

We thank the referee for their thorough assessment of the revised manuscript and helpful suggestions.

We have addressed all comments raised in their annotated pdf copy of our manuscript which can be compared to the revised marked-up document submitted in this round of the reviewing process.

Changes of a more substantial nature than e.g. correction of typos are explicitly listed below (our responses are indicated in blue font):

- Figures should be numbered in the order in which they are first mentioned: *Figures 1-3 have been renumbered to allow for chronological referencing. The original Fig. 1 is now Fig. 3, Fig. 2 became Fig. 1 and Fig. 3 was changed to Fig. 2.*
- *Details of the calculations of monthly and annual fluxes have been added to section 2.3 to comply with the referee's comment pertaining to the caption of Table 1 ("This gap-filling should be mentioned in the methods section of the main text, rather than the figure caption. Otherwise, it looks like you are trying to hide it."):*

"Monthly and annual emissions

Monthly emissions were calculated from mean diurnal flux profiles constructed by averaging half-hourly fluxes into 24 nominal hourly bins. Annual emissions were estimated by summing monthly averages. However, the data period September 2012-March 2013 (no ultrasonic anemometer) was gapfilled using available monthly averages obtained over the remaining measurement period. Due to insufficient temporal coverage, individual annual budgets for 2012-2014 could not be derived for the CO flux. A composite annual emissions estimate was compiled instead which made use of all available monthly averages of F_{CO} over the study period September 2011 to December 2014."

- *Variability in supply pressure is not the only thing that could lead to variability in CH_4 emissions from NG leakage. For example, there could also be variability in the permeability of the soil, and more fugitive emissions when NG appliances are being lit.*

The paragraph this comment refers to has been re-written to address a technical comment raised by referee #2 (comment pertaining to page 9 line 15-29). The point raised here by referee #1 was included in the revised paragraph: "This suggests that fugitive emissions from the natural gas distribution network, which are thought to be the dominant cause of urban CH_4 emissions in developed cities, exhibit diurnal variations and/or that other CH_4 sources with temporal variations (e.g. fugitive emissions from natural gas appliances) are more significant than estimated by LAEI."

- *I still don't understand why you think post-meter emissions are constant in time. Is this sentence referring to Wennberg et al. 2012?*

This point has been clarified by adding the following sentence to section 3.4.2: "Post-meter emissions are made up of time-varying (incomplete combustion upon natural gas appliance ignition/ usage) and constant components (leaking valves/ fittings) which contribute to both the seasonal variability and to the baseline of CH_4 emissions."

- *In the main text, you seemed to give equal emphasis to natural gas and sewage as possible temperature-correlated sources, but in the conclusion, you only mention sewage.*

We thank the referee for pointing out this oversight which has been corrected as follows: "In particular, we hypothesise that the shortfall in inventoried CH_4 emissions can be explained by the existence of temperature-dependent sources related to natural gas usage and perhaps also of biogenic origin (e.g. sewage)."

- Figures S10-S14 appear to not be mentioned in the text. The histograms of sample size in the supplement are so compact that it is difficult to distinguish any detail. It may better to simply state a range of sample sizes in the main text (e.g. $N=50-200$ for each hourly-monthly bin):

We acknowledge the referee's comment regarding the appearance of the sample size histograms. However, we feel that presenting these data in histogram form is more informative than merely providing a range within the manuscript.

We thank the referee for recommending our manuscript for publication in ACP following minor corrections.

We reviewed the manuscript after addressing the comments of referee #1 and #2 and we are satisfied that the results and arguments are consistent throughout the text. We have also addressed all technical comments as detailed below (our responses are indicated in blue font).

Technical corrections

- Page 2, line 12: the original sentence was extended and now specifies that the 70% of global emissions attributed to urban activities include emissions occurring within and outside the urban centre. The revised sentence reads *"Despite 54% of the worldwide population currently living in cities, a figure which could rise to 66% by 2050 (United Nations, 2014), and CO₂ emissions related to urban activities (total of emissions occurring within and outside (e.g. power plants) a conurbation) estimated to represent 70% of the global budget (International Energy Agency, 2012), there have been comparatively few urban studies to evaluate reported GHG emissions)."*
- Section 2.1: a reference to Fig. S1 has been added in Section 2.1.
- Page 8, line 8: Seasons have been defined at the beginning of Section 3.2.1. *"F_{CO₂_CP} and CO₂ fluxes observed at the KCL site (F_{CO₂_KCL}) exhibited a high temporal correlation (Fig. 4a, b; averaging period 15/09/2011 to 31/12/2013) for diurnal patterns in both winter (defined as December – February) and summer (defined as June – August unless otherwise stated)."*
- Page 9, line 5-7: the sentence was indeed speculative and unnecessary. It has hence been replaced with *"Fluxes of CH₄ and CO measured at the BT tower are presented alongside CO₂ in sections 3.3 – 3.5."*
- Page 9 line 15-29: we acknowledge that re-structuring this paragraph is needed to improve its readability. We have taken the referee's suggestions on board and re-written the paragraph which now reads: *"The summertime fluxes of CH₄ measured at the 190 m height did lag slightly behind the fluxes observed at the 50 m height, but this apparent delay could have been caused by differences in flux footprint between the sites (e.g. the source area of the BT tower fluxes has a much higher fraction of vegetation cover than the KCL footprint) and the fact that the diurnal profiles were obtained for a much shorter time period (August-September 2015). The similarity in F_{CH₄} temporal dynamics between the two sites supports the idea that the diurnal variations for that gas represent real variability in its source strength rather than an artefact of atmospheric transport as suggested by Gioli et al. (2012) for the Florence (Italy) case study. Indeed, the diurnal variations in F_{CH₄} measured at the BT tower were mirrored by strongly suppressed night-time CH₄ fluxes observed at a much lower height at the KCL site (Fig. 4c), where the storage error has been demonstrated to be small for CO₂ (Bjorkegren et al., 2015). This suggests that fugitive emissions from the natural gas distribution network, which are thought to be the dominant cause of urban CH₄ emissions in developed cities, exhibit diurnal variations and/or that other CH₄ sources with temporal variations (e.g. fugitive emissions from natural gas appliances) are more significant than estimated by LAEI. This is further supported by F_{CH₄} being smaller at the weekend than on weekdays (Fig. 6g)."*
- Conclusion: We agree that the sub-titles were redundant and improve the readability of the conclusions. They have hence been removed.

Spatial and temporal variability of urban fluxes of methane, carbon monoxide and carbon dioxide above London, UK.

Abstract. We report on more than three years of measurements of fluxes of methane (CH₄), carbon monoxide (CO) and carbon dioxide (CO₂) taken by eddy-covariance in central London, UK. ~~Inter-annual variability in the period 2012-2014 ranged from 36.3 to 40.7 ktons km⁻² y⁻¹ for CO₂, and from 69 to 75 tons km⁻² y⁻¹ for CH₄.~~ Mean annual emissions of CO₂ in the period 2012-2014 (39.1 ± 2.4 ktons km⁻² y⁻¹) and CO (89 ± 16 tons km⁻² y⁻¹) were consistent (within 1% and 5% respectively) with values from the London Atmospheric Emissions Inventory, but measured CH₄ emissions (72 ± 3 tons km⁻² y⁻¹) ~~were~~ over two-fold larger than the inventory value. Seasonal variability was large for CO with a winter to summer reduction of 69%, a- ~~nd m~~Monthly fluxes ~~of CO~~ were strongly anti-correlated with mean air temperature, ~~and the winter emissions accounted for 45% of the annual budget.~~ The winter increment in CO emissions was attributed mainly to vehicle cold starts and reduced fuel combustion efficiency. CO₂ fluxes were 33% higher in winter than in summer and anti-correlated with mean air temperature, albeit to a lesser extent than for CO. This was attributed to an increased demand for natural gas for heating during the winter. ~~The seasonality in~~ CH₄ fluxes ~~exhibited~~ was moderate seasonality (21% larger in winter), ~~and the~~ and a spatially-variable linear anti-correlation with air temperature ~~was spatially variable.~~ Differences in resident population within the flux footprint explained up to 90% of the spatial variability of the annual CO₂ fluxes and up to 99% for CH₄. ~~This suggests a significant influence of anthropogenic sources in the overall emissions budget of these two greenhouse gases.~~ Furthermore, we suggest that biogenic sources of CH₄, such as waste-water which is unaccounted for by the atmospheric emissions inventories, make a substantial contribution to the overall budget and that commuting dynamics in and out of central business districts could explain some of the spatial and temporal variability of ~~the CO₂ and CH₄~~ emissions. To our knowledge, this study is unique given the length of the datasets presented, especially for CO and CH₄ fluxes. This study offers an independent verification assessment of “bottom-up” emissions inventories and demonstrates that the urban sources of CO and CO₂ are well characterised in London. This is however not the case for CH₄ emissions which are heavily-underestimated by the inventory approach. This opens up Our

1 results and others point to opportunities in the UK and abroad to identify and quantify the “missing” sources of urban methane,
2 revise the methodologies of the atmospheric emission inventories and devise emission reduction strategies for this potent
3 greenhouse gas.

4 **1 Introduction**

5 The use of eddy-covariance (EC) for the measurement of turbulent fluxes of heat and mass has grown steadily over the past
6 three decades; recently, there were > 400 active sites worldwide (Baldocchi, 2008) spanning six continents. The vast majority
7 of existing sites were established to measure biosphere-atmosphere exchanges of carbon dioxide (CO₂) and heat (Baldocchi et
8 al., 2001). Due to recent technological advances, i.e. the development of new fast response analysers, measurements of eddy-
9 covariance fluxes of other trace gases such as methane (CH₄) and nitrous oxide (N₂O) are gradually being introduced (Crosson,
10 2008; Fiddler et al., 2009; Peltola et al., 2014). With the negotiation of international agreements to greatly reduce greenhouse
11 gas (GHG) emissions by the end of the 21st century, there is an ever increasing need to verify emissions through independent
12 monitoring approaches. Despite 54% of the worldwide population currently living in cities, a figure which could rise to 66%
13 by 2050 (United Nations, 2014), ~~and urban and~~ CO₂ emissions related to urban activities (total of emissions occurring within
14 and outside (e.g. power plants) a conurbation) estimated to represent 70% of the global budget (International Energy Agency,
15 2012), there ~~are have been~~ comparatively few urban studies to evaluate reported GHG emissions. At the time of writing, 61
16 urban flux towers were listed in the FLUXNET Urban Flux Network database, of which 40 were located in temperate areas
17 (Grimmond and Christen, 2012).

18 At present, most published urban studies have focused on CO₂ at time scales ranging from a few months to a few years (e.g.
19 Christen et al., 2011; Helfter et al., 2011; Pawlak et al., 2011; Jarvi et al., 2012; Liu et al., 2012). Methane, a potent GHG with
20 a global warming potential 28 times larger than that of CO₂ at the 100-year horizon (IPCC, 2013), is receiving increasing
21 attention. Whilst CO₂ emissions are very closely linked to fuel consumption, for which robust statistics can be obtained (at
22 least at country level), CH₄ originates from a much larger range of sources with complex controls. CH₄-Methane emissions are
23 commonly estimated in “bottom-up” inventories at the national scale (e.g. for IPCC reporting), but also at the urban scale (e.g.
24 London Atmospheric Emissions Inventory in the UK (LAEI, 2013) ~~in the UK~~ and the California Air Resources Board (CARB,
25 2016) in the USA). A variety of techniques have recently been applied to provide independent top-down estimates of urban
26 CH₄ emissions. These include ground-based mass balance approaches (McKain et al., 2015), airborne observations (O'Shea et
27 al., 2014; Cambaliza et al., 2015), Fourier Transform Spectrometry (FTS) (Wunch et al., 2009), isotopic source apportionment
28 studies (e.g. Lowry et al., 2001; Zazzeri et al., 2015) and eddy-covariance (Gioli et al., 2012; Pawlak and Fortuniak, 2016).
29 We report on over three years of continuous measurements of fluxes of methane, carbon monoxide and carbon dioxide in the
30 heart of London, UK, the largest European city. This is, to our knowledge, the longest continuous urban record of direct CH₄
31 emission flux measurements. This paper investigates the temporal and spatial emission dynamics of the three pollutants and
32 compares annual budgets with the bottom-up emissions inventory estimates.

1

2 **2 Materials and methods**

3 **2.1 Site description**

4 Fluxes of carbon monoxide (CO), carbon dioxide (CO₂) and methane (CH₄) were measured by eddy-covariance-~~(EC)~~ from the
5 rooftop of a 190 m telecommunication tower (BT tower; located at 51° 31' 17.4''N, 0° 8' 20.04''W; [Fig. S1](#)) in central London,
6 UK. The measurements, which are ongoing at the time of writing, began in September 2011. The period September 2011 to
7 December 2014 is analysed here. The mean building height in a radius of ca. 10 km from the tower is 8.8 m ± 3.0 m and
8 typically 5.6 m ± 1.8 m for suburban areas ([for more details on the local topography and turbulent air flow characteristics of](#)
9 [the site see](#) Wood et al., 2010; Evans, 2009). The Greater London area, which extends ca. 20 km in all directions from the BT
10 tower, has a population of 8.6 million (Mayor of London Office, 2015) and population densities in excess of 10⁴ inhabitants
11 km⁻² in the central boroughs.

12 **2.2 Instrumentation**

13 **2.2.1 BT tower site**

14 The eddy-covariance system used at the BT tower consisted of a 3D ultrasonic anemometer (R3-50, Gill Instruments), a Picarro
15 cavity ringdown spectrometer (CRDS) model 1301-f for the measurement of CO₂, CH₄ and H₂O mole fractions and an
16 Aerolaser fast CO monitor model AL5002. The anemometer was mounted on top of a lattice tower located on the roof of the
17 BT tower giving an effective measurement height of 190 m above street level. The two gas analysers were located a few floors
18 below the roof, in an air conditioned room. Air was sampled from ca. 0.3 m below the anemometer head at 20-25 lpm using a
19 45 m long Teflon tube of OD 9.53 mm (3/8''). The Picarro CRDS was fitted with an in-house auto-calibration system and
20 calibrated weekly using two different mixtures of ~~methane and carbon dioxide~~[CH₄ and CO₂](#) in nitrogen (above and below
21 typical ambient concentrations). The anemometer operated at 20 Hz, the CO analyser at 10 Hz and the Picarro CRDS, which
22 was set to sample in 3-species mode, operated at 1 Hz. The data were captured by an in-house LabViewTM (National
23 Instruments) data acquisition program which also controlled the auto-calibration system and fluxes were processed offline by
24 a custom LabView program. Although the Picarro 1301-f has the capability to measure concentrations at 10 Hz, at this rate,
25 this older instrument can only measure two of the three compounds CO₂, CH₄ and H₂O. Because an internal H₂O measurement
26 is required for accurate corrections (e.g. Peltola et al., 2014), this would mean that in fast-response mode the instrument can
27 only measure the flux of CO₂ or CH₄ at any one time. Due to the high measurement height, it was found that a response time
28 of 1 Hz was sufficient to capture >70% of the flux (see below).

29 In addition to the closed-path system described above, an open-path infrared gas analyser (IRGA model Li7500, LI-COR
30 Biosciences) measuring CO₂ and H₂O at 20 Hz was mounted next to the ultrasonic anemometer on the roof of the BT tower.
31 Both analysers used the same anemometer but data were processed independently with different eddy-covariance software

packages. In ~~what follows~~the following text, subscripts “_CP” and “_OP” will respectively denote the closed-path and open-path eddy-covariance systems, and fluxes derived from them, located at the BT tower.

2.2.2 King’s College London site

Fluxes of CO₂ measured by EC_CP (F_{CO₂_CP}) were compared to fluxes measured at an eddy-covariance site at King’s College London (KCL; use of subscript “_KCL” to identify this eddy-covariance system in what follows) Strand campus, ~~about~~ 2 km south-east of the BT tower (Fig. S1), where long-term EC measurements have been analysed to study energy exchanges (Kotthaus and Grimmond, 2014a, b), carbon dioxide fluxes (Ward et al., 2015) and the F_{CO₂} storage term in a dense urban environment (Bjorgegren et al., 2015). Carbon dioxide fluxes are obtained from observations of an open-path Li7500 gas analyser and a CSAT3 sonic anemometer (Campbell Scientific). KCL is within the flux footprint of the BT tower during south-easterly wind directions. Fluxes of CO₂ from the KCL site were processed as outlined by Kotthaus and Grimmond (2014a). For the time August – September 2015, a ~~methane-CH₄~~ sensor (Aerodyne Quantum Cascade Laser (QCL)) was added to the EC system at KCL to also observe F_{CH₄}. No ~~carbon-monoxideCO~~ was measured at KCL. The EC_KCL system was operated at the top of a tower situated on the roof of a large building resulting in a measurement height of 50 m above mean ground level ~~in the flux footprint~~ (Ward et al., 2015), i.e. ca. 140 m lower than for EC_CP. Given that the KCL site is closer to the urban canopy, ~~the-its~~ source area extends to several hundred metres, while the footprint of the BT tower is much larger, i.e. in the order of kilometres. The QCL measured ~~methaneCH₄~~, nitrous oxide (N₂O) and water vapour simultaneously and at 10 Hz. The instrument was housed in an air-conditioned cabinet to minimise temperature fluctuations. Air was sampled ca. 20 cm below the anemometer head at 20 lpm through a 25 m long Teflon tube with outer diameter 1.27 cm (1/2”). The data was logged using an in-house LabView program and processed offline as outlined in section 2.3.

2.3 Data processing and filtering

Half-hourly fluxes

Half-hourly fluxes were calculated using standard eddy-covariance methodology extensively described elsewhere (e.g. Aubinet et al., 2000; Foken et al., 2004; Moncrieff et al., 2004). The quality control procedures and the performance of the eddy-covariance system at the tall tower are presented in sections 2.3.1 to 2.3.3.

Monthly and annual emissions

Monthly emissions were calculated from mean diurnal flux profiles constructed by averaging half-hourly fluxes into 24 nominal hourly bins. Annual emissions were estimated by summing monthly averages. However, the data period September 2012-March 2013 (no ultrasonic anemometer) was gapfilled using available monthly averages obtained over the remaining measurement period. Due to insufficient temporal coverage, individual annual budgets for 2012-2014 could not be derived for the CO flux. A composite annual emissions estimate was compiled instead which made use of all available monthly averages of F_{CO} over the study period September 2011 to December 2014.

2.3.1 High frequency attenuation

Normalised cospectra ('Co(x)') of wCO₂ and wCH₄ measured by the closed-path system were corrected to match those of wT (where T is sonic temperature) to assess high frequency damping caused by the instrument's limited sampling rate (1 Hz), internal instrument time response and the long inlet line (~ 45 m). Co(wT) followed the theoretical $f^{-5/3}$ (where f denotes frequency) slope for the inertial sub-range (Foken, 2008) over the entire frequency range (Fig. 21). In contrast, Co(wCO₂) and Co(wCH₄) diverged from the theoretical slope for frequencies > 0.1 Hz and followed profiles with slopes of the order of $\sim f^{5/2}$. Relative humidity did not have a significant influence on Co(wCO₂) and Co(wCH₄) for the two regimes tested (RH = 52% and RH = 80%, data not shown) which suggests that the dominant causes of signal attenuation for our system were the sampling rate and the length of the inlet line. Typical corrections for high frequency attenuation ranged from 15% -30% and based on the co-spectra presented in Fig. 21 it can be inferred that eddies of frequency < 0.1 Hz carried > 70% of the flux measured at the 190 m above-street-level sampling height. The net flux loss resulting from high frequency attenuation was of the order of 30% over the entire frequency range. Each half-hourly flux was corrected for high frequency attenuation as part of the offline data processing procedure on a point per point basis.

2.3.2 Quality control and filtering

Half-hourly means were excluded if any of the following quality assurance criteria were not fulfilled:

- The number of raw data points per nominal half hour was < 35000.
- The flow rate in the sampling line was ~~less than~~ \leq 15 lpm (theoretical limit of the transitional phase between laminar and turbulent flow for the sampling tube diameter used in this study).
- The number of spikes in u, v, w (components of the 3D wind vector measured by the ultrasonic anemometer) or any of the trace gas mole fractions was > 360 (i.e. 1% threshold).
- Latent and sensible heat fluxes fell outside the -250 W m⁻² to +800 W m⁻² range.
- The level of turbulence was deemed insufficient for flux measurement (friction velocity, u_* , threshold of 0.2 m s⁻¹). This threshold was used for consistency with previous studies carried out at the BT site (Helfter et al., 2011; Langford et al., 2010).
- The stationarity test which requires that the difference between the half-hourly flux and the fluxes obtained from 6 x 5 min averaging sub-intervals does not exceed 30% is satisfied (Foken and Wichura, 1996; Foken, 2004).

2.3.3 Comparison between closed-path and open-path systems

The performance of the closed-path greenhouse gas eddy-covariance system located on the 35th floor of the BT tower (EC_{CP}) was compared to that of the open-path IRGA located on the roof of the tower (EC_{OP}). ~~EC_{CP} operated at 1 Hz, EC_{OP} at 20 Hz and.~~

After frequency correction, half-hourly CO₂ fluxes measured by an open-path Li7500 infrared gas analyser located on the roof of the BT tower (F_{CO₂OP}) were strongly correlated to the fluxes obtained with the closed-path Picarro analyser (F_{CO₂CP}; Fig. 32). Increased scatter in F_{CO₂CP}, especially during low fluxes, could be due to uncertainties in determining the time-lag through maximisation of the covariance or also to uncertainties arising from the open-path analyser. The slope of near unity indicates that the high frequency attenuation of the turbulent flow due to instrument response time, sampling flow rate and length of the sampling line was adequately and systematically corrected for.

F_{CO₂CP} clearly varied with friction velocity (u^*) with maximum fluxes observed at u^* values around 0.8 m s⁻¹, strongly reduced fluxes at low $u^* < 0.3$ m s⁻¹ and the indication of reduced values at very high values of u^* (Fig. S2). A similar u^* dependence was found for the fluxes from the open-path gas analyser (not shown). Near-zero fluxes were recorded by both systems for u^* values < 0.1 m s⁻¹. For CO₂ flux measurements over vegetation, this type of behaviour is usually attributed to a reduction in the transport to the measurement height, resulting in storage of CO₂ below that height which may be subject to advection. In the urban environment, this u^* dependence could alternatively arise from an actual correlation between u^* and surface emission. Indeed, on average both u^* and traffic counts show a minimum at night. However, it is likely that a loss of coupling with street level sources as a result of limited vertical transport occurred in situations of low turbulence. These situations often coincide with stable night-time conditions during which the boundary layer height can approach that of the measurement height (Barlow et al., 2015). In such conditions the measured flux would be an underestimate of the true surface emission due to change in storage in the air column below the measurement height. An explicit treatment of the storage term based on a gradient approach where concentrations and wind speeds are recorded at multiple heights below the EC measurement point could help probe the low u^* regime. Such additional measurements were however not available for the BT tower site and we therefore speculate that the observation of venting after onset of turbulence, when the boundary layer grows, would capture at least some if not most of the material stored below the measurement height.

2.4 Uncertainty analysis

Random measurement uncertainties were estimated for each half-hourly averaging period using the Finkelstein and Sims (2001) method and subsequently averaged into monthly means. The upper bounds of the random uncertainties associated with the annual emissions estimates were taken as the maximum monthly random uncertainty for each year and trace gas.

1 Unlike random uncertainties, which arise from instrument noise and representativeness of single-point measurements,
2 systematic errors can be minimised by careful data processing and correction. In particular, successive calibration events were
3 linearly interpolated over time, cancelling out errors due to calibration drifts assuming that the drift was linear over time.
4
5 So far we have considered the error in the local flux. In addition, there is an uncertainty of how this local flux relates to the
6 emission at the surface. The effects of advection and storage on the flux measurement are difficult to quantify in a
7 heterogeneous environment like a city. However, whilst individual half-hourly flux values may be a poor representation of the
8 momentary emission, we expect the errors to reduce significantly when long-term averages are analysed. The validity of this
9 assumption is explored in more detail in what follows.

10 **3 Results and discussion**

11 **3.1 Flux footprint**

12 For consistency with a previous study (Helfter et al., 2011), the flux footprint for the BT tower measurement site was estimated
13 with the analytical model of Kormann and Meixner (2001) for non-neutral atmospheric stratification, under the simplifying
14 assumptions that fluxes of heat and momentum were homogenous across the footprint. The frequency of observation of x_{90} ,
15 the distance from the tower where 90% of the measured fluxes originated from, is shown in Fig. 4-3 as a function of wind
16 direction and season for the measurement period 2011-2014. The spatial extent of the flux footprint was highly variable over
17 time with recurring seasonal patterns. Typically, 90% of the flux measured at the BT tower site originated from distances of
18 the order of a few km in spring and summer compared to several tens of km in winter. The flux footprint contains two large
19 parks in the SW (Hyde Park, surface area 142 ha) and NW (Regent's Park, surface area 197 ha), sub-urban residential areas in
20 the N, a mixture of heavily urbanised residential and commercial areas in the E and S and a section of the Thames river in the
21 SE.

22 **3.2 Comparison with flux measurements at a lower height**

23 **3.2.1 Temporal similarities**

24 $F_{\text{CO}_2\text{CP}}$ and CO_2 fluxes observed at the KCL site ($F_{\text{CO}_2\text{KCL}}$) exhibited a high temporal correlation (Fig. 4a, b; averaging period
25 15/09/2011 to 31/12/2013~~for~~) for diurnal patterns in both winter (defined as December – February) and summer (defined as
26 June – August unless otherwise stated)(Fig. 4a, b; averaging period 15/09/2011 to 31/12/2013). Daily minima occurred at
27 around 3:00 at both sites which is consistent with minimum traffic loads (Fig. 4f, g). Fluxes tended to increase from ca. 5:00-
28 6:00 until late morning and declined steadily from ca. 18:00 at both sites, which is again in agreement with the declining traffic
29 numbers in the evening. Methane fluxes exhibited similar temporal dynamics with the lowest emissions recorded during the
30 night and a sharp rise between ca. 5:00 and 8:00. A gradual decrease in F_{CH_4} was observed at both sites following the mid-
31 morning maximum.

1 In winter, carbon dioxide fluxes started to increase slightly earlier (by about 30 min on average) at the KCL site. While this
2 time lag was not evident in the summer for F_{CO_2} , methane fluxes started rising later at the elevated measurement point at BT
3 tower even in summer. Boundary layer growth in the morning transition period might explain some of the time delay observed
4 in the carbon fluxes. Mixing height (MH) estimates for several weeks in winter (6 Jan – 11 Feb 2012) and summer (23 July –
5 17 Aug 2012) derived from Doppler LIDAR turbulence measurements (Bohnenstengel et al., 2015) at sites close to BT tower
6 (Fig. 4d, e) indicate that, on average, turbulent mixing extended above the BT tower measurement height of 190 m in both
7 seasons. However, mixing height exhibits great temporal variability depending on the synoptic background conditions; for
8 London it has been found that MH development depends primarily on the boundary layer winds and stability (Halios and
9 Barlow, 2016) so that these short-term climatology estimates might not be representative for the full period analysed for the
10 turbulent fluxes.

11 Growth of the convective layer was rapid in summer and a plateau was typically reached mid-morning which lasted until late
12 afternoon. In agreement with the shorter day-length in winter, growth of the mixing height was slower, collapsing earlier in
13 the evening after the mid-afternoon maximum. Daytime maximum mixing height was about 30% lower in winter compared to
14 the summer. In both summer and winter, traffic counts rose during the morning transition period i.e. before the mixing layer
15 started growing considerably (Fig. 4f, g); in the evening, traffic counts began decreasing after the mixing height had reduced
16 in height. Given that the mean temporal evolution of ~~carbon dioxide~~ CO_2 fluxes observed at both KCL and BT tower appeared
17 to be closely linked to the profiles of road traffic, vehicle emissions apparently represent a significant control not only for the
18 local-scale observations at KCL (Ward et al., 2015) but also for fluxes at the elevated BT tower measurement point (Helfter et
19 al., 2011). The slight morning delay in wintertime F_{CO_2} (Fig. 4a) observed at BT tower might be explained by the efficacy of
20 vertical turbulent transport between street level and the top of the BT tower which has been shown to depend on atmospheric
21 stability. The timescale of upward vertical turbulent transport was estimated to be of the order of 10 minutes for near-neutral
22 conditions, increasing to 20-50 minutes for stable conditions (Barlow et al., 2011). Low turbulence and prolonged periods of
23 stable atmospheric stratification (Fig. S3) could thus explain the 1-2 hour lag between the timing of the morning increase in
24 traffic counts and fluxes of CO_2 at the BT tower during the winter (Fig. 4a). This is consistent with the lag time observed for
25 profiles of potential temperature, and thus upward mixing, measured at the BT tower and a lower-level measurement site close
26 to the BT tower at 18 m a.g.l. (Barlow et al., 2015). The near-synchronous rise in CO_2 and CH_4 fluxes observed in summer
27 (summer defined as the months (JJA) in the data period 15/09/2011 - 31/12/2013 for F_{CO_2} and the entire period 19/08 –
28 01/10/2015 for F_{CH_4}) at the two measurement sites (BT and KCL) at different heights is consistent with an earlier onset of
29 turbulent mixing (Fig. 4 b,c).

30 Storage fluxes are difficult to quantify accurately in a heterogeneous environment like a city as this would require vertical
31 profile measurements below the measurement height at several locations within the flux footprint. The analysis presented here
32 therefore relies to some extent on the assumption that, over long periods, positive and negative storage fluxes cancel out and
33 that effects of advection on the stored quantity are negligible. This assumption is further supported by the very small storage
34 fluxes (< 2.5 % of the magnitude of the vertical fluxes) calculated at the KCL site (Bjorkegren et al., 2015), although these

would be somewhat larger for the higher measurement height at BT. While the turbulent fluxes observed at the BT tower and KCL show close temporal alignment (Fig. 4a-c) their absolute values can differ considerably (e.g. KCL-to-BT ratios of peak FCO_2 ranged from 1.5 in winter to 0.9 in summer; the summer ratio for FCH_4 was 1.5).

3.2.2 Comparison of flux spatial variability at the elevated and roof-top sites

Both sites are situated in central London where anthropogenic emissions are high due to the elevated density of people and traffic (Ward et al., 2015). While the source area of the BT site includes central business district (CBD) areas with mostly medium density midrise building structures, residential areas as well as large parks, the KCL footprint is dominated by CBD structures with hardly any vegetation (Kotthaus and Grimmond, 2014b). Only the river Thames in its vicinity reduces anthropogenic emission in some parts of the KCL footprint. To evaluate the response of $\text{FCO}_{2\text{-CP}}$ and $\text{FCO}_{2\text{-KCL}}$ to variations in source area characteristics, the observations were grouped into eight sectors based on the wind direction measured at the BT tower (Fig. 5). The ~~carbon-dioxide~~ CO_2 fluxes observed at the two sites are linearly correlated for all eight wind sectors but slopes and goodness of fits vary. This is likely due to differences in flux footprints at the two measurement sites, including the extent (a few km at the BT tower and a few hundred metres at KCL; Kotthaus and Grimmond, 2014b) as well as emission source density (a function of surface types). Near 1:1 agreement was found in the dominant SW wind sector (Fig. 5). For other wind directions, differences in local-scale source area between the two EC sites become apparent: while a large green space (Regent's Park) is located to the NW of BT tower, the surface seen by the KCL measurements is least urbanised towards the S and SE of the site (river Thames; note that busy Waterloo bridge towards the SW of KCL acts as a very strong line source of CO_2 keeping the fluxes relatively high from this wind direction). In response to the surface cover, $\text{FCO}_{2\text{-CP}}$ exceeds $\text{FCO}_{2\text{-KCL}}$ in the E, S and SE wind sectors by 20%, 50% and 70%, respectively, and is lower by 50%-70% in the N, NW and W sectors with the poorest correlation for the NW sector. The smallest $\text{FCO}_{2\text{-CP}}$ fluxes were observed in the NW sector while $\text{FCO}_{2\text{-KCL}}$ was highest in sectors NW and W where the particularly busy Aldwych junction is located (Kotthaus and Grimmond, 2014a). KCL falls within the footprint of the BT tower site for SE wind direction, but clearly the BT tower measurement sees additional sources due to the larger footprint. The focus was placed on discussing CO_2 fluxes in this section ~~is~~ because it is the only compound for which we have a second long-term flux record at a lower measurement height. ~~However, we assume that all the conclusions (pertaining to e.g. spectral corrections, turbulent transport) in this section are also applicable to Fluxes -CH₄ of CH₄ and CO measured at the BT tower are presented alongside CO₂ in sections 3.3 – 3.5.~~

3.3 Diurnal variability of the measured fluxes

The fluxes of all three gases (FCO , FCO_2 and FCH_4) exhibited well-defined diurnal cycles with minimum emissions during the night, typically from midnight until 5:00 GMT (Fig. 6a-c). Emissions increased sharply from 6:00 reaching a daytime maximum at around 12:00, and then declined steadily until early evening when a local maximum was observed at around 18:00-19:00. Mean FCH_4 ranged from 5.7 to 11.0 $\text{kg km}^{-2} \text{hour}^{-1}$ (maximum-to-minimum ratio of 1.9), FCO_2 from 1867 to 6635

1 kg km⁻² hour⁻¹ (maximum-to-minimum ratio 3.5) and F_{CO} from 4.6 to 16.9 kg km⁻² hour⁻¹ (maximum-to-minimum ratio 3.7),
2 demonstrating that the relative dynamic range of F_{CH₄} is less than that of the other compounds.

3 ~~Summer-~~The summertime fluxes of CH₄ measured at the 190 m height did lag slightly behind the fluxes observed at the 50 m
4 height, but this apparent delay could have been caused by differences in flux footprint between the sites (e.g. the source area
5 of the BT tower fluxes has a much higher fraction of vegetation cover than the KCL footprint) and the fact that the diurnal
6 profiles were obtained for a much shorter time period (August-September 2015). ~~Instead,~~The similarity in F_{CH₄} temporal
7 dynamics between the two sites supports the idea that the diurnal variations for that gas represent real variability in its source
8 strength rather than an artefact of atmospheric transport as suggested by Gioli et al. (2012) for the Florence (Italy) case study.
9 Indeed, the diurnal variations in F_{CH₄} measured at the BT tower were mirrored by strongly suppressed night-time CH₄ fluxes
10 observed at a much lower height at the KCL site (Fig. 4c), where the storage error has been demonstrated to be small for CO₂
11 (Bjorkegren et al., 2015). This suggests that ~~either the gas supply pressure in the~~fugitive emissions from the natural gas
12 distribution network, which are thought to be the dominant cause of urban CH₄ emissions in developed cities, exhibits diurnal
13 variations and/or that other CH₄ sources with temporal variations (e.g. fugitive emissions from natural gas appliances) are
14 more significant than estimated by LAEI. This is further supported by F_{CH₄} being smaller at the weekend than on weekdays
15 (Fig. 6g).

17 3.3.1 Dependence of flux magnitude and diurnal patterns on wind sector

18 Segregating emissions by wind direction reveals heterogeneous source distributions at the BT tower site with different temporal
19 patterns (Fig. 6d-f) and source strengths (Fig. S4-S6). The lowest emissions (\pm standard error of the mean) for all three
20 pollutants were recorded for NW winds (F_{CO} = 1.7 ± 0.3 kg km⁻² hour⁻¹, F_{CO₂} = 728 ± 127 kg km⁻² hour⁻¹, F_{CH₄} = 1.9 ± 0.2 kg
21 km⁻² hour⁻¹). The highest emissions of ~~methane-CH₄~~ were found in the SE wind sector (17.8 ± 1.3 kg km⁻² hour⁻¹), in the S
22 sector for ~~carbon dioxide~~CO₂ (9020 ± 515 kg km⁻² hour⁻¹) and in the E sector for ~~carbon monoxide~~CO (25.4 ± 3.9 kg km⁻²
23 hour⁻¹). The difference in emissions between wind sectors was however only statistically significant for the N and NW wind
24 sectors. Maxima of F_{CO}, F_{CO₂} and F_{CH₄} occurred on average at around 7:00-8:00 in the NW sector. Peak emissions for F_{CO₂} and
25 F_{CH₄} in the remaining wind sectors occurred typically between 9:00 and 12:00. The overall diurnal profile of F_{CO} was bimodal,
26 except for NE and NW, with well-defined mid- to late-morning peaks (typically 9:00 to 12:00 GMT) followed by early evening
27 peaks (17:00 to 19:00). F_{CO} and F_{CO₂} reached night time minima at around 3:00 in all wind sectors whereas F_{CH₄} tended to
28 plateau, except in the SE where emissions tended to increase. The onset of an early morning increase in emissions (ca. 5:00-
29 6:00 GMT) was consistent for all wind directions for F_{CO₂} and F_{CO} but it was less clearly defined for F_{CH₄}. In addition to diurnal
30 trends and dependency on wind sector, emissions of all three pollutants were found to be lower on weekends (Fig. 6g-i), with
31 CH₄ again showing the lowest variability (9% reduction on weekends compared to working days for F_{CH₄}, 22% for F_{CO₂} and
32 23% for F_{CO}).

1 3.4 Seasonality of the measured fluxes

2 For the measurement period September 2011 to December 2014, F_{CH_4} , F_{CO_2} and F_{CO} exhibited marked seasonal cycles with
3 minimum emissions in summer (Fig. 7a-c). The lowest emissions of CO were observed in April but this is thought to be an
4 artefact caused by relatively low temporal and spatial coverage for that month resulting from instrument downtime. Whilst not
5 used in the discussion that follows, the April data point is included in Fig. 7 c and f for consistency. For the months December-
6 February, F_{CO_2} and F_{CH_4} were 4.1 ± 0.5 ktons km^{-2} $month^{-1}$ and 7.4 ± 0.8 tons km^{-2} $month^{-1}$, respectively, and decreased to 2.7
7 ± 0.3 ktons km^{-2} $month^{-1}$ (33% reduction) and 5.8 ± 0.4 tons km^{-2} $month^{-1}$ (21% reduction), respectively, in summer (June-
8 August). The difference between winter and summertime emissions of ~~carbon monoxide~~CO was 3-fold with 9.1 ± 2.5 tons
9 km^{-2} $month^{-1}$ in December-February and 2.9 ± 0.1 tons km^{-2} $month^{-1}$ in June-July (due to instrument downtime, no data are
10 available for August).

11 3.4.1 Seasonal controls of fluxes of carbon monoxide and carbon dioxide

13 It is well established that emissions of CO from petrol cars are temperature dependent, e.g. increasing by a factor of 5-6 at
14 ambient temperature $0^\circ C$ compared to $25^\circ C$ (Andrews, 2004) during the first 5-10 minutes following engine warm-up. The
15 strong negative linear dependence of F_{CO} upon air temperature (Fig. 7f) could thus indicate that cold starts and reduced
16 combustion efficiency played an important role during winter. Winter time (December-February) emissions of CO accounted
17 for 45% of the annual budget for this pollutant which is consistent with LAEI (LAEI, 2013) estimates of the combined natural
18 gas and cold start contribution to annual CO emissions (total 32%, with 26% and 6% attributed to cold starts and natural gas
19 consumption, respectively). F_{CO_2} was also correlated with air temperature (Fig. 7e; $R^2 = 0.59$), albeit to a lesser extent than
20 F_{CO} , which reflected the seasonal changes in domestic and commercial natural gas usage, but may also be influenced by
21 increased photosynthetic uptake by vegetation in the footprint during the warmer months. Anti-correlations between monthly
22 F_{CO_2} and air temperature have been reported in other studies (e.g. Beijing, Liu et al., 2012; London, Ward et al., 2015). The
23 gradient between F_{CO_2} and air temperature observed in this study ($-0.94 \mu mol m^{-2} s^{-1} ^\circ C^{-1}$) falls between the values reported
24 for the London site ($-1.95 \mu mol m^{-2} s^{-1} ^\circ C^{-1}$) and the Beijing site ($-0.34 \mu mol m^{-2} s^{-1} ^\circ C^{-1}$).

25 The flux ratio of CO to CO_2 is of the order of $4 mmol mol^{-1}$ in winter (excess CO due to cold starts and incomplete combustion)
26 and $2 mmol mol^{-1}$ in summer despite only moderate seasonal variations in traffic loads (Fig. S7). Traffic loads at Marylebone
27 Road, one of the busiest arteries in central London located < 1 km north of the BT Tower, varied by less than 5% seasonally
28 in the period June 2012 to December 2014 (source Transport for London; personal communication). The seasonality of F_{CO_2}
29 is hence likely controlled by changes in natural gas consumption and vegetation (Gioli et al., 2012; Helfter et al., 2011). This
30 is further supported by relatively constant ratios of F_{CH_4} to F_{CO_2} which suggests that seasonal variations in emissions were of
31 comparable magnitude for these two gases (Fig. S7). On average over the full three years of the study (2012-2014),
32 summertime F_{CO_2} were 30% lower than in winter (29% in 2012, 30% in 2013 and 2014). In comparison, during an earlier study
33 at the same site covering the year 2007, the winter to summer decrement was only 20% (Helfter et al., 2011).

1

2 3.4.2 Seasonal controls of methane emissions

3 Fluxes of CH₄ were 17% lower in summer than in winter (18%, 12% and 20% for 2012, 2013 and 2014 respectively) and the
 4 linear correlation of monthly averages with temperature was not statistically significant (Fig. 7d; $R^2 = 0.31$, p -value = 0.06).
 5 In contrast, the winter to summer decrease was of the order of 63% in the city of Łódź, Poland (Pawlak and Fortuniak, 2016)
 6 and the dependence of F_{CH_4} upon air temperature was statistically significant. The weaker correlation of F_{CH_4} with air
 7 temperature in London suggests that the total methane flux is due to a superposition of sources with constant and time-varying
 8 emission rates, whereas in Florence (Italy) no significant seasonality in CH₄ emissions was observed (Gioli et al., 2012). They
 9 related this to a constant pressure in the gas distribution network serving Florence. However, seasonality in both ~~methane-CH₄~~
 10 concentrations and ~~methane~~ isotopic signature have been reported in the Greater London area (Lowry et al., 2001). The winter
 11 time increase above background in CH₄ concentrations and the accompanying enrichment in $\delta^{13}C$ were consistent with North
 12 Sea natural gas and attributed to losses of CH₄ from over-pressurised pipelines in response to (or anticipation of) an increase
 13 in demand and to incomplete combustion upon boiler ignition. The seasonality of F_{CH_4} in Łódź (Poland) was also attributed to
 14 variations in natural gas usage (Pawlak and Fortuniak, 2016). Urban CH₄ emissions in Boston (USA) attributed to natural gas
 15 use also displayed a modest, albeit not statistically significant, seasonality, with lower emissions during the summer (McKain
 16 et al., 2015). An increase of total CH₄ emissions in summer could indicate temperature-sensitive biogenic sources played an
 17 important role in Boston. Although individually small, fugitive post-meter emissions (i.e. in homes or work place) can make
 18 a non-negligible cumulative contribution at the city scale (Wennberg et al., 2012). ~~If p~~Post-meter emissions are made up of
 19 time-varying (incomplete combustion upon natural gas appliance ignition/ usage) and constant components (leaking valves/
 20 fittings) in time, they which would be part contribute to both the seasonal variability and of to the baseline of CH₄
 21 emissions rather than being seasonally variable. Finally, methane emissions from liquefied petroleum gas (LPG) vehicles,
 22 although small compared to natural gas emissions, exhibit a positive dependence upon temperature (Nam et al., 2004) and are
 23 expected to also contribute to the seasonality and diurnal variation of the total urban CH₄ fluxes.

24 3.5 Annual budgets of methane, carbon monoxide and carbon dioxide emissions

25 Annual emissions of CO₂ ranged from 36.3 to 40.7 ktons km⁻² y⁻¹ with a 3-year mean of 39.1 ± 2.4 ktons km⁻² y⁻¹ (Table 1).
 26 These values are in good agreement with results from a previous measurement campaign at the BT tower in 2007 (35.5 ktons
 27 km⁻² y⁻¹; Helfter et al., 2011) and London Atmospheric Emissions Inventory (LAEI) bottom-up emission estimates for the
 28 central London boroughs of Westminster and Camden, which are the foremost spatial source areas entrained by the BT tower
 29 flux footprint. The good agreement for CO₂ obtained in the present and previous studies using different instrumentation
 30 provides a benchmark for subsequent comparisons between top-down measurements and bottom-up inventory estimates. Due
 31 to insufficient temporal coverage, individual annual budgets for 2012-2014 could not be derived for ~~carbon monoxide~~CO.
 32 Instead, one single annual CO flux value was calculated from individual monthly averages collected in the period September
 33 2011 – December 2014 on the assumption that year-on-year variability was small. Furthermore, emissions of CO for August

1 and September, when no observations were available, were estimated from a linear relation between F_{CO} and air temperature
2 (Fig. 7f). The composite annual emissions estimate of $89 \pm 16 \text{ t km}^{-2} \text{ y}^{-1}$ (range taken as the random uncertainty) is consistent
3 with the LAEI data (Table 1).

4 Flux ratios are less sensitive to limitations in vertical transport and provide an additional means of assessing the quality of the
5 bottom-up emission inventories and identifying poorly represented sources. Measured flux ratios of F_{CO} to F_{CO_2} were consistent
6 with average LAEI emission ratios (Table 2, Fig. S9). Measured flux ratios of F_{CO} to F_{CH_4} were about half the inventoried
7 values and measured ratios of F_{CH_4} to F_{CO_2} were twice the mean LAEI values (Table 2; Fig. S8), consistent with the measured
8 annual CH_4 fluxes (3-year mean $72 \pm 3 \text{ t km}^{-2} \text{ y}^{-1}$) being more than twice the inventory value. This indicates that some CH_4
9 sources were either underestimated or unaccounted for by the LAEI. Of the source categories included in the LAEI and listed
10 in Table 2 only gas leakage has the potential to increase the CH_4/CO_2 flux ratio, but an underestimation in leakage is only a
11 possible explanation if it follows the measured diurnal cycle, either due to changes in the supply pressure or in post-meter
12 emissions. We speculate that the diurnal, seasonal and spatial variations in F_{CH_4} , and the larger F_{CH_4}/F_{CO_2} ratio could be due a
13 contribution of temperature-sensitive CH_4 emissions perhaps of biogenic origin (e.g. increased methanogenesis from sewerage)
14 not included in the inventories. This could explain why the net seasonal decrease in CH_4 was but half that of CO_2 (Fig. 7a and
15 b). Previously reported discrepancies of 1.5 to > 2 between top-down and bottom-up estimates of CH_4 for the South Coast Air
16 Basin in the greater Los Angeles (USA) area have been related to emissions from landfills and other biogenic sources (Hsu et
17 al., 2010; Wunch et al., 2009). In our study, annual methane fluxes exhibited substantial spatial variability when segregated
18 by wind sector (Fig. 8a). Fluxes of methane in the E, S and SE sectors were ca. 30% larger than the mean annual F_{CH_4} estimate
19 and exceeded the top boundary of the overall mean (taken as mean F_{CH_4} + maximum monthly uncertainty; Fig. 8a). In contrast,
20 F_{CH_4} from the N and NW sectors were 40% and 30% of the mean value, respectively, and fell below the lower limit of the
21 overall mean (taken as mean F_{CH_4} – maximum monthly uncertainty). This perhaps suggests more complex, spatially discrete,
22 source distribution and composition for CH_4 compared with CO_2 and CO . The linear correlation between F_{CH_4} and population
23 was strong if the highest emitting wind sectors (E, S and SE) were excluded from the regression (Fig. 8b). Socio-economic
24 temporal dynamics, such as a significant daytime influx of commuters into a business district (e.g. the City of London financial
25 district which is located 3-4 km S-SE of the BT tower), might contribute substantially to CH_4 emissions (e.g. from sewage,
26 natural gas); in addition, the measured CH_4 emissions from such business areas might bear no correlation with the actual
27 resident population reported here (source: London Datastore, Greater London Authority, 2016) which can be considerably
28 smaller than the commuting workforce. Emissions of CH_4 in the E were strongly correlated with air temperature (Table 3),
29 which suggests one or more dominant seasonal source in that wind sector. Finally, neither test was statistically significant for
30 emissions in the SE and S where the flux footprints entrain some of the most heavily urbanised areas of central London as well
31 as part of the river Thames. Further work is needed to investigate the potential presence of additional sources of ~~methane- CH_4~~
32 which might be prevalent in those wind sectors.

33 As for CH_4 , CO_2 fluxes exhibited a dependence upon air temperature in the N, NE, E and W. The seasonality of the CO_2
34 emissions was not statistically significant in the remaining wind sectors which might be due to the presence of substantial

1 constant sources of CO₂ or to the prevalence of seasonal activities which do not emit CO₂ locally (e.g. more electrical heating
2 than natural gas). However, the spatial variability of F_{CO₂} was well-captured by differences in population in the respective flux
3 footprints of all wind sectors, except S (Fig. 8b).

4 4 Conclusions

5 This study presents the results of more than three years of continuous long-term eddy-covariance observations of fluxes of
6 ~~carbon-monoxide~~CO, ~~carbon-dioxide~~CO₂ and ~~methane~~CH₄ at an elevated measurement site (BT tower, 190 m a.g.l.) in central
7 London, UK. This unique vantage point, combined with the length of the study, allowed for the spatial and temporal emission
8 dynamics to be analysed in detail. The main conclusions are that all three trace gases exhibited diurnal cycles consistent with
9 anthropogenic activities (traffic, natural gas use) and underwent marked seasonal dynamics, with reduced emissions in the
10 summer.

12 *Seasonality of the measured fluxes*

13 Emissions of CO were strongly correlated with air temperature which is thought to be due to cold starts and reduced fuel
14 combustion efficiency by the London fleet during the winter. Winter time emissions of CO accounted for 45% of the annual
15 budget. Emissions of CO₂ were also correlated to air temperature and were 33% larger in winter than in summer. CO₂ emissions
16 were predominantly controlled by the seasonal increase in natural gas consumption, although vegetation uptake would also
17 have lowered CO₂ fluxes in summer. CH₄ fluxes averaged over all wind sectors decreased by 21% between winter and summer
18 but unlike CO and CO₂, the correlation with air temperature was not statistically significant. . When segregated by wind sector,
19 CH₄ fluxes in the E and W were strongly correlated with air temperature suggestive of sources with highly seasonal emission
20 rates, possibly leaks from the natural gas distribution network or emissions from sewage. Furthermore, CO₂ and CH₄ fluxes
21 were positively correlated with population density in all wind sectors except S for F_{CO₂} and S, SE and E for F_{CH₄}. This indicates
22 heterogeneous source distributions and/or densities with temporal dynamics which differ from the other wind sectors.

24 *Comparisons with atmospheric emissions inventories*

25 Measured annual emissions of CO₂ (39 ktons km⁻²) were in good agreement with bottom-up estimates from the London
26 Atmospheric Emissions Inventory (LAEI). As CO₂ is the most accurately represented of the three compounds in emission
27 inventories, this provides confidence in the flux measurements. Similarly, the measured annual budget for CO (89 tons km⁻²)
28 was ~~consist~~consistent with LAEI values which confirms that the spatial distribution of the sources of this pollutant is well
29 captured by the inventory. However, the measured annual CH₄ emissions (72 tons km⁻²) were more than double the LAEI
30 value suggesting that sources are not as well-characterised by the inventory. In particular, we hypothesise that the shortfall in
31 inventoried CH₄ emissions can be explained by the existence of temperature-dependent sources related to natural gas usage
32 and, perhaps also of biogenic origin (e.g. sewage).

1 **Acknowledgements**

2 The authors acknowledge a succession of projects for funding this research (NERC-funded projects ClearfLo (H003231/1),
3 GAUGE (NE/K002279/1)) as well as support by NERC National Capability funding, the EU FP7 Infrastructure Project InGOS
4 project (284274), the EU FP7 Grant BRIDGE (211345), and King’s College London.

5 The authors also acknowledge British Telecom (BT) for granting use of the tall tower for research purposes. In particular, we
6 are grateful to Karen Ahern for arranging work permits and facilitating access to the site. Thank you also to aerial riggers
7 Robert Semon, Wayne Loeber and Mark West for help with the installation and maintenance of the rooftop instruments. We
8 are grateful to BT security and facilities staff for their continued support and assistance with day-to-day logistics and to Dr
9 Neil Mullinger (Centre for Ecology and Hydrology) for help with instrument maintenance and visits to the site. Supporting the
10 KCL observations, we thank Dr Arnold Moene at Wageningen University for providing the ECpack software; all staff and
11 students at KCL and University of Reading (Grimmond group) who contributed to the data collection; KCL Directorate of
12 Estates and Facilities for giving us the opportunity to operate the various measurement sites.

2

3

4 **Figure 21:** Normalised cospectra of T (sonic temperature), CO₂ and CH₄ with respect to w (vertical wind component). Each
5 cospectrum is an average of 24 half-hourly cospectra (data period 12/03/2013 7:00 – 18:00). Regression of spectra for frequencies >
6 0.1 Hz marked by solid line for $Co(wT)$ and dashed line for both $Co(wCO_2)$ and $Co(wCH_4)$.

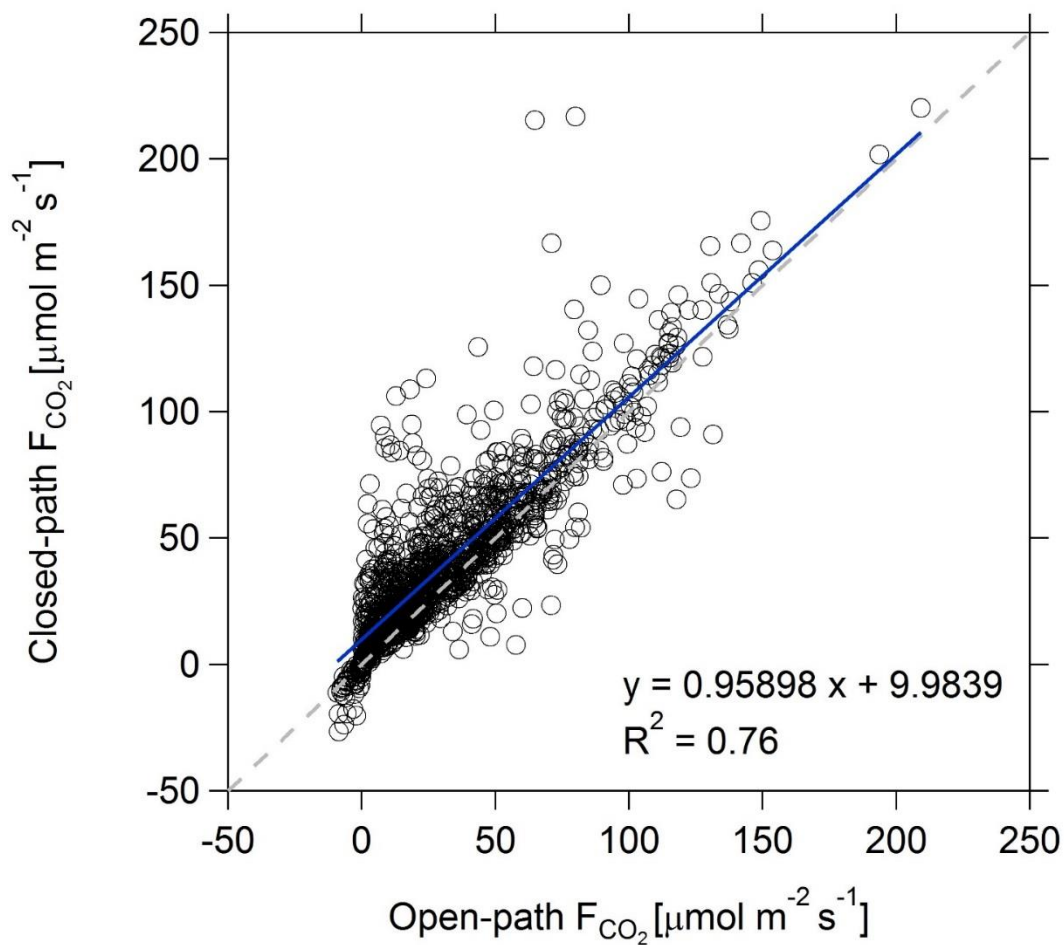

Figure 32: Comparison of half-hourly fluxes of CO_2 measured in March, August and October 2013 by a closed-path Picarro G1301-f operating at 1 Hz following high-frequency loss correction and an open-path Li7500 analyser operating at 20 Hz at the top of BT tower (sensor height: 190 m a.g.l.). Dashed line is 1:1 line.

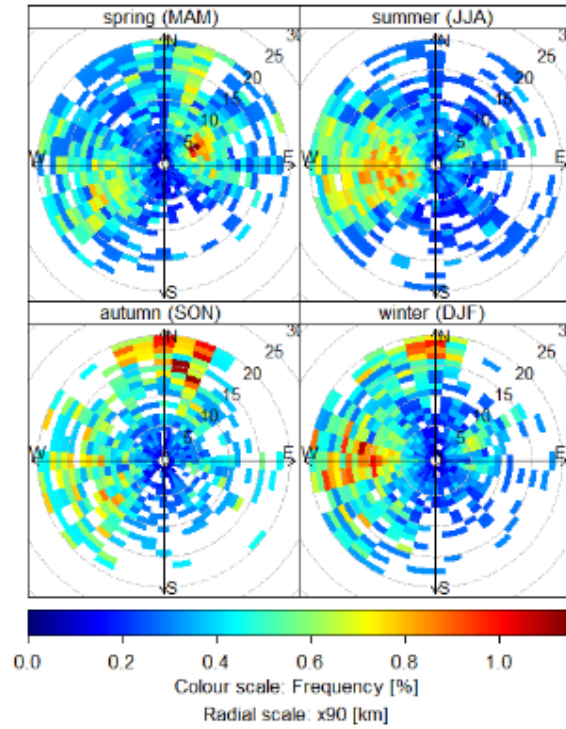

Figure 43: Frequency of occurrence of x_{90} (distance from the tower where 90% of the measured fluxes originated from) centred at the BT tower as a function of wind direction and season for the period 15/09/2011-31/12/2014. The flux footprint was estimated using an analytical model for non-neutral stratification (Kormann and Meixner, 2001) and the plots were produced using the openair package for R (Carslaw and Ropkins, 2012; Carslaw and Ropkins, 2016). Bin dimensions: 10° (angular scale) \times 1 km (radial scale).

Figure 2: Normalised cospectra of T (sonic temperature), CO₂ and CH₄ with respect to w (vertical wind component). Each cospectrum is an average of 24 half hourly cospectra (data period 12/03/2013 7:00 – 18:00). Regression of spectra for frequencies > 0.1 Hz marked by solid line for Co(wT) and dashed line for both Co(wCO₂) and Co(wCH₄).

Figure 3: Comparison of half hourly fluxes of CO_2 measured in March, August and October 2013 by a closed path Picarro G1301-f operating at 1 Hz following high frequency loss correction and an open path Li7500 analyser operating at 20 Hz at the top of BT tower (sensor height: 190 m a.g.l.). Dashed line is 1:1 line.

Figure 4: Mean diurnal profiles of CO_2 fluxes for (a) winter (DJF), and (b) summer (JJA) for the data period 15/09/2011 – 31/12/2013; (c) CH_4 fluxes in summer observed at the BT tower site (190 m a.g.l.) and the KCL site (50 m a.g.l.) over the period 19/08 – 01/10/2015; mixing height obtained from Doppler LIDAR measurements for (d) winter and (e) summer (Bohnenstengel et al., 2015); road traffic counts (f) winter and (g) summer (average of 246 counting stations distributed throughout the London conurbation; source: Transport for London, 2012 data). The shaded areas represent the 95% confidence interval.

1
2
3
4
5

Figure 5: Comparison between average diurnal profiles of CO₂ fluxes measured at the BT tower (190 m a.g.l.) and at the KCL site (50 m a.g.l.) in the period 15/09/2011 – 31/12/2013, separated into eight wind-direction sectors based on the wind direction observed at BT tower.

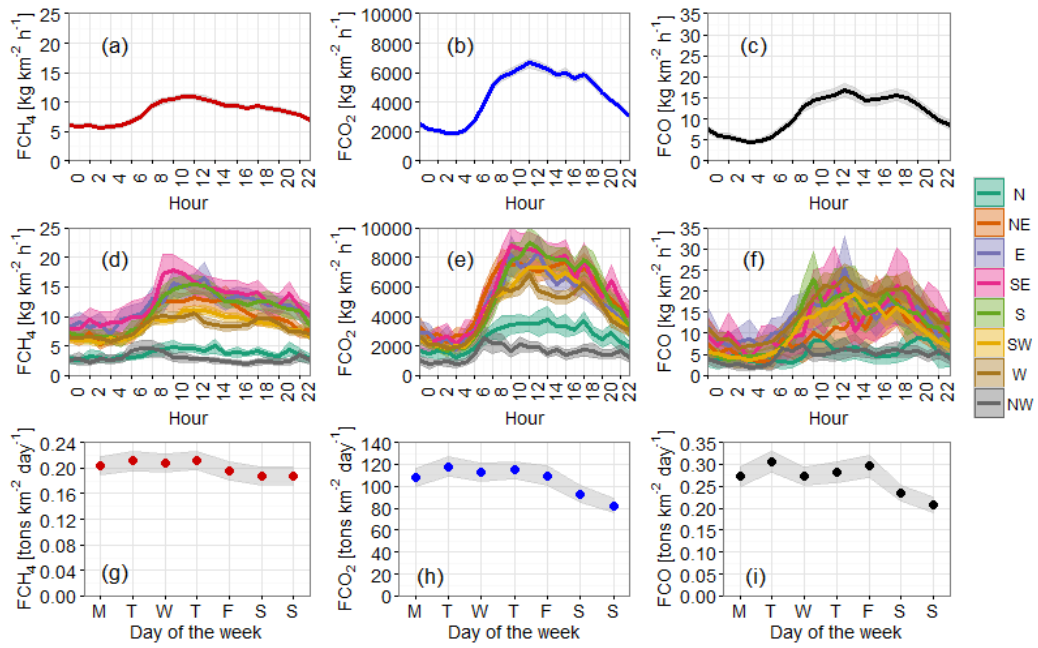

Figure 6: Fluxes of (a, d, g) methane (F_{CH_4}), (b, e, h) carbon dioxide (F_{CO_2}) and (c, f, i) carbon monoxide (F_{CO}) observed at BT tower with a closed-path gas analyser (from 15/09/2011 to 31/12/2014): (a)-(c) mean diurnal patterns with 95% confidence interval (shading), (d)-(f) as (a)-(c) but segregated into wind sectors and (g)-(i) by day of the week.

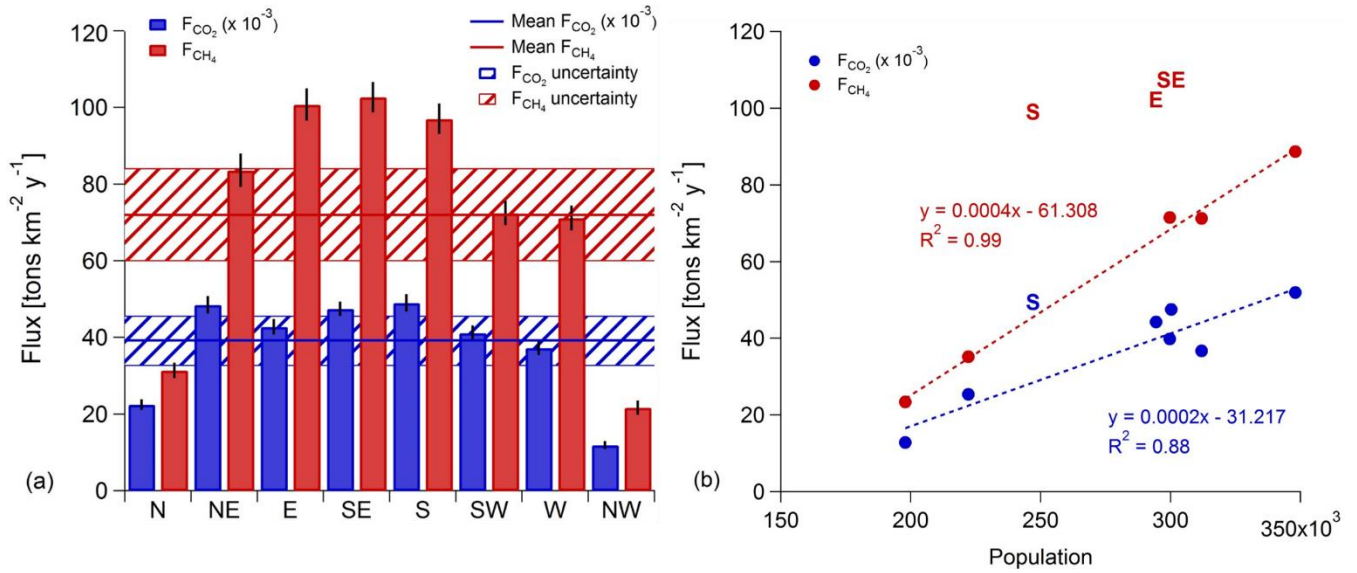

Figure 7: (a)-(c): Monthly averages of F_{CH_4} , F_{CO_2} and F_{CO} (September 2011-December 2014); (d)-(f): F_{CH_4} , F_{CO_2} and F_{CO} as a function of monthly mean air temperature. Solid lines are linear regressions and shaded areas are 95% confidence intervals. No F_{CO} measurements were available in August and September due to instrument downtime.
