20 **Abstract**

21 This work presents an analysis of the physical properties of sub-micrometer aerosol particles  
22 measured at the high Arctic site Villum Research Station, Station Nord (VRS), northeast Greenland  
23 between July 2010 and February 2013. The study focuses on particle number concentrations,  
24 particle number size distributions, the occurrence of new particle formation (NPF) events and their  
25 seasonality in the high Arctic, where observations and characterization of such aerosol particle  
26 properties and corresponding events are rare and understanding of related processes is lacking.

1 A clear accumulation mode was observed during the darker months from October until mid-May,  
2 which became considerably more pronounced during the prominent Arctic haze months from March  
3 to mid-May. In contrast, nucleation and Aitken-mode particles were predominantly observed during  
4 the summer months. Analysis of wind direction and wind speed indicated possible contributions of  
5 marine sources from the easterly side of the station to the observed summertime particle number  
6 concentrations, while southwesterly to westerly winds dominated during the darker months. NPF  
7 events lasting from hours to days were mostly observed from June until August, with fewer events  
8 observed during the months with less sunlight March, April, September, and October. The results  
9 tend to indicate that ozone ( $O_3$ ) might be weakly anti-correlated with particle number  
10 concentrations of the nucleation mode range (10-30 nm) in almost half of the NPF events, while no  
11 positive correlation was observed. Calculations of air-mass back trajectories using the Hybrid  
12 Single Particle Lagrangian Integrated Trajectory (HYSPPLIT) model for the NPF event days  
13 suggested that the onset or interruption of events could possibly be explained by changes in air mass  
14 origin. A map of event occurrence probability was computed, indicating that southerly air masses  
15 from over the Greenland Sea were more likely linked to those events.

## 16 **1. Introduction**

17 Climate change driven by anthropogenic greenhouse gas emissions is a global challenge. In the  
18 Arctic, the warming climate has already led to an earlier onset of spring-ice melt, later freeze-up  
19 and decreasing sea-ice extent (Zwally et al., 2002; Markus et al., 2009; Stroeve et al., 2012). The  
20 reduction of the Earth's albedo due to ice loss subsequently impacts the radiative balance of the  
21 Earth through a positive feedback, leading to further warming. As a result, the Arctic has been  
22 considered a manifestation of global warming with the rate of temperature increase in the region  
23 being twice as high as the rest of the world (IPCC, 2013; ACIA, 2005), up to 8 - 9 °C along the east  
24 coast of Greenland (Stendel et al., 2008). In addition to long-lived greenhouse gases, short-lived  
25 climate forcers including tropospheric ozone, aerosols and black carbon also play a significant role  
26 affecting the radiative balance in the Arctic (Quinn et al., 2008; Bond et al., 2013; IPCC, 2013).

27 Aerosol particles influence the radiative balance in the Arctic in many ways, through their ability to  
28 absorb and scatter incoming solar radiation or by acting as cloud condensation nuclei to form cloud  
29 and fog droplets. The presence of low level liquid clouds above bright ice- and snow-covered  
30 surfaces in the Arctic could lead to increasing near-surface temperature as opposed to a cooling  
31 effect observed in most other global regions (Shupe and Intrieri, 2004; Bennartz et al., 2013),  
32 though the effect is probably small (AMAP, 2011). At the same time, deposition of black carbon on  
33 Arctic snow- and ice-covered surfaces accelerates surface heating and ice melting in early spring

1 (Hansen and Nazarenko, 2004; Flanner et al., 2007; Flanner et al., 2009). It is thus crucial to  
2 investigate the dynamics of atmospheric aerosol particles observed in the Arctic (involving the  
3 formation, concentration, physico-chemical properties, temporal variability and transport) to  
4 understand their direct and indirect effects on the radiation budget.

5 It is well known that during each winter extending into spring, Arctic aerosol particles containing  
6 mineral dust, black carbon, heavy metals, elements, sulfur and nitrogen compounds are detected in  
7 elevated concentrations. This has been attributed to the annually recurring Arctic haze phenomenon,  
8 which is related to distant latitude anthropogenic pollution (Li and Barrie, 1993; Quinn et al., 2002;  
9 Ström et al., 2003; Heidam et al., 2004; Heidam et al., 1999; Nguyen et al., 2013). The focus was  
10 thus on long-range transported aerosols, which are expected to be aged due to the long transport  
11 distance from mid-latitude source regions.

12 A number of studies have reported in-situ formation of new aerosol particles in the Arctic, which  
13 mostly involved new particle formation in the Arctic boundary layer. The first observations of the  
14 occurrence of an ultrafine particle mode ( $< 20$  nm) in the Arctic marine boundary layer during  
15 summer and autumn were reported by Wiedensohler et al. (1996) and Covert et al. (1996).  
16 Observations of small aerosol particles during the summer period have also been reported at the  
17 Zeppelin mountain site, Svalbard ( $11.9^{\circ}\text{E}$ ,  $78.9^{\circ}\text{N}$ , 478 m a.s.l.) within the Arctic boundary layer  
18 (Ström et al., 2003; Tunved et al., 2013). The current understanding on mechanisms of new particle  
19 formation in the marine boundary layer over the Arctic Ocean is unclear, due to the low  
20 concentration of nucleating agents such as sulfuric acid in the marine boundary layer (Pirjola et al.,  
21 2000; Karl et al., 2012), in addition to the limited number of observational data. Growth of ultrafine  
22 particles has been observed at Summit, Greenland ( $38.4^{\circ}\text{W}$ ,  $72.6^{\circ}\text{N}$ , 3200 m a.s.l.) (Ziemba et al.,  
23 2010). Quinn et al. (2002) also found an increase in particle number concentrations during the  
24 summer months at Barrow, Alaska ( $156.6^{\circ}\text{W}$ ,  $71.3^{\circ}\text{N}$ , 8 m a.s.l.), which was attributed to the  
25 formation of smaller particles. A correlation between summertime particle number concentrations  
26 and the biogenic production of methane sulfonate ( $\text{MSA}^-$ ) was shown, indicating that the production  
27 of summertime particles may be associated with biogenic sulfur (Quinn et al., 2002). Similar  
28 finding has been recently reported by Leaitch et al. (2013) based on observations from Alert,  
29 Nunavut. Heintzenberg et al. (2015) observed newly formed small aerosol particles during several  
30 cruises to the summer central Arctic Ocean and suggested that they could originate from around the  
31 Arctic region, more specifically related to air masses passing by open waters prior to the  
32 observation point. Asmi et al. (2016) also recently suggested that NPF was more common in marine  
33 air masses compared to continental air flows. Meanwhile, source regions of aerosol particles in the  
34 Arctic could be very different (Hirdman et al., 2010). Barrow is mostly influenced by North

1 America and Arctic basin with some Russian and Siberian sources (Quinn et al., 2002). Summit,  
2 which is located above the planetary boundary layer, receives frequent long-range transported  
3 pollution from North America and extensively from Eurasia during wintertime (Kahl et al., 1997;  
4 Hirdman et al., 2010). The mountainous site Zeppelin (Tunved et al., 2013) and the ground level  
5 site VRS (16°40'W, 81°36'N, 30 m a.s.l.) (Heidam et al., 2004; Nguyen et al., 2013) both receive  
6 long range transported pollution predominantly from Eurasia during winter and spring. Zeppelin is  
7 often located south of the Polar Front receiving transport from the Atlantic Ocean during summer  
8 (Tunved et al., 2013). Svalbard is also influenced by the Gulf Stream (Pnyushkov et al., 2013) and  
9 surrounded by open sea during summertime. VRS is influenced by the ice stream from the Arctic  
10 Ocean along the east coast of Greenland (Stendel et al., 2008; Kwok, 2009) and surrounded by  
11 multi-year sea ice, with limited first-year ice along the coast. Such differences could have  
12 considerable impacts on NPF events and also aerosol particle properties, which requires  
13 investigations at high spatial resolution in the Arctic.

14 VRS, Station Nord is a unique coastal station located close to sea level, representing the conditions  
15 of the high Arctic throughout the year. Until date, there is only one observation and characterization  
16 of NPF events at Alert, Nunavut (Leitch et al., 2013). Understanding of particle size distribution,  
17 seasonality as well as related mechanisms and processes of NPF events are thus lacking from high  
18 Arctic region.

19 This study aims to characterize the formation, concentration, physical properties and seasonality of  
20 atmospheric aerosols based on particle number size distributions at VRS. The occurrence of NPF  
21 events was investigated in detail. The events were classified and analyzed together with ozone (O<sub>3</sub>)  
22 and nitrogen oxides (NO<sub>x</sub> = NO + NO<sub>2</sub>). Wind direction and wind speed were analyzed to  
23 investigate the impacts of source regions on the observed seasonality of particle number size  
24 distribution. The source regions of new particle formation were mapped based on calculations of air  
25 mass back trajectories using the HYSPLIT model during event days and non-event days. A  
26 probability map for NPF event occurrence was computed.

## 27 **2. Methods**

### 28 **2.1. Measurement site**

29 Aerosol particles and trace gases were measured at the measurement site “Flyger’s Hut”, VRS,  
30 Station Nord in northeast Greenland (81°36'N, 16°40'W, 30 m a.s.l.). The site is located on a small  
31 peninsula (Princess Ingeborgs Peninsula) at approximately 2.5 km southeast of a small Danish  
32 military base housing a crew of five soldiers (**Fig. 1**). Electricity at “Flyger’s Hut” is supplied from  
33 a local JET A-1 fuel generator located inside the military base. The remote location of the station

1 implies a minor, though unavoidable, contribution of local anthropogenic pollution originating from  
2 the military camp. The station is surrounded by multi-year sea ice, with limited bare ground  
3 occasionally and limited first-year ice along the coast of Greenland during the summer months. At  
4 VRS, Station Nord, polar sunrise is observed in the end of February, while polar day prevails from  
5 mid-April to the beginning of September and polar night prevails from mid-October to the end of  
6 February.

## 7 **2.2. Instrumentation**

### 8 **2.2.1. Mobility Particle Size Spectrometer**

9 Measurement of particle number size distributions at Station Nord was initiated in July 2010 using a  
10 TROPOS-type Mobility Particle Size Spectrometer as described in Wiedensohler et al. (2012).  
11 Briefly, the instrument consists of a medium Vienna-type Differential Mobility Analyzer (DMA)  
12 followed by a butanol-based Condensation Particle Counter (CPC 3772 by TSI Inc., Shoreview,  
13 USA). The DMA design is described in Winklmayr et al. (1991). The system is operated at  $1 \text{ l min}^{-1}$   
14 aerosol flow rate and  $5 \text{ l min}^{-1}$  sheath air flow rate. The DMA sheath flow is circulated in closed  
15 loop, facilitated by a regulated air blower. This technical setup allows measurements across a  
16 particle size range from 10 to 900 nm in diameter. The time resolution of the instrument is 5 min,  
17 including up-scan and down-scan.

18 The instrument was specifically designed to allow long-term operation with minimum maintenance  
19 as follows. The DMA sheath air flow rate was continuously measured using a calibrated mass flow  
20 sensor. The DMA aerosol flow rate was monitored by a pressure drop measurement over a  
21 calibrated capillary. A computer-based control program adjusted the sheath air flow rate after each  
22 measurement of the particle number size distribution. Systematic deviations in the sample flow rate,  
23 which was controlled by a critical orifice in the CPC were monitored and corrected for in the  
24 successive size distribution evaluation. Additionally, absolute pressure was measured at the inlet of  
25 the system to detect any substantial technical problems such as clogging of the inlet. Temperature  
26 and relative humidity (RH) were monitored at several positions inside the instrument. The RH  
27 inside the DMA is the most critical parameter, since excessive moisture would allow particles to  
28 grow much beyond their nominal dry diameter. At VRS, Station Nord, RH is usually not a critical  
29 issue, as the climate is cold and arid with low humidity most of the year. The temperature in the  
30 laboratory is mostly considerably higher than outdoor temperature, implying that substantial drying  
31 of the aerosol is not needed most of the time during sample intake into the laboratory.

1 Sampling was provided from a conductive flow tube. An air blower was used to suck a main air  
2 flow (much higher than the sample flow) into the main sampling inlet, and the air sampling was  
3 probed from this main air flow using a ¼ inch tubing directed into the main air flow. The main  
4 sampling inlet was not heated; however no icing issue was observed for the inlet. The main  
5 sampling inlet did not have any size cut-off. Sampling was performed at standard conditions of  
6 about 20 °C.

### 7 **2.2.2. Data processing**

8 The raw particle electrical mobility distributions collected by the mobility particle size spectrometer  
9 were processed by a linear inversion algorithm presented in Pfeifer et al. (2014). Specific DMA  
10 transfer function was used for inverting the data, while CPC efficiency and diffusion losses were  
11 corrected for during the inversion.

12 As a first part of quality control, any data associated with DMA excess air RH above 50 % and  
13 sheath air temperature above 30 °C were excluded from further data analysis, as recommended by  
14 ACTRIS and WMO-GAW ([http://www.wmo-gaw-wcc-aerosol-physics.org/recommen-](http://www.wmo-gaw-wcc-aerosol-physics.org/recommendations.html)  
15 [dations.html](http://www.wmo-gaw-wcc-aerosol-physics.org/recommendations.html)). These incidents were only observed on a few days during the study period.

16 Subsequently, daily particle number size distributions were plotted to inspect any sudden increase in  
17 the particle number concentration above the background. If such sudden increase in particle number  
18 concentration (without any detectable particle growth) coincided with sudden elevation of of NO<sub>x</sub>  
19 concentration, they were interpreted as local pollution events and excluded from the data set. These  
20 local pollution events were observed throughout the year at the station. **Fig. 2** shows the extent of  
21 data coverage over the study period. Gaps in the data set (most notably in 2011) were due to  
22 excluded data with flow uncertainties. 2012 was the year with the best data coverage, with the  
23 lowest percentage of ca. 78 % in March while exceeding 90 % in most other months. The year 2012  
24 was therefore chosen to examine the seasonality of Arctic aerosols in detail. Data from the other  
25 years were used to support the analysis of event statistics. Details of the data period used are  
26 provided in the caption of the relevant tables or figures.

### 27 **2.2.3. Gas phase and meteorological parameters**

28 O<sub>3</sub> was measured using an API photometric O<sub>3</sub> analyzer (M400). The results were averaged to a  
29 time resolution of 30 min. The detection limit was 1 ppbv with an uncertainty of 3 % and 6 % for

1 measured concentrations above and below 10 ppbv, respectively. The uncertainties were calculated  
2 at 95 % confidence interval.

3 NO<sub>x</sub> was averaged to a time resolution of 30 min (Teledyne API M200AU, San Diego, CA) with a  
4 precision of 5 % and a detection limit of 150 ppt. The calibration was checked weekly using 345  
5 ppb NO span gas while zero gas was added each 25 hour. NO<sub>x</sub> was sampled at a flow rate of 1 l  
6 min<sup>-1</sup>. Coverage of O<sub>3</sub> and NO<sub>x</sub> data in this study are indicated as the corresponding blue and red  
7 line in **Fig. 2**.

8 Wind speed and wind direction data were obtained from a sonic anemometer (METEK, USA-1,  
9 heated) for the period from April 2011 to April 2013. The sonic is placed on a horizontal boom at  
10 the top of a 9 meter mast. The mast is situated about 36 m east-southeast from the measurement hut  
11 at ca. 62 meter asl. This means that the fetch limited wind direction is 300 degree where the hut (2.8  
12 m) is an obstacle. The area is flat for 10-20 km in all wind directions. In winter periods fewer data  
13 were obtained due to frost on the anemometer when temperature was below approximately -35 °C.

### 14 **2.3. Classification of new particle formation events**

15 NPF events were identified and classified following a scheme adapted from Dal Maso et al. (2005).  
16 A brief description is given here.

17 A plot was compiled for each day with available particle number size distribution data, plotting the  
18 particle diameter on the y-axis, time of the day (from midnight to midnight) on the x-axis, with the  
19 particle number concentration in each size interval displayed as a contour plot. A panel of three  
20 persons performed visual inspection, identification and classification of data to avoid subjective  
21 bias. In order to be classified as an event day, the occurrence of a new particle mode below 20 nm  
22 with concentrations substantially higher than during the previous hours must be observed. If a clear  
23 diameter growth of newly formed particles could be traced for several hours, that specific day  
24 would be classified as a class I event day. If the growth of newly formed particles was not  
25 continuous over several hours, that specific day would be classified as a class II event day. The  
26 identified NPF events at Station Nord typically lasted from hours to days. In case of a multi-day  
27 event, only the first day, during which the event onset was identified, was counted as an event day.  
28 The panel must agree on all classifications, otherwise the specific day would be classified as an  
29 undefined event. Other options for classifications are non-event day or bad data in case of missing  
30 data or observed instrumental problems.

### 1 **3. Results and Discussion**

2 This section presents the observed overall seasonality of particle number size distributions  
3 measured at VRS, Station Nord during the time period from July 2010 to February 2013, with an  
4 analysis of NPF event cases together with the atmospheric oxidation capacity at the station.  
5 Analysis of local wind speed, wind direction and air mass back trajectories was used to support the  
6 interpretation of the seasonality of particle number size distributions and the dynamics of NPF  
7 events.

#### 8 **3.1. Particle number size distributions and seasonality**

##### 9 **3.1.1. Overview**

10 A clear seasonality of particle number size distributions was observed during 2012 (**Fig. 3-4**). A  
11 persistent accumulation mode appeared in the end of September, which became more prominent in  
12 the end of February lasting until mid-May. The Arctic summer (June - August) was coupled with a  
13 higher abundance of nucleation mode and Aitken mode aerosol particles and a very low abundance  
14 of accumulation mode particles (Table 1). The small particles were also observed to a lesser extent  
15 in September and only during one episode in mid-October. This observation of strong seasonality  
16 was supported by observations from the available scattered data in the other years 2010, 2011 and  
17 2013. The elevated concentrations of accumulation mode particles observed in this study generally  
18 followed the varying pattern of aged total suspended particles during the Arctic haze period  
19 previously reported at VRS, Station Nord (Heidam et al., 2004; Nguyen et al., 2013) and other  
20 Arctic stations (Quinn et al., 2002; Ström et al., 2003). It should also be noted that the sun rises in  
21 the end of February at Station Nord, so the period thereafter is affected by photochemical processes.  
22 Observations of smaller particles during this period were in accordance with previous studies in the  
23 Arctic (Ström et al., 2003; Tunved et al., 2013; Wiedensohler et al., 1996; Covert et al., 1996;  
24 Quinn et al., 2002; Heintzenberg et al., 2015; Leaitch et al., 2013). During this period, the Arctic is  
25 considerably cleaner with respect to long-range transport of atmospheric pollutants and  
26 characterized by constant daylight.

##### 27 **3.1.2. Statistics of the particle number size distribution**

28 **Fig. 4** and **Table 1** describe detailed statistics of the particle number size distributions measured at  
29 the site, showing the prominent accumulation mode during February - May and the prominent  
30 nucleation/Aitken mode during June - August. **Table 2** provides detailed median and average  
31 particle number concentration (N), particle volume concentration (V) and particle mass

1 concentration (M) values calculated using the particle number size distributions at VRS, Station  
2 Nord during 2012. Higher values of median or average N were observed from April to September.  
3 During this period, largest discrepancies between the median and the average values were also  
4 found, especially during June (Median N = 137 particles cm<sup>-3</sup>, Average N = 277 particles cm<sup>-3</sup>) and  
5 August (Median N = 227 particles cm<sup>-3</sup>, Average N = 313 particles cm<sup>-3</sup>). This was attributed to the  
6 occurrence of intense NPF events during these months (**Fig. 3**), skewing the average N towards  
7 higher values compared to median N. June and August also showed highest average N in 2012,  
8 followed by May, April and July, whereas the months with the lowest average N were October,  
9 November and December.

10 Newly formed particles are usually high in number and therewith significantly influence the total  
11 number concentration N as discussed above; however they do not contribute considerably to the  
12 total particle volume concentration V. As a result, June and August were among the months with  
13 the lowest median or average V together with other sunlit months July and September (**Table 2**). In  
14 contrast, the highest median and average V were observed during the most prominent haze months  
15 March - May. Simple log-normal fitting applied to the accumulation mode observed in the monthly  
16 particle number size distributions in 2012 revealed a geometrical mean diameter of approximately  
17 170 nm during the winter and spring months (**Table 1**). This indicates that the particles can  
18 originate from distant locations due to their longer lifetimes determined by their size (Massling et  
19 al., 2015).

20 The total particle mass concentrations M were derived directly from the total particle volume  
21 concentration V, assuming a density of 1.4 g cm<sup>-3</sup> and particle sphericity. Average monthly  
22 estimates of M ranged from 0.21 µg m<sup>-3</sup> (June) to 1.58 µg m<sup>-3</sup> (March) (**Table 2**).

23 Similar distribution of the major modes was also observed at the Zeppelin mountain site by Tunved  
24 et al. (2013). However, the nucleation mode - Aitken mode observed during the summer months  
25 seemed considerably more pronounced at VRS, Station Nord compared to Zeppelin. This indicates  
26 higher number concentrations of smaller particles at Station Nord, which were visible until October  
27 (**Fig. 3-4**). In regards of the total particle mass concentration, Tunved et al. (2013) reported summer  
28 M mostly below 0.2 µg m<sup>-3</sup> and higher M below 0.8 µg m<sup>-3</sup> observed at Zeppelin during the  
29 prominent haze months March - April (with an assumed lower density of 1 g cm<sup>-3</sup>). Clearly, the  
30 particle mass concentration at Villum Research Station, VRS, Station Nord seemed comparable  
31 during summer while showing higher concentrations during the Arctic haze months compared to

1 Zeppelin with different assumed particle densities already accounted for. This difference between  
2 the two sites could be partially attributed to their different locations as discussed above. In addition,  
3 the study periods and lengths of the studies were also different, as the Zeppelin data was averaged  
4 for March 2000 - March 2010 whereas the descriptive distribution statistics in this work was  
5 derived solely from data in 2012. Nevertheless, similar observations at both stations show the  
6 consistent and predictable annual behavior of the particle number size distributions in the Arctic.

### 7 **3.1.3. Impacts of seasonal wind pattern**

8 Analysis of wind direction and wind speed was performed to investigate the impacts of wind pattern  
9 on the particle number size distributions at the station. **Fig. 5** demonstrates monthly wind roses  
10 during 2012, where two distinct patterns could be identified during the darker (September - April)  
11 and the summer (June - August) period. The early haze months (January and February) and the  
12 prominent haze months (March and April) showed prevailing wind arriving from the southwesterly  
13 to westerly direction. During May, some northerly wind was observed while the frequency of  
14 southwesterly wind seemed to decrease. During the summer period (June - August), when smaller  
15 and freshly formed particles were observed, easterly wind became more prominent, especially  
16 during July and August. September marked a prompt change in the wind direction back to  
17 southwesterly direction. The wind speed became higher during November - December, which is  
18 probably due to increasing katabatic winds from the ice sheet. During the other years 2011 and  
19 2013 (data not shown), considerably similar patterns were observed for the corresponding months.

20 Earlier studies on source apportionment of total suspended particles (TSP) observed during the  
21 Arctic haze period at VRS mostly identified Siberian industries and long-range transport from mid-  
22 latitudes as major factors (Nguyen et al., 2013; Heidam et al., 2004) . However, the wind pattern  
23 shown here may indicate an immediate impact of the adjacent southwesterly to westerly regions  
24 contributing to the properties of particles prior to arrival at the station.

25 Based on the summer wind pattern, the smaller particles observed during June - August were  
26 probably linked to sources from the easterly side of the station, with some marine contribution.  
27 During summer, the marine contribution from the easterly direction is possibly driven by the retreat  
28 of sea-ice cover, which exposes areas of open waters (“open leads”) and melt water on top of sea  
29 ice to wind stress, especially along the coastal line of Greenland due to the presence of first-year-ice  
30 in these regions. This would result in enhanced primary emissions of sea spray particles (Korhonen  
31 et al., 2008). Surface active organic species in the ocean surface layer, which are more abundant due

1 to increased biological activity during summer, could also be released into the atmosphere by  
2 bubble bursting (Middlebrook et al., 1998; Tervahattu et al., 2002) and become mixed with other  
3 sea spray particles. It was suggested by Sellegri et al. (2006) that this could also alter the number  
4 size distributions of particles. Another study by Karl et al. (2013) proposed that new nanoparticles  
5 in the high Arctic could be marine granular nanogels injected into the atmosphere from evaporating  
6 cloud droplets. Recent analysis of particle number size distributions and back trajectories during  
7 summer cruises in the Arctic by Heintzenberg et al. (2015) also showed a strong coupling of newly  
8 formed particles and the traveling of air masses over open water. At the same time, it must be noted  
9 that wind measurements using the sonic anemometer were confined to local observations at ground  
10 level, which according to radio sound measurements by Batchvarova et al. (2013), do not capture  
11 activities such as transport of air masses at higher altitudes, or regional transport of air masses. The  
12 extent of wind impacts on the particle size distributions at the station is thus not well constrained.

13 Previous studies reported a dependence of particle number concentrations on wind speed in the  
14 Arctic (Leck et al., 2002) and North Atlantic (Odowd and Smith, 1993). However, in this study the  
15 accumulation mode particles (110 - 900 nm) only showed positive correlation with wind speed  
16 during eight out of 12 months of 2012 with a moderate Pearson correlation coefficient range of 0.05  
17 - 0.38. The reason could be partly attributed to the larger size ranges (500 nm up to 16  $\mu\text{m}$  in  
18 diameter) measured in the other studies, which are more influenced by wind speed.

## 19 **3.2. New particle formation events**

### 20 **3.2.1. Description of exemplary NPF events**

21 NPF events were observed at the station during the sunlit months, especially during the summer  
22 months June – August, though events were also identified during the months with relatively low  
23 sunlight March and October. The onset of NPF events was observed during various hours of the day  
24 (Supplementary Fig. 1). Examples of three events were shown in **Fig. 6**. As apparent from the  
25 figure, the events showed clear but slow growth over considerably long periods up to a few days.

### 26 **3.2.2. The role of atmospheric oxidants**

27 **Fig. 6** also shows an overlay of  $\text{O}_3$ , NO and  $\text{NO}_x$  on the NPF event plots to allow analysis of the  
28 role of atmospheric oxidants during those events.

### 29 **Ozone**

1 O<sub>3</sub> shows a strong seasonality in the Arctic troposphere with maximum springtime concentration  
2 observed in the free troposphere, which is however poorly understood (Monks, 2000; Law and  
3 Stohl, 2007). It has long been indicated that tropospheric O<sub>3</sub> in the Arctic is enriched from intruding  
4 stratospheric air masses (Gregory et al., 1992; Gruzdev and Sitnov, 1993). A recent model study has  
5 also suggested that summertime photochemical production of O<sub>3</sub> by NO<sub>x</sub> in the Arctic could also be  
6 a dominant source (Walker et al., 2012). This was attributed to NO<sub>x</sub> emissions from the thermal  
7 decomposition of the long-lived reservoir species peroxyacetyl nitrate (PAN) during summer (Fan  
8 et al., 1994). Meanwhile, transport from mid-latitude source regions could also contribute to the O<sub>3</sub>  
9 budget in the Arctic during autumn and winter (Walker et al., 2012). Sources of O<sub>3</sub> in the Arctic  
10 could therefore be a combination of different factors, including among others stratospheric  
11 influence, local production and transport from mid-latitude sources. Finally, surface O<sub>3</sub> is also  
12 depleted every spring due to reactions with Br atoms released from sea-ice and surface snow (Barrie  
13 et al., 1988; Simpson et al., 2007; Skov et al., 2004; Bottenheim et al., 1990; Pratt et al., 2013;  
14 Abbatt, 2013), similar to O<sub>3</sub> depletion in the stratosphere.

15 In this work, O<sub>3</sub> was used as a tracer of atmospheric chemical processes, and the concentration of  
16 O<sub>3</sub> was found to be related to the formation and growth of new particles at Station Nord during  
17 summer based on case studies of NPF events in 2012 (**Fig. 6**).

18 **Event A, Fig. 6:** Event A is in fact a “double” event, with the first event occurring over June 15 - 16  
19 followed by another event starting on June 17 with traceable growth until June 20.

20 During June 15, the O<sub>3</sub> level (black line) increased considerably to ~45 ppbv, which was  
21 significantly higher than the average summer (June - August, 2012) concentration of O<sub>3</sub> (~26 ppbv).  
22 As the NPF event on June 15 started followed by particle growth up to ~25 nm, the O<sub>3</sub> level  
23 dropped dramatically, then somewhat stabilized when the approximate mean particle size reaches  
24 the lower Aitken mode. The next drop in O<sub>3</sub> concentration (from ~37 ppbv to ~27 ppbv) coincided  
25 with the occurrence of the second NPF event observed around noon of June 17. As the new particles  
26 grew beyond ~30 nm in diameter, the O<sub>3</sub> concentration seemed to stabilize again.

27 In the late hours of June 19, the O<sub>3</sub> concentration suddenly dropped by ~5 ppbv, coinciding with an  
28 interruption of the event. By midday June 20, the O<sub>3</sub> concentration increased back to the pre-  
29 interruption level, while that interrupted event also seemed to be brought back to the station. It was  
30 unclear if this drop of O<sub>3</sub> concentration on June 19 was associated with any NPF, as nucleation  
31 sized particles were also observed for a few hours during early hours on June 20. However, a full

1 justification of this observation was not possible due to the detection limit of the Mobility Particle  
2 Size Spectrometer system (~10 nm) confining to only aged nucleation particles. Another  
3 explanation could be that both O<sub>3</sub> and the nucleation event were transported to the station from a  
4 common source, with the interruption probably indicating for instance a displacement of air mass.

5 During *Event A* case study, the NO and NO<sub>x</sub> level remained mostly below 0.1 ppbv. This was  
6 approximately the background level of NO<sub>x</sub> at Station Nord throughout the year. At the same time,  
7 it must be noted that this level is below the detection limit of the instrument (150 ppt), and thus  
8 must be treated with caution. NO and NO<sub>x</sub> concentration did not seem to relate to O<sub>3</sub> concentration  
9 level, or observations of new particle formation events.

10 **Event B, Fig. 6:** This *Event B* on August 2 showed that a lower level of O<sub>3</sub> concentration (~25  
11 ppbv) could also be associated with a new particle formation event. During the event, the episode of  
12 traceable particle growth lasted for approximately 12h, coinciding with a concurrent drop of the O<sub>3</sub>  
13 concentration. This event was also considerably less intensive in regards of particle number  
14 concentrations compared to *Event A*. Until the end of the event, particles were mostly below 30 nm  
15 in size.

16 **Event C, Fig. 6:** During this event on August 9 - 10, new particle formation was also observed  
17 together with lower O<sub>3</sub> concentrations (~25 ppbv), which was similar to *Event B*. The anti-  
18 correlation between growth of newly formed particles and O<sub>3</sub> concentration was also observed  
19 during this event. However, such anti-correlation was visible until particles almost reached 40-50  
20 nm in diameter, which was higher than that observed during *Event A* and *Event B*.

21 The three events seemed to visually display an anti-correlation between the concentration level of  
22 O<sub>3</sub> and the growth trend of smaller particles. A Pearson correlation coefficient between O<sub>3</sub>  
23 concentration and integrated particle number concentrations for the nuclei mode range (10-30 nm)  
24 was calculated for each event observed during 2012, where O<sub>3</sub> data was available, and NO<sub>x</sub> data  
25 was also available to eliminate local pollution spikes. Out of a total of 35 NPF events observed  
26 during 2012, 16 events (46% of total events) displayed a weak to moderate anti-correlation (Pearson  
27 correlation coefficient below -0.5) between the integrated particle number concentrations for the  
28 nuclei mode range (10-30 nm) and O<sub>3</sub>, with an average coefficient value of -0.71. Meanwhile 12  
29 events (34% of total events) displayed a negative correlation coefficient from -0.05 to -0.41, with an  
30 average value of -0.25; and 7 events (20% of total events) showed a positive correlation in the range  
31 of 0.09 to 0.44, with an average value of 0.30. In these later cases (54 % of total events), it can be

1 deemed that there is no relationship between O<sub>3</sub> and the nucleation mode particle number  
2 concentrations. No positive Pearson correlation coefficient stronger than 0.5 was observed.

3 It is generally agreed that particle nucleation involves sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) via the oxidation of  
4 SO<sub>2</sub> by the hydroxyl (OH) radical (Kulmala et al., 2001), while particle growth depends  
5 considerably on vapor uptake and condensation of low-volatile organic vapor products produced by  
6 photo-oxidation of volatile organic compounds (VOCs) (Donahue et al., 2011; Riipinen et al., 2011;  
7 Riipinen et al., 2012). Naturally, O<sub>3</sub> is a major atmospheric oxidant, which also undergoes  
8 photolysis to form the OH radical oxidant. These oxidants oxidize VOCs to form a variety of low-  
9 volatile products. A reduction of O<sub>3</sub> could thus be an indirect indicator of increased availability and  
10 thus uptake of low-volatile compounds, contributing to particle growth. Meanwhile, it should also  
11 be noted that the role of halogen chemistry contributing to new particle formation is unknown, due  
12 to a lack of relevant data as discussed above.

13 The source of VOCs at VRS, Station Nord is unclear. There might be some biogenic emissions of  
14 VOCs at the station during summer, expected due to retreated snow and ice cover, exposed bare  
15 ground and thus possibly increased biogenic activity. However, since this area is arid, this is  
16 expected to be extremely limited. Meanwhile, the presence of VOC oxidation products such as  
17 organic acids and organosulfates at the station has been reported by Hansen et al. (2014), though at  
18 very low concentrations. The low mass or surface loading of organic materials (Nguyen et al., 2014)  
19 and total suspended particles (Nguyen et al., 2013) and thus low condensation sink observed at the  
20 station during summer would inhibit removal of small particles by condensation and also  
21 coagulation to a lesser extent, thus allowing particle growth and prolonged NPF events. At the same  
22 time, no considerable difference in particle mass or surface was observed at the onset of events  
23 compared to the average particle mass or surface of the corresponding months during 2012.

24

## 25 NO<sub>x</sub>

26 As mentioned above, sparks of particle formation, which did not grow further, were considered as  
27 local pollution events, which related to NO<sub>x</sub> emitted by the car engine during service of the station.  
28 There was probably some additional contribution from emissions from the military base, which is  
29 located at a distance of about 2.5 km from the measurement site. An example of such interference is  
30 illustrated during the early hours of August 2 (*Event B*, **Fig. 6**), during which a higher NO<sub>x</sub>  
31 concentration of ~0.15 ppbv was detected together with a short episode of new particle formation

1 without further growth. Such interference could also be observed around midday of the same event  
2 day (*Event B*, **Fig. 6**). In contrast, it must be noted that NO<sub>x</sub> concentrations in the range ~0.1-0.2  
3 ppbv were mostly not associated with any noticeable observations of new particle formation. Such  
4 episodes with NO<sub>x</sub> interference are also demonstrated here as example and were not included in any  
5 calculations of data.

6 The summer period June - August was associated with a lower level of background NO<sub>x</sub> (NO<sub>x</sub> ~0.1  
7 ppbv) compared to the rest of the year (NO<sub>x</sub> ~0.2 ppbv). As mentioned above, this low level of  
8 background NO<sub>x</sub> was mostly below the detection limit of the instrument. NO<sub>x</sub> emissions into the  
9 Arctic atmosphere other than the direct local anthropogenic emissions could originate from the  
10 thermal decomposition of PAN, which is the major atmospheric NO<sub>x</sub> reservoir species (Singh et al.,  
11 1995). This process is nevertheless limited by low temperature during winter and spring and low  
12 PAN levels during summer (Beine and Krognes, 2000). NO<sub>x</sub> also contributes via photochemistry to  
13 the local formation of tropospheric O<sub>3</sub> and thus enhances O<sub>3</sub> levels during summer (Walker et al.,  
14 2012; Beine and Krognes, 2000).

### 15 **3.2.3 Analysis of air mass back trajectories**

16 As mentioned above, the Mobility Particle Size Spectrometer system employed at VRS, Station  
17 Nord is limited to particles larger than 10 nm in size, capturing only aged nucleation particles. It is  
18 thus uncertain whether the formation of the freshly nucleated particles actually occurred at the site,  
19 or if they were transported from elsewhere or produced aloft.

20 Air mass back trajectories were analyzed in order to investigate possible source regions for the  
21 observed events. The trajectories were calculated using HYSPLIT (Draxier and Hess, 1998). The  
22 model runs were based on meteorological data obtained from the Global Data Assimilation System  
23 (GDAS), which is maintained by the US National Centers for Environmental Prediction (NCEP).

24 In order to facilitate the interpretation of the events shown in Figure 6, hourly air mass back-  
25 trajectories were calculated going 72h backwards for air masses arriving at the station at 50 m and  
26 500 m above sea level. The trajectories are presented in **Fig. 7**, with the names of the events kept  
27 consistent with those in **Fig. 6**. Calculations of air mass back trajectories were performed for three  
28 day periods, in order to minimize the uncertainties associated with calculating longer trajectories.

29 As can be seen in **Fig. 7, Event A**, westerly air masses were arriving at the station during the hours  
30 before the onset of the event. At 21h on June 15, air masses started to originate from the  
31 southwesterly direction instead, which also marks the observation of the first NPF event. In fact,

1 during both NPF events identified on June 15 and June 17, during *Event A*, air masses seemed to be  
2 fast-moving, originating from longer distances in the southwesterly direction. During the late hours  
3 of June 17 to early June 19, the station started to receive more air masses arriving from northerly  
4 direction (for example 19 June, 06:00 local time), which may associate with the faded nucleation  
5 mode particles observed during this exact time period. The “interrupted period” observed on June  
6 19-20 also seemed to overlap with the time period where air masses were locally confined (for  
7 example 19 June, 15:00 local time), and nucleation mode particles started to be observed again as  
8 the air masses started to arrive from a westerly direction instead (20 June, 16:00 local time). It  
9 should be noted that this interrupted period was off by about 2 hours compared to changes in  
10 HYSPLIT air mass trajectories, which might be attributed to uncertainties in HYSPLIT output,  
11 especially for calculating air mass movement over small distances in an area with few  
12 meteorological measurement data.

13 The trajectories for *Event B* (**Fig. 7**) show that from 5-18h on August 2, air masses seemed to arrive  
14 constantly along the coastal line from the northerly direction (which is shown by the example of  
15 August 2, 06:00 local time), compared to the non-event period on that same day, where air masses  
16 were arriving from inland instead (August 2, 03:00 and 18:00 local time). The air masses thus might  
17 involve the Arctic sea-ice region (Supplementary Fig. 2) and related sources such as open leads or  
18 melted water on top of sea ice due to wind stress as discussed above.

19 At the same time, the onset of an observed event cannot always be traced using HYSPLIT air mass  
20 back trajectories. For example, Event C was observed at the site around 0h on August 9 (**Fig. 7**,  
21 *Event C*) despite no clear changes in HYSPLIT air mass back trajectories. This was a rather weak  
22 event which seemed to stem from particle size below 10 nm, which was not able to be captured by  
23 the Mobility Particle Size Spectrometer. This also highlights the uncertainty with using HYSPLIT  
24 to trace the onset of the NPF event, as the onset time might be only for particles above 10 nm in  
25 diameter, whereas the air masses transporting particles below 10 nm in size might have arrived at  
26 the site prior to this so-called onset time. On the other hand, the interruption of this *Event C* was  
27 easier to trace, as it seemed to coincide with the time where the air masses were confined to the  
28 inland westerly region prior to arriving at the station (August 10, 04:00 local time). Air mass back  
29 trajectories were also calculated three-days backwards, at one hour after the starting time of each  
30 identified event using HYSPLIT, whereas for the other days, trajectories arriving at 12:00 p.m. local  
31 time were used. The region around Station Nord was split into one degree latitudinal and six degree  
32 longitudinal grid boxes. Every time a trajectory passed one grid box, a count was registered for that

1 grid box. The probability of registering an event, when the air mass originated from a specific grid  
2 box was obtained by dividing the total counts during event days by the sum of total counts during  
3 event days, undefined and non-event days. The probability results are shown in **Fig. 8**.

4 As apparent from the figure, the probability of observing an event at the station is low when the air  
5 masses arrive from the southwesterly direction over Greenland. Other directions of air mass origin  
6 however showed relatively similar probability of registering an event. A slightly higher probability  
7 range was observed for southeasterly air masses that passed over region, where open waters and  
8 melting ponds on ice are more likely to occur. As particles typically grow very slowly at Villum  
9 Research Station, the time gap from particle nucleation occurring around 1.5 nm in diameter until  
10 the point when they are observed at the site (~10 nm in diameter) could range from hours to days.  
11 The corresponding probability for observing nucleation mode particles (~10 nm in diameter) at the  
12 site should therefore serve as an indication of probable air mass origin of the grown nucleation  
13 mode instead of freshly nucleated particles.

#### 14 **3.2.4. Analysis of wind pattern during NPF events**

15 The wind pattern was also investigated on specific event days in 2011 and 2012 (figure not shown).  
16 However, they were found very similar to the general wind patterns of the corresponding month or  
17 period. Therefore, it is unlikely that any change in local wind direction during the specific event  
18 days could have an impact on the occurrence of new particle formation events observed at the site.  
19 This indicates the possibility of other factors, which may have changed during the event days  
20 affecting new particle formation such as precursors. In fact, Quinn et al. (2002) indicated that the  
21 abundant dimethyl sulfide (DMS) could affect particle production during summer, as evidenced by  
22 a strong correlation between particle number concentrations and methanesulfonate (MSA)  
23 concentrations (resulting from the oxidation of DMS). Similar observations were reported by  
24 Leaitch et al. (2013). Other examples of factors influencing NPF are atmospheric oxidation capacity  
25 and transport of air masses.

#### 26 **3.2.5. Event statistics**

27 In general, the event days accounted for 17 - 38 % of the classified days during June - September,  
28 with the highest percentages of event days observed in August (38 %) and July (33 %) (**Table 3**).  
29 The period from June to early September was also the period during which longer events up to  
30 several days were observed and most class I events were identified (**Table 3**).

1 The observed frequencies of event days during these months at VRS, Station Nord were relatively  
2 high compared to reported values from sub-Arctic stations during the same months, such as Värriö  
3 (20 - 25%) (Kyro et al., 2014), Pallas (10 - 20 %) (Asmi et al., 2011) or Abisko (< 20 %) (Vaananen  
4 et al., 2013), while overlap with the values 30-40 % reported by Asmi et al. (2016) from Tiksi,  
5 Russian Arctic. In fact, the observed new particle formation events at the sub-Arctic stations and  
6 other Nordic stations seemed to show a spring maximum of event occurrence (Vehkamaki et al.,  
7 2004; Dal Maso et al., 2007; Kristensson et al., 2008), as opposed to the summer maximum of  
8 events observed at VRS, Station Nord. Interestingly, Asmi et al. (2016) found the highest NPF  
9 event frequencies in March (50%), whereas such frequency was only 10 % at VRS, Station Nord  
10 during the same month. It should also be noted that Asmi et al. (2016) reported measuring particle  
11 diameter from 7 nm at Tiksi, whereas only those above 10 nm were reported in this study. NPF  
12 events were still observed at the sub-Arctic stations Värriö , Pallas and Abisko during the darker  
13 months (November - February), though the fraction of event occurrence was typically much lower  
14 compared to other seasons (Kyro et al., 2014; Asmi et al., 2011; Vaananen et al., 2013). Notably,  
15 not a single event was observed at VRS, Station Nord during the Arctic night in the absence of  
16 sunlight.

#### 17 **4. Conclusion**

18 In this work, the seasonality of particle number size distributions, total particle number, volume and  
19 mass concentrations was examined. A strong seasonal pattern was found, showing the abundance of  
20 smaller particles during the sunlit period of the year, especially during summer and a persistent  
21 accumulation mode during the darker months caused by long-range transport of particles to the  
22 Arctic. Analysis of wind data showed a dominance of easterly winds during the summer months and  
23 southwesterly winds during the darker months of the year.

24 The observed NPF events at the station lasted from hours to days with various onset time. O<sub>3</sub> was  
25 possibly related to the observed NPF events, with 46% of NPF cases showing a weak to moderate  
26 anti-correlation (with an average coefficient value of -0.71) between O<sub>3</sub> concentration and  
27 integrated particle number concentrations for the nucleation mode range (10-30 nm), while no  
28 positive correlation was found and the remainder of events showed no correlation. Calculations of  
29 air mass back trajectories on the days with new particle formation events using HYSPLIT indicated  
30 that the onset or interruption of events might be explained by changes in air mass origin. Air masses  
31 arriving from the southwesterly direction over Greenland were least linked to NPF event, whereas

1 air masses arriving from southeasterly direction over Greenland sea was associated with slightly  
2 higher probabilities. Meanwhile, the local wind direction did not seem to relate to NPF events  
3 observed at the station

#### 4 **Acknowledgements**

5 This work was financially supported by the Danish Environmental Protection Agency with means  
6 from the MIKA/DANCEA funds for Environmental Support to the Arctic Region, which is part of  
7 the Danish contribution to “Arctic Monitoring and Assessment Program” (AMAP) and to the  
8 Danish research project “Short lived Climate Forcers” (SLCF). The findings and conclusions  
9 presented here do not necessarily reflect the views of the Agency. This work was also supported by  
10 the Nordic Centre of Excellence Cryosphere-Atmosphere Interactions in a Changing Arctic Climate  
11 (CRAICC). The Villum Foundation is acknowledged for funding the construction of Villum  
12 Research Station, Station Nord. The authors are also grateful to the staff at Station Nord for their  
13 excellent support.

1 **List of Figures**

2 **Fig. 1.** The high Arctic site Villum Research Station, Station Nord (81°36' N, 16°40'W, 30 m a.s.l.)  
3 in northeast Greenland. The main measurement site is Flyger's hut, which is located about 2.5 km  
4 southeast of the Danish military base.

5 **Fig. 2.** SMPS, O<sub>3</sub> and NO<sub>x</sub> data coverage at Station Nord from July 2010 - February 2013.

6 **Fig. 3.** Time series of particle number size distributions as dN/dlogDp (cm<sup>-3</sup>) during 2012. The  
7 original 5 min time resolution was used in the plots.

8 **Fig. 4.** Monthly median particle number size distribution at Station Nord during 2012. The  
9 corresponding lognormal-fitting parameters are shown in **Table 1**. The shade area shows the 75<sup>th</sup>  
10 (upper) and 25<sup>th</sup> (lower) percentile of the actual data.

11 **Fig. 5.** Windroses showing monthly wind direction and wind speed at Station Nord during 2012.  
12 The concentric rings show the percentage of wind arriving from a particular direction.

13 **Fig. 6.** Demonstration of the impacts of O<sub>3</sub>, NO and NO<sub>x</sub> on the summer new particle formation  
14 events occurring on June 15-20 (Event A), Aug 2 (Event B) and Aug 9-10 (Event C) in 2012.

15 **Fig. 7.** Demonstration of air mass back trajectories calculated hourly using HYSPLIT for arrival at  
16 50 m and 500 m at the station for the case study events.

17 **Fig. 8.** The probability of observing an event at Station Nord (bottom tip of the black triangle) as a  
18 function of air mass origin. This figure uses all available data (62 events) from the study period July  
19 2010 – February 2013.

20 **Fig. 9.** Monthly variation of total number of days with good data (left vertical axis) and frequency  
21 percentages (%) of event days, non-event days and undefined days (right vertical axis) during the  
22 study period (July 2010 - February 2013).

1 **List of Tables**

2 **Table 1.** Three modes were fitted to the average monthly data of 2012 using lognormal fitting. The  
3 parameters shown for each mode include the modal number concentration ( $N$ ,  $\text{cm}^{-3}$ ), the modal  
4 geometrical mean diameter ( $D_g$ , nm) and the modal geometrical standard deviation (GSD). A fitted  
5 sum of three lognormal distributions was calculated for the entire particle size range (averaged  
6 monthly particle number size distributions) and the difference of the sum of the squares of each  
7 number concentration at the specific sizes between the real and the fitted data was minimized using  
8 the Excel solver add-in.

9 **Table 2.** Median and average particle number concentration ( $N$ ), particle volume concentration ( $V$ )  
10 and particle mass concentration ( $M$ ) for the 12 months of 2012.  $M$  was calculated from  $V$  assuming  
11 a density of  $1.4 \text{ g cm}^{-3}$  and particle sphericity.

12 **Table 3.** Percentage of total new particle formation events (marked in blue) versus non-events and  
13 undefined days during the period July 2010 to February 2013. The total events were further divided  
14 into Class I and Class II events. A column of total days (by month) over the studied years was also  
15 provided.

16 **Supplementary Fig. 1.** Onset hour of NPF events based on 62 NPF events observed during the  
17 period July 2010 – February 2013.
