Abstract. Currently, the atmospheric methane burden is rising rapidly, but the extent to which shifts in coal production contribute to this rise is not known. Coalbed methane emissions into the atmosphere are poorly characterised, and this study provides representative $\delta^{13}\text{CCH}_4$ signatures of methane emissions from specific coalfields. Integrated methane emissions from both underground and opencast coal mines in the UK, Australia and Poland were sampled and isotopically characterised. Progression in coal rank and secondary biogenic production of methane due to incursion of water are suggested as the processes affecting the isotopic composition of coal-derived methane. An averaged value of -65 ‰ has been assigned to bituminous coal exploited in open cast mines and of -55 ‰ in deep mines, whereas values of -40 ‰ and -30 ‰ can be allocated to anthracite opencast and deep mines respectively. However, the isotopic signatures that are included in global atmospheric modelling of coal emissions should be region or nation specific, as greater detail is needed, given the wide global variation in coal type.

1 Introduction

Methane emissions from the energy sector have been driven in recent years by the impact of a shift from coal to natural gas, in the US and Europe, whereas in China coal production has increased in this century. Currently, the atmospheric methane burden is rising rapidly (Nisbet et al., 2014), but the extent to which shifts in coal production contribute to this rise is not known. Coalbed methane emissions into the atmosphere are poorly characterised, as they are dispersed over large areas and continue even after the mines' closure (IPCC, 2006). Methane is emitted in coal processing (crushing and pulverisation) and during the initial removal of the overburden; it can be diluted and emitted through ventilation shafts in underground coal mines, or directly emitted to atmosphere from open-cut coal mining, where releases may occur as a result of deterioration of the coal seam.

For the UN Framework Convention on Climate Change, national emissions are estimated by a "bottom-up" approach, based upon a general equation where the coal production data are multiplied by an emission factor that takes into account the mine's gassiness, which in turn is related to the depth of the mine and the coal rank (i.e. carbon content of coal) (U.S. EPA, 2013). These modelled estimates are often reported without an error assessment, and therefore the level of accuracy of the emissions is not known. "Top-down" assessment of methane

39 emissions can be made by chemical transport models constrained by atmospheric measurements (Bousquet et al.,
40 2006; Locatelli et al., 2013). However, this top-down approach provides the total amount of methane emissions
41 into the atmosphere, which has to be distributed among the different methane sources in order to quantify each
42 source contribution.

43 For methane emissions from fossil fuels (coal and natural gas), the source partitioning is mainly “bottom-up”,
44 based on energy use statistics and local inventories, which might be highly uncertain. Conversely, the “top-down”
45 study of the carbon isotopic composition of methane, which is indicative of the methane origin, provides a valuable
46 constraint on the budget appraisal, allowing different sources in a source mix to be distinguished and their
47 individual strength to be evaluated (Hein et al., 1997; Liptay et al., 1998; Lowry et al., 2001; Townsend-Small et
48 al., 2012).

49 Measurements of methane mole fractions can be complemented in atmospheric models by typical $\delta^{13}\text{CCH}_4$
50 signatures of the main methane sources in order to estimate global and regional methane emissions and assess
51 emissions scenarios throughout the past years (Fung et al., 1991; Miller, 2004; Whiticar and Schaefer, 2007;
52 Bousquet et al., 2006; Monteil et al., 2011; Mikaloff Fletcher et al., 2014). However, even though isotopic values
53 are fairly distinctive for specific methanogenic processes, the variety of production pathways and local
54 environmental conditions that discriminate the methane formation process leads to a wide range of $\delta^{13}\text{CCH}_4$
55 values. The global isotopic range for coal is very large, from -80 to -17 ‰ (Rice, 1993), but it can be narrowed
56 down when a specific basin is studied. While there are several studies of isotopic composition of methane
57 generated from coal in Australia, U.S.A. and China (Smith and Rigby, 1981; Dai et al., 1987; Rice et al., 1989;
58 Aravena et al., 2003; Flores et al., 2008; Papendik et al., 2011), there is a significant lack of information about the
59 isotopic characterisation of methane emissions from coal mines in Europe.

60 The purpose of this study was to determine links between $\delta^{13}\text{CCH}_4$ signatures and coal rank and mining setting,
61 and to provide representative ^{13}C signatures to be used in atmospheric models in order to produce more accurate
62 methane emission estimates for the coal exploitation sector.

63 **Process of coalification and parameters affecting the $\delta^{13}\text{C}$ signature of methane emissions**

64 The process of coalification involves both biochemical and geochemical reactions. The vegetal matter firstly
65 decays anaerobically under water; the simple molecules derived from initial decomposition (i.e. acetate, CO_2 , H_2 ,
66 NH_4^+ , HS^- , long chain fatty acids) are metabolised by fermentative archaea, which produce methane via two
67 methanogenic paths: acetoclastic reaction or CO_2 reduction (Whiticar, 1999). Different pathways lead to diverse
68 $\delta^{13}\text{CCH}_4$ isotopic signatures - methane from acetate is ^{13}C enriched relative to methane from CO_2 reduction,
69 ranging from -65 ‰ to -50 ‰ and -110 ‰ to -50 ‰ respectively (Levin et al., 1993; Waldron et al., 1998). With
70 increasing burial and temperatures, coal is subjected to thermal maturation, which implicates more geochemical
71 changes.

72 As coalification proceeds, the carbon content increases, accompanied by a relative depletion in volatile
73 compounds, such as hydrogen and oxygen, emitted in the form of water, methane, carbon dioxide and higher
74 hydrocarbons through decarboxylation and dehydration reactions (Stach and Murchison, 1982). At higher degrees
75 of coalification and temperature, the liquid hydrocarbons formed in previous stages are thermally cracked to
76 methane, increasing the amount of methane produced (Faiz and Hendry, 2006). Peat and brown coal represent the
77 first stage of the coalification process. The vertical pressure exerted by accumulating sediments converts peat into

78 lignite. The intensification of the pressure and heat results in the transition from lignite to bituminous coal, and
79 eventually to anthracite, the highest rank of coal (O'Keefe et al., 2013).

80 During peat and brown coal stages, primary biogenic methane is formed and it is mainly dissolved in water or
81 released during burial, as coal is not appropriately structured for gas retention (Kotarba and Rice, 2001). At more
82 mature stages, thermogenic methane is produced by thermal modification of sedimentary organic matter, which
83 occurs at great depths and intensive heat. Following the basin uplift, methane production can be triggered in the
84 shallower sediments by the meteoric water inflow into the coal (secondary biogenic gas) (Rice, 1993; Scott et al.,
85 1994).

86 The isotopic signature of the methane produced during the coalification process is controlled by the methane
87 origin pathway (Whiticar, 1996). Thermogenic methane is isotopically enriched in ^{13}C ($\delta^{13}\text{C} > -50 \text{‰}$) compared
88 to biogenic methane, as methanogens preferentially use the lightest isotopes due to the lower bond energy (Rice,
89 1993). Intermediate isotopic compositions of methane might reflect a mixing between microbial and thermogenic
90 gases or secondary processes. Indeed, many controlling factors co-drive the fractionation process, and several
91 contentions about their leverage still persist in literature. Deines (1980) asserts that no significant trend is observed
92 in the isotopic signature of methane in relation to the degree of coalification. Conversely, Chung et al. (1979)
93 observed that the composition of the parent material does affect the isotopic composition of the methane
94 accumulated. While the link between isotopic composition and coal rank is not that straightforward, studies carried
95 out in different worldwide coal seams confirm a stronger relationship between coal bed gas composition and
96 depth. Rice (1993), using data from Australian, Chinese and German coal beds, shows that shallow coal beds tend
97 to contain relatively isotopically lighter methane when compared to those at greater depths. In the presence of
98 intrusions of meteoric water, secondary biogenic methane, isotopically lighter, can be generated and mixed with
99 the thermogenic gas previously produced. Colombo et al. (1966) documented a distinct depth correlation in the
100 Ruhr Basin coal in Germany, with methane becoming more ^{13}C -depleted towards the surface zone, independently
101 from coalification patterns. This tendency can be explained either by bacterial methanogenesis, or by secondary
102 processes such as absorption-desorption of methane. Also Scott (2002), in a study about coal seams in the Bowen
103 Basin, Australia, ascribes the progressive methane ^{13}C -enrichment with depth to the meteoritic recharge in the
104 shallowest seams, associated with a higher bacterial activity and a preferential stripping of ^{13}C - CH_4 by water flow.
105 The migration of methane from the primary zone as a consequence of local pressure release can affect the isotopic
106 composition, since $^{12}\text{CH}_4$ diffuses and desorbs more readily than $^{13}\text{CH}_4$ (Deines, 1980), but the fractionation effect
107 due to migration is less than 1 ‰ (Fuex, 1980). A much larger variation in the isotopic composition is associated
108 with different methanogenic pathways (variation of $\sim 30 \text{‰}$) and thermal maturation stage (variation of $\sim 25 \text{‰}$)
109 (Clayton, 1998). The measurement of Deuterium, coupled with $\delta^{13}\text{CCH}_4$ values, would help to distinguish the
110 pathways of secondary biogenic methane generation, acetoclastic reactions or CO_2 reduction (Faiz and Hendry,
111 2006), but such distinction is beyond the scope of this study.

112 Overall, the $\delta^{13}\text{C}$ values of methane from coal show an extremely wide range and understanding the processes
113 driving the methane isotopic composition needs to focus on the particular set of geological conditions in each
114 sedimentary basin.

115 Here we analyse the isotopic signatures of methane plumes emitted to atmosphere, from the dominant bituminous
116 and anthracite mines in Europe and Australia, of both deep and open cut type, to test the theory of isotopic change
117 due to coal rank.

118 2 Material and Methods

119 2.1 Coal basins investigated and type of coal exploited

120 2.1.1 English and Welsh coal mines

121 Coal-derived methane emissions in the UK are estimated at 66 Gg in 2013 (naei.defra.gov.uk), representing 0.4%
122 of global emissions from mining activity (US EPA, 2012). The major coalfields of England and Wales belong to
123 the same stage in the regional stratigraphy of northwest Europe (Westphalian Stage, Upper Carboniferous).
124 Mining has ceased in many areas. Of those remaining some are located in South Yorkshire (Hatfield and Maltby
125 collieries), where 50% of the coalfield's output came from the Barnsley seam, which includes soft coal overlaying
126 a semi-anthracitic coal and bituminous coal in the bottom portion.

127 The coal of the South Wales basin exhibits a well-defined regional progression in rank, which varies from highly
128 volatile bituminous coal in the south and east margin to anthracite in the north-west part, and the main coal-bearing
129 units reach 2.75 km in thickness toward the south-west of the coalfield (Alderton et al., 2004). The coal is now
130 preferentially extracted in opencast mines, as the extensive exploitation of the coal has left the accessible resources
131 within highly deformed structures (e.g. thrust overlaps, vertical faults) that cannot be worked by underground
132 mining methods (Frodsham and Gayer, 1999). Emissions from two deep mines, Unity and Aberpergwm, were
133 investigated, where mine shafts reach depths up to approximately 750 m ([http://www.wales-
134 underground.org.uk/pit/geology.shtml](http://www.wales-underground.org.uk/pit/geology.shtml)).

135 2.1.2 Upper Silesian Coal Basin in Poland

136 The Upper Silesian Coal Basin extends from Poland to the Czech Republic and is one of the largest coal basins
137 in Europe, with an area of ~7400 km² (Jureczka and Kotas, 1995), contributing 1.3% to global coal-derived
138 methane emissions (US EPA, 2012). Emissions from the Silesian Region of Poland are estimated to be in the
139 range of 450-1350 Gg annually (Patyńska, 2013). The upper Carboniferous coal-bearing strata of this region are
140 associated with gas deposits of both thermogenic and microbial origin, and the methane content and spatial
141 distribution are coal rank related (Kędzior, 2009) - i.e. the sorption capacity of coal in the basin is found to increase
142 with coal rank. Most of the methane generated during the bituminous stage in the coalification process has escaped
143 from the coal source following basin uplift during Paleogene (Kotarba and Rice, 2001) and diffused through
144 fractures and faults occurring in tectonic zones. The late-stage gas generated by microbial reduction of CO₂ in the
145 coal seams at the top of the Carboniferous sequence accumulated under clay deposition in the Miocene (Kędzior,
146 2009).

147 2.1.3 Australia: Hunter Coalfield (Sydney Basin)

148 The Hunter Coalfield is part of the Sydney Basin, on the east coast of New South Wales in Australia, and consists
149 of 3 major coal measures. The deepest is the early Permian Greta Coal Measures, which is overlain by the late
150 Permian Whittingham Coal Measures and upper Newcastle Coal Measures. Throughout the Hunter coalfield all
151 sedimentary strata are gently folded, and the same coal seam can be mined at the ground surface and at depths of
152 several hundred meters. In the region surveyed both the opencast and underground mines are extracting coal from
153 the Whittingham coal measures, which are generally high volatile bituminous coals, although some medium to
154 low bituminous coals are extracted (Ward and Kelly, 2013). The mining operation is on a much larger scale than

155 in the UK - the total coal production for the Hunter Coalfield was 123.63 Mt in 2011, of which 88.24 Mt was
156 saleable (State of New South Wales, 2013) - and methane emissions are estimated to contribute 4.6% to global
157 coal-derived methane (US EPA, 2012). Several studies have attested to the dispersion of thermogenic methane
158 formed at higher degrees of coalification (i.e. high temperatures and pressures) during the uplift and the
159 subsequent erosion of the basin, followed by the replenishment of the unsaturated basin with more recently formed
160 methane of biogenic origin (Faiz and Hendry, 2006; Burra, 2010). Gas emplacement is related to sorption capacity
161 of coal strata, in particular to the pore pressure regime, which is influenced by the local geological features
162 (compressional or extensional) of the basin. The south of the Hunter Coalfield is characterised by higher gas
163 content and enhanced permeability than the northern area, with a large potential for methane production, mainly
164 biogenic (Pinetown, 2014).

165 **2.2 Sampling and measurement methodology**

166 For isotopic characterisation of the methane sources, integrated methane emissions were assessed through
167 detection of the offsite downwind plume. In fact, even when emissions are focused on defined locations, such as
168 vent pipes in underground mines, the methane provenance cannot be localised, since most of collieries are not
169 accessible. For sample collection and measurements of methane emissions downwind of coal mines in the UK
170 and Australia the mobile system described by Zazzeri et al. (2015) has been implemented. The system utilises a
171 Picarro G2301 CRDS (Cavity Ring-Down Spectroscopy) within the survey vehicle, for continuous CH₄ and CO₂
172 mole fraction measurements, and a mobile module including air inlet, sonic anemometer and GPS receiver on the
173 roof of the vehicle. The entire system is controlled by a laptop, which allows methane mole fractions and the
174 methane plume outline to be displayed in real time on a Google Earth platform during the survey to direct plume
175 sampling. When the plume was encountered, the vehicle was stopped and air samples collected in 3L Tedlar bags,
176 using a diaphragm pump connected to the air inlet. Samples were taken at different locations along the plume
177 transect in order to obtain a wide range of methane mole fractions and isotopic signatures in the collected air. The
178 Upper Silesian basin was surveyed with a Picarro 2101-i measuring continuous CO₂ and CH₄ mole fractions and
179 $\delta^{13}\text{C}\text{CO}_2$ isotopic ratio. Samples were collected on site for analysis of $\delta^{13}\text{C}\text{CH}_4$ isotopic ratio.

180 The carbon isotopic ratio ($\delta^{13}\text{C}\text{CH}_4$) of bag samples was measured in the greenhouse gas laboratory at RHUL
181 (Royal Holloway University of London) in triplicate to high precision (± 0.05 ‰) by continuous flow gas
182 chromatography isotope ratio mass spectrometry (CF GC-IRMS) (Fisher et al., 2006). CH₄ and CO₂ mole fractions
183 of samples were measured independently in the laboratory with a Picarro G1301 CRDS analyser, calibrated
184 against the NOAA (National Oceanic and Atmospheric Administration) WMO-2004A and WMO-X2007
185 reference scales respectively. The $\delta^{13}\text{C}\text{CH}_4$ signature for each emission plume was calculated using the Keeling
186 plot approach, according to which the $\delta^{13}\text{C}$ isotopic composition of samples and the inverse of the relative mole
187 fractions have a linear relationship, whose intercept represents the isotopic signature of the source (Pataki et al.,
188 2003). Source signatures were provided with the relative uncertainty, computed by the BCES (Bivariate
189 Correlated Errors and intrinsic Scatter) estimator (Akritas and Bershaday, 1996), which accounts for correlated
190 errors between two variables and calculates the error on the slope and intercept of the best interpolation line. Mole
191 fraction data and co-located coordinates were used to map the mole fraction variability using the ArcGIS software.

192 3 Results and Discussion

193 While most of the emissions from deep mines come specifically from ventilation shafts, which are point sources,
194 emissions from open-cut mines are wide-spread, and difficult to estimate. However, the objective of this study is
195 not the quantification of emissions, but the assessment of the overall signature of methane released into the
196 atmosphere, made through the sampling of integrated emissions from the whole area. Therefore, even though
197 onsite access to collieries was not possible, by driving around the contiguous area, methane emissions could be
198 intercepted and their mole fractions measured. Table 1 summarises $\delta^{13}\text{CCH}_4$ signatures of all the coal mines and
199 coal basins surveyed with the Picarro mobile system.

200 3.1 English coal mines

201 Methane plumes from Hatfield colliery, one of the few UK deep mines still open at the time of this study, were
202 detected during surveys on 10th July and 26th September 2013. The methane desorbed from coal heaps within the
203 colliery area and methane vented from shafts might explain the relatively high mole fractions measured (up to 7
204 ppm). Keeling plots based on the samples collected (4 on the first and 5 on the second survey) give intercept
205 values of -48.3 ± 0.2 and -48.8 ± 0.3 ‰ (2SD).

206 Maltby colliery is one of the largest and deepest mines in England and was closed in March 2013. The coal mine
207 methane was extracted and used for electricity, but over 3 ppm mole fractions were detected in ambient air during
208 both surveys in July and September 2013, giving evidence of methane releases from the recovery system and
209 ventilation shafts. The Keeling plot intercepts based on the samples collected in July and in September are -45.9
210 ± 0.3 and -45.4 ± 0.2 ‰ (2SD) respectively, ~ 3 ‰ heavier than the isotopic source signatures calculated for Hatfield
211 Colliery on the same sampling days. Both source signatures are in good agreement with the value of -44.1 ‰
212 observed for desorbed methane of the Barnsley coal seam, in a study conducted by Hitchman et al. (1990b).

213 Kellingley colliery is a still open deep mine situated in North Yorkshire. A surface drainage plant for electrical
214 power generation has been implemented (Holloway et al., 2005), and methane releases from the power plant might
215 justify the mole fractions peak of 9 ppm that was observed while driving on the north side of the coal mine on 10th
216 July 2013. The Keeling plot analysis of the samples collected indicates a source signature of -46.5 ± 0.3 ‰ (2SD).
217 The highest mole fractions detected around Thoresby mine, in Nottinghamshire, approached 5 ppm. Nine samples
218 were collected, giving a source signature of -51.2 ± 0.3 ‰ (2SD).

219 During the sampling of methane plumes from Daw Mill colliery, the highest methane mole fractions (~ 5 ppm)
220 were recorded close to the edge of the colliery, whereas, driving downwind of the site at further distances, only
221 background values were measured. Indeed, the estimated methane content of the coal seam exploited in Daw Mill
222 colliery, closed in March 2013, is low (typically about $1.7 \text{ m}^3/\text{tonne}$) and, furthermore, a ventilation system is
223 implemented, so that the coal mine methane potential is curtailed (Drake, 1983). Keeling plot analysis reveals a
224 source signature of -51.4 ± 0.2 ‰ (2SD).

225 3.2 Welsh coal mines

226 Methane emissions from coal mines in Wales were sampled in order to characterise methane releases from a
227 different rank of coal. The area investigated extended from Cwmllynfell to Merthyr Tydfil. The South Wales
228 coalfield is estimated to have the highest measured seam gas content in the UK (Creedy, 1991).

229 **3.2.1 Deep Mines**

230 The deep mine Aberpergwm, which closed in December 2012, did not operate coal mine methane schemes and
231 methane was vented up to the surface as part of standard operation systems (Holloway et al., 2005). That is
232 consistent with methane mole fractions peaks of 6 ppm observed when approaching the colliery. Air samples were
233 also collected near Unity deep mine, Wales' largest drift mine, which reopened in 2007 and is located in the town
234 of Cwmgwrach, only 1.5 km away from Aberpergwm. Isotopic source signatures of $-33.3 \pm 1.8 \text{ ‰}$ and -30.9 ± 1.4
235 ‰ result from the Keeling plots based on samples collected respectively near Aberpergwm and Unity colliery,
236 both highly ^{13}C enriched relative to all English collieries.

237 **3.2.2 Opencast Mines**

238 The Picarro mobile system was driven around opencast mines at Cwmllynfell and Abercrave, in the Swansea
239 Valley. Up to 3 ppm methane mole fractions were recorded near the two mines, which were closed in the 1960s
240 as drift mines and are currently exploited as opencast mines. Our measurements confirm that they are still emitting
241 methane, even though the methane mole fractions recorded downwind of the mines were not significantly above
242 background. ^{13}C signatures between -41.4 ± 0.5 and $-41.2 \pm 0.9 \text{ ‰}$ (2SD) result from isotopic analysis of samples
243 collected downwind of the opencast mines, approximately 10 ‰ lower than the isotopic signature characterising
244 Welsh deep anthracite mines.

245 **3.3 Polish coal mine**

246 A Picarro mobile survey of the Upper Silesian basin took place on 10th June 2013 and 12 air samples were
247 collected for isotopic analysis. All the mines in this area are deep mines, exploiting the coal at depths ranging
248 from 300 to 900 m. The Keeling plot analysis includes 8 samples collected around the area of Radoszowy,
249 downwind of the KWK Wujek deep mine shafts. Methane mole fractions in the range of 3-5 ppm were measured
250 in the majority of the area of Katowice and over 20 ppm mole fractions were detected when transecting the plume
251 originating from the exhaust shafts, which confirms the high level of methane that the mine contains. A source
252 signature of $-50.9 \pm 0.6 \text{ ‰}$ (2SD) was calculated by Keeling plot analysis, which is consistent with the values
253 obtained for the deep mined English bituminous coal.

254 **3.4 Australia: Hunter Coalfield**

255 On 12th and 18th March 2014 12 samples in total were collected along the route in the Hunter Coalfield, where the
256 bituminous coal strata of the Sydney Basin are extracted both in opencast and underground mines. The methane
257 plume width was in the range of 70 km (Fig. 1). A maximum mole fraction of 13.5 ppm was measured near a vent
258 shaft associated with the Ravensworth underground mine (see white star in Fig. 1b). The source signature
259 calculated by the Keeling plot analysis based on all the samples collected during both surveys (grey markers in
260 Fig. 2c) is $-66.4 \pm 1.3 \text{ ‰}$ (2SD) and this signature likely includes a mixture of methane derived both from
261 underground and opencast mines. Two samples collected downwind of the Ravensworth ventilation shaft (red
262 pushpins in Fig. 1b) fall off the Keeling plot trend for March 2014 and are not included in the calculation, because
263 they are likely dominated by methane from the vent shaft and are not representative of the regional mixed isotopic
264 signature.

265 In January 2016, 10 samples were collected downwind of a ventilation fan in the Bulga mine (second white star
266 in Fig. 1b). The Keeling plot for these (black circles in Fig. 2c) indicates a $\delta^{13}\text{C}$ source signature of $-60.8 \pm 0.3 \text{ ‰}$
267 (2SD). The samples collected next to the Ravensworth ventilation shaft in 2014 fit on this Keeling plot, suggesting
268 that the $\delta^{13}\text{CCH}_4$ isotopic signature of emissions from underground works in the Hunter Coalfield is consistent.

269 **3.5 New representative $\delta^{13}\text{CCH}_4$ isotopic signatures for coal-derived methane**

270 The $\delta^{13}\text{CCH}_4$ isotopic values for coal have been found to be characteristic of single basins, but general assumptions
271 can be made to characterise coal mines worldwide. Table 2 provides the literature $\delta^{13}\text{CCH}_4$ isotopic values
272 characteristic of specific coal basins. The isotopic signatures of emissions from English bituminous coal are
273 consistent with the range of -49 to -31 ‰ suggested by Colombo et al. (1970) for in situ coal bed methane in the
274 Ruhr basin in Germany, which contains the most important German bituminous coal of Upper Carboniferous age
275 and low volatile anthracite (Thomas, 2002). Progression in coal rank might explain the value of -50 ‰ for
276 emissions from English underground mined bituminous coal and -30 ‰ for anthracite deep mines, followed by a
277 $5\text{-}10 \text{ ‰}$ ^{13}C -depletion likely caused by the incursion of meteoric water in the basin and the subsequent production
278 of secondary biogenic methane (Scott et al., 1994), resulting in -40 ‰ for methane plumes from Welsh open-cut
279 anthracite mines.

280 The link between coal rank and $\delta^{13}\text{CCH}_4$ isotopic signature is appreciable in the study of UK coal mines, but
281 differences in the $^{13}\text{C}/^{12}\text{C}$ isotopic ratio within the same coal sequences could be ascribed to other parameters,
282 such as the depth at which the coal is mined - as methane migrates towards the surface, diffusion or microbial
283 fractionation may occur, especially if there is water ingress (see section 1). In particular, emissions from Thoresby
284 are more ^{13}C depleted than those measured around Maltby, although both mines exploit the Parkgate seam (see
285 Table 1), meaning that different isotopic signatures cannot be entirely linked to the coal rank. Biogenic methane
286 produced in a later stage due to water intrusion might have been mixed with the original thermogenic methane
287 formed during the coalification process.

288 Differences in methane emissions and their isotopic signature between opencast and deep mines have been
289 assessed by surveying both surface and underground mines, in the Welsh anthracite belt, and in the Hunter
290 Coalfield. The shallower deposits are more exposed to the weathering and meteoric water, most likely associated
291 with the production of some isotopically lighter microbial methane. Mole fractions up to 2.5 ppm were measured
292 around opencast mines in the Hunter Coalfield, in Australia, within a methane plume of more than 70 km width.
293 The highest methane mole fractions were consistently measured downwind of vent shafts in underground mines.
294 The difference in the source isotopic signature for methane emissions between the two types of mining both in
295 the Hunter Coalfield (from -61 to -66 ‰) and in Wales (from -31 to -41 ‰) reflects the isotopic shift of $5\text{-}10 \text{ ‰}$
296 that might be attributed to the occurrence of secondary biogenic methane.

297 The $\delta^{13}\text{C}$ signatures for coalbed methane emissions from the Upper Silesian basin are highly variable, with the
298 most ^{13}C depleted methane associated with diffusion processes or secondary microbial methane generation
299 (Kotarba and Rice, 2001), but the value of -51 ‰ measured for methane emissions from the KWK Wujek deep
300 mine is consistent with the value of -50 ‰ inferred for emissions from English bituminous coal extracted in
301 underground mines.

302 Figure 3 shows the $\delta^{13}\text{CCH}_4$ signatures ranges for each coal type, based on the results of this study and isotopic
303 values found in literature.

304 **4 Conclusions**

305 By measuring the isotopic signatures of methane plumes from a representative spread of coal types and depths,
306 we show that the $\delta^{13}\text{C}$ isotopic value to be included in regional and global atmospheric models for the estimate of
307 methane emissions from the coal sector must be chosen according to coal rank and type of mining (opencast or
308 underground). For low resolution methane modelling studies, our measurements suggest an averaged value of -
309 65 ‰ for bituminous coal exploited in open cast mines and of -55 ‰ or less negative, in deep mines, whereas
310 values of -40 ‰ and -30 ‰ can be assigned to anthracite opencast and deep mines respectively. However, the
311 ranges of isotopic signatures of methane emitted from each of these categories are wide (see Fig. 3), and the
312 isotopic ratios of methane from Chinese coal mines is little studied. Further measurements would be required in
313 other coal mining areas, especially China, to determine appropriate values for global modelling of methane
314 isotopes.

315 Global methane budget models that incorporate isotopes have used a $\delta^{13}\text{C}$ signature of -35 ‰ for coal or a value
316 -40 ‰ for total fossil fuels (e.g. Hein et al., 1997; Mikaloff Fletcher et al., 2004; Bousquet et al., 2006; Monteil
317 et al., 2011), but, given the relative rarity of anthracite global coal reserves and the dominance of bituminous coal
318 (1% and 53% respectively) (World Coal Institute, 2015), it seems likely that a global average emission from coal
319 mining activities will be lighter, with the -50 ‰ recorded for deep-mined bituminous coal in Europe being a closer
320 estimate. However, for detailed global modelling of atmospheric methane, isotopic signatures of coal emissions
321 should be region or nation specific, as greater detail is needed given the wide global variation. The assignment of
322 an incorrect global mean, or a correct global mean but inappropriate for regional scale modelling, might lead to
323 incorrect emissions estimates or source apportionment. The new scheme gives the possibility for an educated
324 estimate of the $\delta^{13}\text{C}$ signature of emission to atmosphere to be made for an individual coal basin or nation, given
325 information on the type of coal being mined and the method of extraction.

326 In conclusion, high-precision measurements of $\delta^{13}\text{C}$ in plumes of methane emitted to atmosphere from a range of
327 coal mining activities have been used to constrain the isotopic range for specific ranks of coal and mine type,
328 offering more representative isotopic signatures for use in methane budget assessment at regional and global
329 scales.

Powder River Basin, U.S.A.	Sub-bituminous coal	-68.4 to -59.5	Flores et al. (2008)	
Illinois Basin, U.S.A.	Bituminous coal	-66.6 to -56.8	Strapoć et al. (2007)	
Elk Valley Coalfield, Canada	Bituminous coal	-65.4 to -51.8	Aravena et al. (2003)	
Bowen basin, Australia	Bituminous coal	-62.2 to -48	Kinnon et al. (2010)	
Queensland Basin, Australia	From Sub-bituminous to high volatile bituminous	-57.3 to -54.2	Papendick et al. (2011)	
Tara region, Queensland Basin, Australia	From Sub-bituminous to high volatile bituminous	-56.7	Maher et al. (2014)	
San Juan basin, New Mexico and Colorado	High-volatile Bituminous coal	-43.6 to -40.5	Rice et al. (1989)	
Michigan Basin, U.S.A.	Bituminous coal	-56 to -47	Martini et al. (1998)	
UK, Barnsley seam	Bituminous coal	-44.1	Hitchman et al. (a, b)	-48.8 \pm 0.3 to -45.4 \pm 0.2
Upper Silesian Coal Basin, Poland	Sub-bituminous coal to anthracite	-79.9 to -44.5	Kotarba and Rice (2001)	-50.9 \pm 0.6
Eastern China	Sub-bituminous to anthracite	-66.9 to -24.9	Dai et al. (1987)	
Ruhr basin, Germany	Bituminous coal, Anthracite	-37 (-60 to -14)	Deines (1980)	
Western Germany	High-volatile bituminous to anthracite.	-70.4 to -16.8	Colombo et al. (1970)	
Eastern Ordos Basin, China	Bituminous Coal	-42.3 to -39.8	Guo et al. (2012)	
South-eastern Ordos Basin, China	Low-volatile bituminous and semi-anthracite	-48.1 to -32.8	Yao et al. (2013)	
Qinshui, China	Anthracite	-41.4 to -34.0	Qin et al. (2006)	
Qinshui Basin, China	Semi-anthracite to Anthracite	-36.7 to -26.6	Su et al. (2005)	
Sichuan Basin, China	Bituminous to anthracite	-36.9 to -30.8	Dai et al. (2012)	
Wales, UK	Anthracite		Xiong et al. (2004)	-33.3 \pm 1.8 to -30.9 \pm 1.4

514 **Table 2 Literature isotope values obtained by methane samples CBM (Coalbed Methane) wells across the basin. Errors are not included in the sources.**
