-94 (48-94)	13.1-41.8 (13.1-41.8)
15-Jun-2013	7am-7pm	117.0	17-31 (18-31)	45-94 (45-90)	11.6-53.4 (11.6-53.4)
16-Jun-2013	7am-7pm	108.2	22-32 (22-32)	53-93 (53-84)	2.6-41.7 (23.1-41.7)
20-Jun-2013	8am-5pm	131.5	20-30 (21-30)	55-98 (59-94)	4.8-52.2 (6.2-42.8)
21-Jun-2013	10am-6pm	104.4	20-30 (25-30)	50-93 (50-78)	16.6-45.2 (30.3-45.2)
29-Jun-2013	7am-7pm	92.0	21-31 (22-31)	43-100 (43-100)	16.3-53.7 (16.3-53.7)
30-Jun-2013	7am-7pm	98.7	20-30 (20-30)	38-100 (38-100)	1-53.5 (1-53.5)

Table 2: Elemental formulas assigned to precursor ions using ESI-FT-ICR MS in the positive ionization mode and Midas Molecular Formula Calculator. MS/MS fragmentation data is also shown.

Precursor peak using ESI-MS	Positive mode <i>m/z</i> (using FT-ICR)	[M+Na] ⁺ or [M+H] ⁺	Mol. Wt.	Double bond equivalents
187	187.0942	C ₇ H ₁₆ O ₄ Na	164.1043	0
	155.0680	C ₆ H ₁₂ O ₃ Na	132.0786	1
173	173.0782	C ₆ H ₁₄ O ₄ Na	150.0887	0
	141.0523	C ₅ H ₁₀ O ₃ Na	118.0625	1
	129.0524	C ₄ H ₁₀ O ₃ Na	106.0625	0
143	143.0676	C ₅ H ₁₂ O ₃ Na	120.0781	0
129	129.0520	C ₄ H ₁₀ O ₃ Na	106.0625	0
125	125.096	C ₈ H ₁₃ O	124.0883	3

770

Figure 1. Positive ions (ESI-MS) exhibiting precursor-like trends during aqueous OH-radical oxidation experiments with the ambient mixtures collected on June 30. All days show similar trends, with all 5 reactant masses showing statistically significant decreasing trends as compared to the control experiments. Controls (sample + UV, sample + H₂O₂) shown for *m/z* 187; other masses show similar trends.

780

Figure 2. Proposed structure for the positive ion at m/z 187. The top structure is the parent compound detected as a reactant in the ESI-MS; the following structures show the MS/MS fragments. This compound would take the forms shown in the shaded boxes when present in atmospheric air and water.

785

Figure 3. Proposed structure for the positive ion at m/z 173. The top structures in each panel are the parent compound detected as a reactant in the ESI-MS; the following structures show the MS/MS fragments. This compound would take the forms shown in

790

the shaded boxes when present in atmospheric air and water.

Figure 4: Gas-phase oxidation of (a) *E*-2-hexenal and (b) *Z*-3-hexenal and (c) (*E*)-2-methyl-2-butenal.

800

Figure 5. (a) Oxalate (by IC) for all OH radical oxidation experiments conducted with ambient samples (Table 1). (b) Abundance of the negative ion at m/z 87 (pyruvate) as observed in the ESI-MS when the ambient SOAS samples are exposed to OH. Error bars represent the pooled coefficient of variation calculated across experimental days. Note that oxalate and pyruvate are formed in all samples in the presence, but not the absence, of OH. Gray points represent control experiments (June 11 sample + UV, June 11 sample + H₂O₂, June 30 field water blank + OH).
