Response to Referee #1

We would like to thank the reviewer for the review that has enabled us to improve our manuscript; our responses to the review points and comments are found below.

Review Point 1: Generally, the paper needs clearer focus and to supply more model details/results/discussion pertinent to this focus. While the stated goal is to assess the temperature dependence of ozone chemistry as a function of NOx, at the end, I am not exactly sure what new has been learned. Really, what I think is missing is just a dedicated discussion section, the 'Results' read like a true results section, rather than combined results and discussion, so it is difficult for the reader to understand the significance of the calculations.

Author Response: We thank the reviewer for communicating these concerns. In order to address these concerns, we have updated each subsection in the 'Results and Discussion' section to include further discussion. The changes to the manuscript are detailed in the responses to the review comments on each subsection below.

Review Point 2: The reasons behind the ozone impacts from temperature-dependent reaction rates are unclear because it is not stated explicitly what this term includes. If I understand correctly, only temperature-dependent reaction rates, k(T), are being tested (page 4, lines 16). Generally, the model description does not give the reader sufficient information to understand what causes the changes reported in Table 2. For example, the text states the RONO2 formation is temperature dependent, at least in some mechanisms, but does this refer to the RONO2 branching ratio?

Author Response: The reviewer is correct in saying that only temperature-dependent reaction rates, k(T), are tested in our study. In Sect. 2.1 (Page 4, Line 2), the temperature-dependent processes included in the chemical mechanisms are presented. We have clarified that the branching ratio of $RONO_2$ formation is not represented as a temperature-dependent process by any chemical mechanism by adding the following text to the manuscript at Page 4, Line 6: *Furthermore, none of the chemical mechanisms in our study represent the $RONO_2$ branching ratio as a temperature dependent process. Laboratory experiments have shown the temperature dependence of the $RONO_2$ branching ratio for some VOCs (Atkinson et al., 1987) but generally $RONO_2$ chemistry is not well known (Pusede et al., 2015) and this level of detail is not represented by the chemical mechanisms. Before chemical mechanisms can include the temperature-dependence of the $RONO_2$ branching ratio, further research is required.*

Review Point 3: It is interesting to see how the five different mechanisms capture these effects; however, there is little discussion of what is learned about the different mechanisms by testing them in this way. Can the last paragraph of Sect. 3.1 be expanded? Also, I have difficulty discerning differences between panels in Fig. 2. Is there a way to highlight key differences here? Regarding Fig. 3, something has been lost in translation - there are some floating numbers in the upper left corner of the top-left panel, but the different colors are not labeled, either in the text or caption. I deduce that green is CB05, purple is MCM3.2, blue is MOZART-4, and orange and yellow are each either

RADM2 or CRIv2. I would be interested to read more, not just about what causes the differences between the curves, but also the implications for studying air quality and chemistry. Finally, the NOx regime distinction is derived from each individual model's H2O2:HNO3. Why not simply use the shape of simulated PO3 versus NOx. A missing piece of information is whether maximal O3 - at different temperatures - occurs at the same NOx level in each mechanism. Differences in the NOx level of maximal O3 for different mechanisms have consequences for air quality decision-making.

Author Response: We thank the reviewer for the comments on Sect. 3.1 of the manuscript and have made changes to the manuscript based on these points. Figure 2 has been updated with a subfigure (Fig. 2b) displaying the relative differences in ozone mixing ratios in each chemical mechanism at each temperature, NO_x condition from the MCMv3.2 when using a temperature-independent and temperature-dependent source of isoprene emissions. Based on this figure, a discussion of the differences between the chemical mechanisms is included in the manuscript (Page 5, Line 26): *As shown in Fig. 2b, regions of high temperatures and high NO_x emissions generally lead to the largest inter-mechanism differences between ozone mixing ratios using reduced chemical mechanisms from the MCMv3.2 (up to 13 %). These differences in peak ozone mixing ratio produced from the reduced chemical mechanisms compared with the MCMv3.2 in each NO_x condition are consistent with Fig. 3 (described below) where RADM2 and CB05 generally produced higher ozone levels than the MCMv3.2. Also consistent with Fig. 3, CRIv2 produced the most similar amounts of ozone to the MCMv3.2 in each NO_x condition whereas MOZART-4 tended to produce lower ozone mixing ratios than the MCMv3.2 in High-NO_x conditions. In Fig. 3, a maximum difference of 10 ppbv between ozone mixing ratios produced using the chemical mechanisms is reached at 40 °C in the High-NO_x state when using both a temperature-independent and temperature-dependent source of isoprene emissions.*

The issue with the display of the figures appears to be an issue with the default pdfviewer of the Chrome browser, downloading the file from the default pdfviewer in Chrome does not correct this issue. Opening the ACPD pdf using the Firefox browser and a pdfviewer extension of the Chrome browser (Kami) solves the issue and the manuscript is displayed as intended by the authors. We shall ensure that the updated manuscript does display correctly with the default pdfviewer in Chrome.

We used the H2O2:HNO3 ratio to assign a NOx regime as this has been used previously in other studies for this purpose, we have updated the manuscript to include examples. Sect. 3.1 (Page 6, Line 1) was updated: *This ratio was used by Sillman (1995) and Staffelbach et al. (1997) to designate ozone to NO_x regimes based on NO_x and VOC levels.*

The manuscript (Page 6, Line 17) was also updated to include further discussion on the NO_x emission required for the Maximal-O3 regime with each chemical mechanism, to aid this discussion a new figure was generated and included in the updated supplementary material: *The NO_x emissions required for maximum ozone production (the contour ridges in Fig. 2a) at each temperature is displayed in Fig. 1 of the supplementary material. This figure illustrates that RADM2 and CB05 require higher NO_x emissions than the MCMv3.2 to achieve maximum ozone production at each temperature for*

both a temperature-independent and temperature-dependent source of isoprene emissions. At 20 °C, maximum ozone production is reached with ∼ 30 % more NO_x emissions using CB05 and RADM2 than the MCMv3.2 with a temperature-independent and temperature-dependent source of isoprene emissions. The CRIv2 and MOZART-4 chemical mechanisms require very similar NO_x emissions to the MCMv3.2 at each temperature to produce maximum levels of ozone. Thus when modelling the air quality over a particular region using RADM2 and CB05, these mechanisms would be expected to simulate more NO_x-sensitive chemistry than the MCMv3.2, CRIv2 and MOZART-4 chemical mechanisms for the same conditions (i.e. emissions, meteorology and radiation). These differences in the ozone production regime using different chemical mechanisms highlight the need for air quality studies to assess the chemical scheme used by the model, otherwise differing mitigation strategies may be proposed.

Review Point 4: Provide a statement as to why the ozone production and consumption budget is informative for understanding the temperature dependence of ozone, i.e. what is gained compared to thinking about production alone. Also, can an equation be provided for the production and consumption budgeting? This section is in need of discussion and summary. There are many panels in Fig. 4 and it is not obvious to me what the take-away point(s) are.

Author Response: We agree with these review points and have provided additional information about the analysis of ozone production and consumption budgets, including equations and further description of how Fig. 4 was obtained. Section 3.2 of the manuscript (Page 7, Line 1) was updated: *Since chemical reactions contributing to both production and consumption of O_x ($\equiv O_3 + NO_2 + O(^1D) + O$) have temperature-dependent rate constants, we analysed the production and consumption budgets of O_x to determine the temperature-dependent chemical processes controlling the increase of ozone with temperature which was shown in Fig. 3. The O_x budgets displayed in Fig. 4 are assigned to each NO_x regime for each chemical mechanism and source of isoprene emissions. The net production or consumption of O_x is also indicated in Fig. 4.*

Figure 4 was obtained by determining the chemical reactions producing and consuming O_x and then allocating these reactions to important categories. Reactions of peroxy radicals with NO produce O_x and the peroxy radicals are divided into 'HO2', 'RO2', 'ARO2' categories representing the reactions of NO with HO_2, alkyl peroxy radicals and acyl peroxy radicals respectively. Thus at each time step the O_x production rate is given by

$$k_{HO_2+NO}[HO_2][NO] + \sum_i k_{RO_{2,i}+NO}[RO_{2,i}][NO] + \sum_j k_{ARO_{2,j}+NO}[ARO_{2,j}][NO] \qquad (1)$$

for each alkyl peroxy radical i and acyl peroxy radical j. The net contributions of peroxy nitrates, inorganic reactions and any other remaining organic reactions to the O_x budget are represented by the 'RO2NO2', 'Inorganic' and 'Other Organic' categories in Fig. 4. The net contributions of these categories to the O_x budget was calculated by subtracting the consumption rate from the production rate of the reactions contributing to each category. For example, peroxy nitrates produce O_x when

thermally decomposing or reacting with OH and consume O_x when produced. Hence, at each time step the net contribution of RO2NO2 to the O_x budget was calculated by

$$\sum_k k_{RO_2NO_{2,k}}[RO_2NO_{2,k}] + \sum_k k_{RO_2NO_{2,k}+OH}[RO_2NO_{2,k}][OH] - \sum_k k_{RO_{2,k}+NO_2}[RO_{2,k}][NO_2]$$

(2)

for each peroxy nitrate species k. The cumulative day-time budgets were calculated by summing the net contributions of the reaction rates of each category over the day-time period. The ratio of net ozone to net O_x production was practically constant with temperature in all cases showing that using O_x budgets as a proxy for ozone budgets was suitable at each temperature in our study.

The main results of the section are summarised and discussed in the final paragraph of Sect. 3.2 (Page 8) of the updated manuscript: *Our results indicate that increased VOC reactivity due to faster rate constants for the reaction with OH and the decomposition rate of peroxy nitrates are the temperature-dependent chemical processes leading to increased production of O_x with temperature. Out of these two chemical processes, the increased VOC reactivity with OH with temperature had a larger influence on the increase of O_x production with temperature. These results are consistent between each chemical mechanism and each NO_x condition.*

Review Point 5: Before the authors talk about mixing, the WRF-CHEM and box MOZART-4 results should be compared directly and discussed. The importance of atmospheric mixing appears for the first time in Section 3.3, at which time, the paper states it is the most important term in mO3-T. At this stage in the manuscript, I am left wondering what is this paper actually about. How does Section 3.3 relate to the previous two sections? A subsequent discussion would be helpful.

Author Response: We thank the reviewer for these comments on Sect. 3.3, we have updated the introductory part of this section to include further details of the motivations of the analysis and also discuss the use of the metric of $m_{O3\text{-}T}$ for comparing the box model, observations and WRF-Chem output. Furthermore the box model simulations looking at the effect of mixing on the increase of ozone with temperature are discussed in more detail. Accordingly, Section 3.3 (Page 8, Line 5) of the manuscript was updated: *The final step in our study was to compare how well our idealised box model simulations represent the real-world relationship between ozone and temperature. Firstly, we compared the box model simulations to the interpolated observations of the maximum daily 8 h mean (MDA8) of ozone from Schnell et al. (2015) and the meteorological data of the ERA-Interim re-analysis (Dee et al., 2011). Using this data set, Otero et al. (2016) showed that temperature is the main meteorological driver of ozone production during the summer (JJA) months over many regions of central Europe. A further test was to compare the box model simulations to the output from a regional 3D model as 3D models include explicit representations of transport and mixing processes which influence ozone production, and which are not well represented in our box model. We used the WRF-Chem 3D model set-up over the European domain to simulate ozone production in the year 2007 using MOZART-4 chemistry, further details are described in Mar et al. (2016).*

Directly comparing the ozone mixing ratios from our idealised box model simulations to the

WRF-Chem output is difficult due to significant differences in the setups of the models. For example, WRF-Chem used gas-phase and aerosol chemistry whereas our box model setup used only gas-phase chemistry, also the treatment of photolysis and VOC and NO_x emissions differ between our box model and WRF-Chem. In addition to this, to include the effects of transport and mixing, the box model includes a simple mixing term representing the entrainment of clean free tropospheric air into the growing daytime boundary layer. Stagnant atmospheric conditions are characterised by low wind speeds slowing the transport of ozone and its precursors away from sources and have been correlated with high-ozone episodes in the summer over eastern US (Jacob et al., 1993). Hence, out of the metereological conditions not represented by our box model, stagnation could have the largest influence on the increase of ozone with temperature In order to investigate the sensitivity of ozone production to mixing, further box model simulations were performed without mixing approximating stagnant conditions.

Figure 5 compares the ERA-Interim reanalysis and WRF-Chem output from summer 2007 averaged over central and eastern Germany, where summertime ozone values are driven by temperature (Otero et al., 2016), to the MDA8 values of ozone from the box model simulations for each chemical mechanism with mixing (solid lines) and without mixing (dotted lines). We compare the rate of change of ozone with temperature ($m_{O3\text{-}T}$) between the box model, WRF-Chem and ERA-Interim reanalysis data. This metric has been used to quantify future ozone pollution due to the warmer temperatures predicted by climate change (Dawson et al., 2007; Rasmussen et al., 2013) and is discussed further in the review of Pusede et al. (2015). $m_{O3\text{-}T}$ is calculated as the linear slope of the increase of ozone with temperature in ppbv of ozone per $^\circ C$. Polluted areas have larger $m_{O3\text{-}T}$ values than rural areas corresponding to the High-NO_x and Low-NO_x conditions simulated in our study. Table 3 summarises the calculated slopes of the box model simulations displayed in Fig. 5.

The final paragraph of Sect. 3.3 in the manuscript (Page 9, Line 4) was updated and additional discussion was included: Analysis of the O_x budgets, similar to that presented in Sect. 3.2, shows an increase in absolute net production of O_x when simulating stagnant conditions compared to simulations including mixing (Fig. 4a). Moreover, the O_x budgets normalised by the chemical loss rate of VOC for the simulations without mixing show no appreciable difference to the simulations including mixing. This analysis is displayed in the supplementary material and is consistent for each chemical mechanism and each NO_x condition. Thus we conclude that the increased ozone production seen in the box model simulations with reduced mixing is due to enhanced OH reactivity from secondary VOC oxidation products.

A slower rate of increase of ozone with temperature with our box model was obtained compared to the rate of increase of ozone with temperature of observational and 3D model simulations. The reason for this discrepancy was that the box model did not represent stagnation conditions which are relevant to real-world conditions. The lack of mixing meant that secondary VOC oxidation products were allowed to accumulate, leading to further degradation and increased production of peroxy radicals compared with simulations including mixing. Thus the chemical processes driving

the increase of ozone with temperature determined in Sect. 3.2 (faster VOC oxidation and peroxy nitrate decomposition) are not altered by stagnant condition but proceed at a faster rate. Thus during stagnant conditions, stronger reductions in NO_x are required to minimise the impact of increased ozone production at higher temperatures on the urban population.

Minor Comments 1: More information should be provided in the introduction. The three sentences in the papers first paragraph do not really follow logically. I am not familiar with the Otero paper and this single-sentence description does not stand on its owntemperature was shown to be a driver of which process?

Author Response: We thank the reviewer for this comment and have updated the introduction (Page 1, Line 21): *In particular, heatwaves, characterised by high temperatures and stagnant meteorological conditions, are correlated with high ozone levels as was the case during the European heatwave in 2003 (Solberg et al., 2008; Vautard et al., 2005).*

Minor Comments 2: Fig. 2: The ozone contours are labeled left to right: 5, 50, 55, 0, 5, 0, 5. The y-axis reads: 10, 10, 30, 50. On the x-axis, the 4 of 40 has been lost.

Author Response: As discussed in the answer to Review Point 3, the issue with figures appears to be a problem with the default pdfviewer of the Chrome browser. We shall ensure that the updated manuscript does display correctly with the default pdfviewer in Chrome.

Minor Comments 3: Fig. 5: The majority of measured O3 data are found at lower temperatures, so fitting the calculated O3 with a straight line across the whole temperature range may not be representative.

Author Response: We agree with the reviewer that a linear regression may not be the best choice for the observation. However, as a metric m_{O3-T}, defined as the linear slope of the increase of ozone with temperature, was the most appropriate with which to compare the observations not only to other studies but also to the box model and WRF-Chem output. The manuscipt was updated as outlined in the response to Review Point 5 and Page 8, Line 14 was also updated to compare m_{O3-T} of the observational data to that from other studies: *The linear slope of the observational data indicates an increase of 2.15 ppbv ozone per $^{\circ}C$, this is comparable to the increase of ozone with temperature from other recent studies over urban areas: 2.2 ppbv/$^{\circ}C$ obtained over the Northeast US (Rasmussen et al., 2013) and Milan, Italy (2.8 ppbv/$^{\circ}C$, Baertsch-Ritter et al. (2004)).*

Minor Comments 4: Fig. 5: y-axis reads 25, 50, 5, 100, 125; on the x-axis, the 4 of 40 has been lost.

Author Response: See response to Minor Comments 2.

Response to Referee #2

We would like to thank the reviewer, we feel that this review has enabled us to improve our manuscript; our responses to the review points and comments are found below.

Review Point 1: Generally the paper is very short. I realise that keeping things brief and to the point is sometimes a good thing and can help the reader concentrate on the salient points, however I would suggest in this case that some of the supplementary material be moved to the main text. In particular I think the model setup section would benefit from having more description in the main text rather than most of it being in the supplementary. This is important information for the paper and in this case I believe it would assist the reader to expand the model description.

Author Response: We agree that a more detailed methodology description is beneficial to the paper and this was addressed in the published ACPD paper. The supplementary material published in ACPD includes only the information related to the speciated VOC emissions used in each chemical mechanism and no other information pertaining to the model setup. We believe that the reviewer may be commenting on a previous uploaded version, the only difference between the published ACPD paper and this previous version is the description of the model setup that was previously included in the supplement. Thus all other review comments be the reviewer are valid and addressed below.

Furthermore, the methodology section has also been updated in reponse to Specific Comments #1 and #2 below and Review Point #2 from the first referee.

Specific Comments 1: In section 2.1 (page 3 line 30 page 4 line 4), several statements are made about the setup of the model that would benefit from expansion. The authors state that isoprene emissions from vegetation are the most important BVOC emissions on a global scale, however if the study was to be used for mechanisms in regional as well as global models, then could other BVOCs and other isoprene sources become important? For example in moderate to high NOx conditions of large cities could anthropogenic isoprene be important? And could monoterpene emissions (which have a potentially large effect on O3 chemistry due to their reaction rate with OH and O3 itself) also be significant? In general this seems to be a big statement to make without further discussion. The authors also state (page 4 line 3) that AVOC emissions can be effected by increased temperature due to increase evaporation but then have no further discussion as to how omitting this temperature dependence from the study may affect the results.

Author Response: We agree that further discussion of these statements is required. In order to respond to this review point and also Review Point #1, we have updated the manuscript (Sect. 2.1, Page 4, Line 7) with the following text: *Many types of VOCs are emitted from vegetation with isoprene and monoterpenes globally having the largest emissions, 535 and 162 Tg yr^{-1} respectively (Guenther et al., 2012). Temperature-dependent emissions of these highly-reactive BVOC in urban areas during the summer months have been linked to high levels of ozone pollution. For example, Wang et al. (2013) attributed high summertime levels of ozone in Taipei to increased isoprene emissions from vegetation during the hotter summer months. Vegetation in urban areas also provides additional*

ozone sinks through stomatal uptake and ozonolysis of emitted BVOCs, the review of Calfapietra et al. (2013) discusses the role of BVOCs emitted by trees in urban areas in more detail.

Biogenic emissions of monoterpenes and isoprene are included in all model simulations. Model runs using a temperature-dependent source of BVOC emissions considered only the temperature-dependence of isoprene emissions as specified by MEGAN2.1 (Guenther et al., 2012), Sect. 2.3 provides further details. Since isoprene is the most important BVOC on the global scale, we focused on the influence of the temperature-dependent biogenic emissions of isoprene on ozone levels. Future work should assess the influence of temperature-dependent biogenic emissions of monoterpenes on ozone production. In the temperature-dependent set of model simulations, only isoprene emissions were dependent on temperature and all other emissions were constant in all simulations. In reality, evaporative emissions from anthropogenic sources increase with temperature (Rubin et al., 2006) and isoprene has also been measured from vehicular exhausts (Borbon et al., 2001). Representing a temperature-dependent evaporative source of AVOC and an anthropogenic source of isoprene requires detailed local knowledge of these emission sources (such as the traffic fleet). Since our box modelling study was designed as an idealised study and not to characterise the influence of all temperature-dependent emission sources in a particular region, we have not considered the potentially larger increase of ozone at higher temperatures due to these additional emission sources. Further modelling work assessing the influence of these temperature-dependent emission sources on ozone production would be useful for mitigating ozone pollution in urban areas.

Specific Comments 2: On page 4 line 30 it is described how isoprene emissions with varying temperature using MEGAN2.1 lead to different isoprene mixing ratios in the model, and this is then compared to isoprene measured at different temperatures during a campaign over Essen, Germany. This needs expanding. I presume MEGAN was run in the model for the particular area that the campaign took place over but this needs stating explicitly. Could the authors check their model with other campaigns that have measure isoprene (of which there are numerous worldwide in the literature)?

Author Response: Our idealised study was not designed to represent the biogenic emissions of isoprene over a particular region. For this reason we did not run MEGAN over a particular area as this requires detailed knowledge of the specific vegetation. The aim of the study was to determine the additional influence of temperature-dependent isoprene emissions on top of the temperature-dependent chemistry used by different chemical mechanisms. Thus the study was designed to produce similar isoprene mixing ratios at a reference temperature (we chose 20 °C) and using MEGAN to specify the temperature-dependent profile of isoprene emissions. We have updated the manuscript to further clarify our reasoning in Page 5, Line 4: *The aim of the study was to determine the additional influence of temperature-dependent isoprene emissions on top of the temperature-dependent chemistry. In order to achieve this aim, we chose the MEGAN2.1 parameters used to calculate isoprene emissions online by the model to give similar isoprene mixing ratios at 20 °C to the temperature-independent emissions of isoprene. MEGAN2.1 was used to reflect the*

temperature-dependent emission profile of isoprene emissions and not to accurately represent the isoprene emissions of a particular region.

Specific Comments 3: On page 5 line 30 a description is given that the increase in ozone due to chemistry is large than that due to increased emissions. The results are shown in figure 3 and table 2, however the paper would greatly benefit from a summary of the results in the text.

Author Response: We agree with the reviewer and have updated the manuscript (Page 6, Line 31) to include a summary of this section: *Our simulations produced a non-linear relationship between ozone, temperature and NO_x with the absolute increase in ozone with temperature due to temperature-dependent chemistry larger than the increase in ozone with temperature due to temperature-dependent isoprene emissions. These results are consistent between each chemical mechanism, although for the same NO_x and VOC conditions RADM2 and CB05 simulate a more NO_x-sensitive regime at the same temperature than the other chemical mechanisms (MCMv3.2, CRIv2, MOZART-4).*

Specific Comments 4: On page 7 line 16, there is a paragraph describing how faster reaction of VOCs with OH with increased temperature can increase ozone production. This is backed up by references to other studies that have seen this effect. Why have the authors not included the results of their study here? Could they include some description of which VOC + OH reactions are most dependant on temperature, which would assist readers in coming to a conclusion about which reactions and their temperature dependence should be included in any given model?

Author Response: We agree with the reviewer and have included further information (Page 8, Line 4) about which VOC are most important for the increase of ozone with temperature: *When using a temperature-independent source of isoprene emissions, the increased VOC reactivity with temperature is dominated by the increased reactivity of aldehydes at higher temperatures (up to 50 % at 40 °C), alkene and alkane emissions also have large contributions to the total VOC reactivity. The increase in VOC reactivity with temperature is primarily due to the increased emissions of isoprene with temperature in simulations using a temperature-dependent source of isoprene, aldehydes and alkanes also contribute to the total VOC reactivity when using a temperature-dependent source of isoprene. The supplementary material illustrates the contributions of different VOC functional groups to the total reactivity. The large contribution of aldehyde reactivity to total reactivity at higher temperatures is due to the increased production of aldehydes during the secondary degradation of other VOC.*

Specific Comments 5: In section 3.3, a description is given of how the box model simulations in this study compare to real-world observations and the output of various 3-D models. I must admit I am a bit confused what this section is trying to say. It seems that the result is that mixing in the box model is more important to ozone formation that the choice of mechanism (which is not surprising) and I am not quite sure how any useful comparison can be made between the different mechanisms in this study and a few real world and 3-d model studies. Maybe the authors could better explain what they are trying to achieve with this section. Would a better approach be to

assess what mechanisms were used in the various studies they look at and then give some steer as to whether it is the temperature dependence of the chemistry or of the emissions that is the key driver in these different cases?

Author Response: Based on the comments of Reviewer #1 as well as this review point, we have updated Section 3.3 to include more details of the motivation of this comparison and a more appropriate discussion of the results. The changes to the manuscript are found in the response to Review Point 5 of Reviewer #1.

Minor Comments:

Minor Comments 1: Page 1 line 22: Could more references be added here especially with respect to the many studies of the 2003 European heatwave ozone events?

Author Response: We agree and have included more references in the updated manuscript: *In particular, heatwaves, characterised by high temperatures and stagnant meteorological conditions, are correlated with high ozone levels as was the case during the European heatwave in 2003 (Solberg et al., 2008; Vautard et al., 2005).*

Minor Comments 2: Page 3 line 13: What was broadly representative of urban conditions of central Europe mean. Please be more specific with the conditions the model was run at.

Author Response: We have updated the manuscript to provide further information (Page 3, Line 14): *Our simulations were designed were designed as an idealised case and not to be exact representations of any particular place. The simulations used a latitude of 51 °N, broadly representative of conditions in central Europe, and were run for daylight hours in one full day.*

Minor Comments 3: Page 3 line 27: The Stockwell 1990 reference seems very old. Has there been more recent advances in the knowledge of ozone production chemistry that might make this obsolete?

Author Response: We agree with the reviewer that RADM2 is indeed an old reference, however this chemical mechanism is still used by many modelling groups. We have clarified this further in the manuscript (Page 3, Line 34): *These reduced chemical mechanisms were chosen as they are all currently used by modelling groups in 3D regional and global models (Baklanov et al., 2014).*

Minor Comments 4: Page 8 line 25: The authors should consider showing the actual production and consumption budgets in the main text rather than the supplementary.

Author Response: We agree with the reviewer and have updated Fig. 4 to show the absolute production and consumption budgets as well as the normalised production and consumption budgets. The manuscript was updated to reflect this and details are found in the response to Review Point 4 of Reviewer #1.

Abstract. Surface ozone is a secondary air pollutant produced during the atmospheric photochemical degradation of emitted volatile organic compounds (VOCs) in the presence of sunlight and nitrogen oxides (NO_x). Temperature directly influences ozone production through speeding up the rates of ~~the~~ chemical reactions and increasing the emissions of VOCs, such as isoprene, from vegetation. In this study, we used ~~a~~ an idealised box model to examine the non-linear relationship between

5 ozone, NO_x and temperature, and compared this to previous observational studies. Under high-NO_x conditions, an increase in ozone from 20 °C to 40 °C of up to 20 ppbv was due to faster reaction rates while increased isoprene emissions added up to a further 11 ppbv of ozone. The increased oxidation rate of emitted VOC with temperature controlled the rate of O_x production, the net influence of peroxy nitrates increased net O_x production per molecule of emitted VOC oxidised. The rate of increase in ozone mixing ratios with temperature from our box model simulations was about half the rate of increase in

10 ozone with temperature observed over central Europe or simulated by a regional chemistry transport model. Modifying the box model setup to approximate stagnant meteorological conditions increased the rate of increase of ozone with temperature as the accumulation of oxidants enhanced ozone production through the increased production of peroxy radicals from the secondary degradation of emitted VOCs. The box model simulations approximating stagnant conditions and the maximal ozone production chemical regime reproduced the 2 ppbv increase in ozone per °C from the observational and regional model

15 data over central Europe. The simulated ozone-temperature relationship was more sensitive to mixing than the choice of chemical mechanism. Our analysis suggests that reductions in NO_x emissions would be required to offset the additional ozone production due to an increase in temperature in the future.

1 Introduction

Surface-level ozone (O_3) is a secondary air pollutant formed during the photochemical degradation of volatile organic com-

20 pounds (VOCs) in the presence of nitrogen oxides ($NO_x \equiv NO + NO_2$). Due to the photochemical nature of ozone production, it is strongly influenced by meteorological variables such as temperature (Jacob and Winner, 2009). In particular, heatwaves, characterised by high temperatures and stagnant meteorological conditions, are correlated with high ozone levels as was the case during the European heatwave in 2003 (Solberg et al., 2008; Vautard et al., 2005). Furthermore, Otero et al. (2016) showed

that temperature was a major meteorological driver ~~for summertime ozone~~ of summertime ozone concentrations in many areas of central Europe.

Temperature primarily influences ozone production in two ways: speeding up the rates of many chemical reactions, and increasing emissions of VOCs from biogenic sources (BVOCs) (Sillman and Samson, 1995). While emissions of anthropogenic VOCs (AVOCs) are generally not dependent on temperature, evaporative emissions of some AVOCs do increase with temperature (Rubin et al., 2006). The review of Pusede et al. (2015) provides further details of the temperature-dependent processes impacting ozone production.

Regional modelling studies over the US (Sillman and Samson, 1995; Steiner et al., 2006; Dawson et al., 2007) examined the sensitivity of ozone production during a pollution episode to increased temperatures. These studies noted that increased temperatures (without changing VOC or NO_x-conditions) led to higher ozone levels, often exceeding local air quality guidelines. Sillman and Samson (1995) and Dawson et al. (2007) varied the temperature dependence of the PAN (peroxy acetyl nitrate) decomposition rate during simulations of the eastern US determining the sensitivity of ozone production with temperature to the PAN decomposition rate. In addition to the influence of PAN decomposition on ozone production, Steiner et al. (2006) correlated the increase in ozone mixing ratios with temperature over California to increased mixing ratios of formaldehyde, a secondary degradation production of many VOCs and an important radical source. Steiner et al. (2006) also noted increased emissions of BVOCs at higher temperatures in urban areas with high NO_x emissions also increased ozone levels with temperature.

The modelling study of Vogel et al. (1999) looked at the NO_y transition value as an indicator of ozone production sensitivity at different VOC and NO_x conditions and investigated the sensitivity of this transition value with different meteorological conditions. Higher temperatures led to a higher transition value of NO_y which was attributed to the faster thermal decomposition of PAN. Vogel et al. (1999) also showed vertical mixing and dry deposition decreased the transition value of NO_y showing that ozone production is sensitive to other non-chemical processes.

Pusede et al. (2014) used an analytical model constrained by observations over the San Joaquin Valley, California to infer a non-linear relationship between ozone, temperature and NO_x, similar to the well-known non-linear relationship of ozone production on NO_x and VOC levels (Sillman, 1999). Moreover, Pusede et al. (2014) showed that temperature can be used as a surrogate for VOC levels when considering the relationship of ozone under different NO_x conditions.

Environmental chamber studies have also been used to analyse the relationship of ozone with temperature using a fixed mixture of VOCs. The chamber experiments of Carter et al. (1979) and Hatakeyama et al. (1991) showed increases in ozone from a VOC mix with temperature. Both studies compared the concentration time series of ozone and nitrogen-containing compounds (NO_x, PAN, HNO_3) at various temperatures linking the maximum ozone concentration to the decrease in PAN concentrations at temperatures greater than 303 K.

~~Despite many studies considering the ozone-temperature relationship from an observational and chamber study perspective, modelling studies focusing on the detailed chemical processes of the ozone-temperature relationship~~ The review of Pusede et al. (2015) highlights a general lack of modelling studies looking at the relationship of ozone with temperature under different NO_x conditions~~have not been performed (to our knowledge)~~. The regional modelling studies described previously concentrated on

reproducing ozone levels (using a single chemical mechanism) over regions with known meteorology and NO_x conditions then varying the temperature. These regional modelling studies did not consider the relationship between ozone, NO_x and temperature. ~~The review of also highlights a lack of modelling studies looking at the relationship of ozone with temperature under different conditions~~Vogel et al. (1999) only considered the effect of faster reaction rates at higher temperature and not the additional contribution of increased biogenic emissions to ozone levels at higher temperatures.

Comparisons of different chemical mechanisms, such as Emmerson and Evans (2009) and Coates and Butler (2015), showed that different representations of tropospheric chemistry influenced ozone production. Neither of these studies examined the ozone-temperature relationship differences between chemical mechanisms. Furthermore, Rasmussen et al. (2013) acknowledged that the modelled ozone-temperature relationship may be sensitive to the choice of chemical mechanism and recommended investigating this sensitivity. Comparing the ozone-temperature relationship predicted by different chemical mechanisms is potentially important for modelling of future air quality due to the expected increase in heatwaves (Karl and Trenberth, 2003).

In this study, we use an idealised box model to determine how ozone levels vary with temperature under different NO_x conditions. We determine whether faster chemical reaction rates or increased BVOC emissions have a greater influence on instantaneous ozone production with higher temperature under different NO_x conditions. Furthermore, we compare the ozone-temperature relationship produced by different chemical mechanisms and determine which chemical processes drive the increase of ozone with temperature. Finally, we compare the rate of increase of ozone with temperature obtained from the box model to both observations and regional model ouput and consider the role of stagnation on the rate of increase of ozone with temperature.

2 Methodology

2.1 Model Setup

We ~~used~~ performed idealised simulations using the MECCA box model (Sander et al., 2005) to determine the important gas-phase chemical processes for ozone production under different temperatures and NO_x conditions. The MECCA box model was set up as described in Coates and Butler (2015) and updated to include vertical mixing with the free troposphere using a diurnal cycle for the PBL height. The ~~supplementary material includes further details of these updates~~vertical mixing scheme was based on the approach of Lourens et al. (2016) with the model using the mean mixing layer height from the BAERLIN campaign over Berlin, Germany (Bonn et al., 2016).

~~Simulations were~~ Our simulations were designed as an idealised case and not to be exact representations of any particular place. The simulations used a latitude of 51 °N, broadly representative of ~~urban~~ conditions in central Europe, and were run for daylight hours in one full day. Methane was fixed at 1.7 ppmv throughout the model run, carbon monoxide (CO) and ozone were initialised at 200 ppbv and 40 ppbv and then allowed to evolve freely throughout the simulation. All VOC emissions were held constant until noon simulating a plume of freshly-emitted VOC. the mixing ratios of O_3, CO and CH_4 in the free troposphere were respectively set to 50 ppbv, 116 ppbv and 1.8 ppmv. These conditions were taken from the MATCH-MPIC chemical

weather forecast model on the 21st March (the start date of the simulations). The model results (http://cwf.iass-potsdam.de/) at the 700 hPa height were chosen and the daily average was used as input into the boxmodel.

Separate box model simulations were performed by systematically varying the temperature between 288 and 313 K (15–40 °C) in steps of 0.5 K. NO emissions were systematically varied between 5.0×10^9 and 1.5×10^{12} molecules(NO) cm^{-2} s^{-1} in steps of 1×10^{10} molecules(NO) cm^{-2} s^{-1} at each temperature step. At 20 °C, these NO emissions corresponded to peak NO_x mixing ratios of 0.02 ppbv and 10 ppbv respectively, this range of NO_x mixing ratios covers the NO_x conditions found in pristine and urban conditions (von Schneidemesser et al., 2015).

All simulations were repeated using different chemical mechanisms to investigate whether the relationship between ozone, temperature and NO_x changes using different representations of ozone production chemistry. The reference chemical mechanism was the near-explicit Master Chemical Mechanism, MCMv3.2, (Jenkin et al., 1997, 2003; Saunders et al., 2003; Rickard et al., 2015). The reduced chemical mechanisms in our study were Common Representative Intermediates, CRIv2 (Jenkin et al., 2008), Model for OZone and Related Chemical Tracers, MOZART-4 (Emmons et al., 2010), Regional Acid Deposition Model, RADM2 (Stockwell et al., 1990) and the Carbon Bond Mechanism, CB05 (Yarwood et al., 2005). ~~described the implementation of these chemical mechanisms in MECCA.~~ These reduced chemical mechanisms were chosen as they are ~~commonly~~ all currently used by modelling groups in 3D regional and global models (Baklanov et al., 2014). Coates and Butler (2015) described the implementation of these chemical mechanisms in MECCA.

The chemical mechanisms use temperature-dependent rate constants, k(T), to represent temperature-dependent chemical processes, including the initial oxidation of VOC, peroxy nitrate (RO_2NO_2) formation and destruction, and reactions between peroxy radicals and NO leading to alkyl nitrate ($RONO_2$) formation. However, not all chemical mechanisms represent the same chemical processes by a temperature-dependent rate constant. For example, in CB05, the rate constant of $RONO_2$ formation during isoprene degradation is temperature dependent while $RONO_2$ formation during alkane degradation is temperature independent. Furthermore, none of the chemical mechanisms in our study represent the $RONO_2$ branching ratio as a temperature dependent process. Laboratory experiments have shown the temperature dependence of the $RONO_2$ branching ratio for some VOCs (Atkinson et al., 1987) but generally $RONO_2$ chemistry is not well known (Pusede et al., 2015) and this level of detail is not represented by the chemical mechanisms. Before chemical mechanisms can include the temperature-dependence of the $RONO_2$ branching ratio, further research is required.

Model runs were repeated using a ~~temperature-dependent and~~ temperature-independent and temperature-dependent source of BVOC emissions to determine the relative importance of increased emissions of BVOC and faster reaction rates of chemical processes for the increase of ozone with temperature. Many types of VOCs are emitted from vegetation with isoprene and monoterpenes globally having the largest emissions, 535 and 162 Tg yr^{-1} respectively (Guenther et al., 2012). Temperature-dependent emissions of these highly-reactive BVOC in urban areas during the summer months have been linked to high levels of ozone pollution. For example, Wang et al. (2013) attributed high summertime levels of ozone in Taipei to increased isoprene emissions from vegetation during the hotter summer months. Vegetation in urban areas also provides additional ozone sinks through stomatal uptake and ozonolysis of emitted BVOCs, the review of Calfapietra et al. (2013) discusses the role of BVOCs emitted by trees in urban areas in more detail.

Biogenic emissions of monoterpenes and isoprene are included in all model simulations. Model runs using a temperature-dependent source of BVOC emissions considered only the temperature-dependence of isoprene emissions as specified by MEGAN2.1 (Guenther et al., 2012), Sect. 2.3 provides further details. Since isoprene is the most important BVOC on the global scale, we focused on the influence of the temperature-dependent biogenic emissions of isoprene on ozone levels. Future work should assess the influence of temperature-dependent biogenic emissions of monoterpenes on ozone production. In the temperature-dependent set of model simulations, only isoprene emissions were dependent on temperature and all other emissions were constant in all simulations. In reality, evaporative emissions from anthropogenic sources increase with temperature (Rubin et al., 2006) and isoprene has also been measured from vehicular exhausts (Borbon et al., 2001). Representing a temperature-dependent evaporative source of AVOC and an anthropogenic source of isoprene requires detailed local knowledge of these emission sources (such as the traffic fleet). Since our box modelling study was designed as an idealised study and not to characterise the influence of all temperature-dependent emission sources in a particular region, we have not considered the potentially larger increase of ozone at higher temperatures due to these additional emission sources. Further modelling work assessing the influence of these temperature-dependent emission sources on ozone production would be useful for mitigating ozone pollution in urban areas.

Simulations were also performed to assess the role of mixing on the increase of ozone with temperature. In these box model simulations, the box model was set up as described previously but without mixing of the chemical species with the free troposphere. Thus, these simulations approximate stagnant conditions that favour accumulation of secondary VOC oxidation products and enhanced ozone production.

2.2 VOC Emissions

Emissions of urban AVOC over central Europe were taken from the TNO-MACC_III emission inventory for the Benelux (Belgium, Netherlands and Luxembourg) region for the year 2011. TNO-MACC_III is the updated TNO-MACC_II emission inventory created using the same methodology as Kuenen et al. (2014) and based upon improvements to the existing emission inventory during AQMEII-2 (Pouliot et al., 2015).

Temperature-independent emissions of isoprene and monoterpenes from biogenic sources were calculated as a fraction of the total AVOC emissions from each country in the Benelux region. This data was obtained from the supplementary data available from the EMEP (European Monitoring and Evaluation Programme) model (Simpson et al., 2012). Temperature-dependent emissions of isoprene are described in Sect. 2.3.

Table 1 shows the quantity of VOC emissions from each source category and the temperature-independent BVOC emissions. These AVOC emissions were assigned to chemical species and groups based on the profiles provided by TNO. The NMVOC emissions were speciated to MCMv3.2 species as described by von Schneidemesser et al. (2016). For simulations done with other chemical mechanisms, the VOC emissions represented by the MCMv3.2 were mapped to the mechanism species representing VOC emissions in each reduced chemical mechanism based on the recommendations of the source litera-

ture and Carter (2015). The VOC emissions in the reduced chemical mechanisms were weighted by the carbon numbers of the MCMv3.2 species and the emitted mechanism species, thus keeping the amount of emitted reactive carbon constant between simulations. The supplementary data outlines the primary VOC and calculated emissions with each chemical mechanism.

2.3 Temperature Dependent Isoprene Emissions

5 Temperature-dependent emissions of isoprene were estimated using the MEGAN2.1 algorithm for calculating the emissions of VOC from vegetation (Guenther et al., 2012). Emissions from nature are dependent on many variables including temperature, radiation and age of vegetation but for the purpose of our study all variables except temperature were held constant.

~~The~~ The aim of the study was to determine the additional influence of temperature-dependent isoprene emissions on top of the temperature-dependent chemistry. In order to achieve this aim, we chose the MEGAN2.1 parameters ~~were chosen~~ used to
10 calculate isoprene emissions online by the model to give similar isoprene mixing ratios at 20 °C to the temperature-independent emissions of isoprene~~in order to compare the effects of increased isoprene emissions with temperature~~. MEGAN2.1 was used to reflect the temperature-dependent emission profile of isoprene emissions and not to accurately represent the isoprene emissions of a particular region. The estimated emissions of isoprene with MEGAN2.1 using these assumptions are illustrated in Fig. 1 and show the expected exponential increase in isoprene emissions with temperature (Guenther et al., 2006).

15 The estimated emissions of isoprene at 20 °C lead to 0.07 ppbv of isoprene in our simulations while at 30 °C, the increased emissions of isoprene using MEGAN2.1 estimations lead to 0.35 ppbv of isoprene in the model. A measurement campaign over Essen, Germany (Wagner and Kuttler, 2014) measured 0.1 ppbv of isoprene at temperature 20 °C and 0.3 ppbv of isoprene were measured at 30 °C. The similarity of the simulated and observed isoprene mixing ratios indicates that the MEGAN2.1 variables chosen for calculating the temperature-dependent emissions of isoprene were suitable for simulating urban conditions
20 over central Europe.

3 Results and Discussion

3.1 Relationship between Ozone, NO_x and Temperature

Figure 2a depicts the contours of peak mixing ratio ~~from ozone of~~ of ozone from each simulation as a function of the total NO_x emissions and temperature when using a temperature-independent and temperature-dependent source of isoprene emissions
25 for each chemical mechanism. The relative difference in ozone mixing ratios produced using each chemical mechanism from the MCMv3.2 is shown in Fig. 2b. A non-linear relationship of ozone mixing ratios with NO_x and temperature is produced by each chemical mechanism. This non-linear relationship is similar to that determined by Pusede et al. (2014) using an analytical model constrained to observational measurements over the San Joaquin Valley, California.

Higher peak ozone mixing ratios are produced when using a temperature-dependent source of isoprene emissions (Fig. 2a).
30 The highest mixing ratios of peak ozone are produced at high temperatures and moderate emissions of NO_x regardless of the temperature dependence of isoprene emissions. Conversely, the least amount of peak ozone is produced with low emissions of

NO$_x$ over the whole temperature range (15 – 40 °C) when using both a temperature-independent and temperature-dependent source of isoprene emissions. The larger increases in ozone levels in the Maximal-O3 and High-NO$_x$ regimes indicate that strong reductions in NO$_x$ emissions are neccessary to offset the increase in ozone pollution at higher temperatures, especially in urban areas containing a significant amount of isoprene emitting vegetation.

5   As shown in Fig. 2b, regions of high temperatures and high NO$_x$ emissions generally lead to the largest inter-mechanism differences between ozone mixing ratios using reduced chemical mechanisms from the MCMv3.2 (up to 13 %). These differences in peak ozone mixing ratio produced from the reduced chemical mechanisms compared with the MCMv3.2 in each NO$_x$ condition are consistent with Fig. 3 (described below) where RADM2 and CB05 generally produced higher ozone levels than the MCMv3.2. Also consistent with Fig. 3, CRIv2 produced the most similar amounts of ozone to the MCMv3.2

10 in each NO$_x$ condition whereas MOZART-4 tended to produce lower ozone mixing ratios than the MCMv3.2 in High-NO$_x$ conditions. In Fig. 3, a maximum difference of 10 ppbv between ozone mixing ratios produced using the chemical mechanisms is reached at 40 °C in the High-NO$_x$ state when using both a temperature-independent and temperature-dependent source of isoprene emissions.

     The NO$_x$ emissions required for maximum ozone production (the contour ridges in Fig. 2a) at each temperature is displayed

15 in Fig. 1 of the supplementary material. This figure illustrates that RADM2 and CB05 require higher NO$_x$ emissions than the MCMv3.2 to achieve maximum ozone production at each temperature for both a temperature-independent and temperature-dependent source of isoprene emissions. At 20 °C, maximum ozone production is reached with ~ 30 % more NO$_x$ emissions using CB05 and RADM2 than the MCMv3.2 with a temperature-independent and temperature-dependent source of isoprene emissions. The CRIv2 and MOZART-4 chemical mechanisms require very similar NO$_x$ emissions to the MCMv3.2 at each temperature

20 to produce maximum levels of ozone. Thus when modelling the air quality over a particular region using RADM2 and CB05, these mechanisms would be expected to simulate more NO$_x$-sensitive chemistry and a lower increase of ozone with temperature than the MCMv3.2, CRIv2 and MOZART-4 chemical mechanisms for the same conditions (i.e. emissions, meteorology and radiation).

     The contours of ozone mixing ratios in Fig. 2a as a function of NO$_x$ and temperature can be split into three NO$_x$ regimes

25 (Low-NO$_x$, Maximal-O$_3$ and High-NO$_x$), similar to the NO$_x$ regimes defined for the non-linear relationship of ozone with VOC and NO$_x$. The Low-NO$_x$ regime corresponds with regions having little increase in ozone with temperature, also called the NO$_x$-sensitive regime. The High-NO$_x$ (or NO$_x$-saturated) regime is when ozone levels increase rapidly with temperature. The contour ridges correspond to regions of maximal ozone production; this is the Maximal-O$_3$ regime. Pusede et al. (2014) showed that temperature can be used as a proxy for VOC, thus we assigned the ozone mixing ratios from each box model

30 simulation to a NO$_x$ regime based on the H$_2$O$_2$:HNO$_3$ ratio. This ratio was used by Sillman (1995) and Staffelbach et al. (1997) to designate ozone to NO$_x$ regimes based on NO$_x$ and VOC levels. The Low-NO$_x$ regime corresponds to H$_2$O$_2$:HNO$_3$ ratios less than 0.5, the High-NO$_x$ regime corresponds to ratios larger than 0.3 and ratios between 0.3 and 0.5 correspond to the Maximal-O$_3$ regime.

     The peak ozone mixing ratio from each simulation was assigned to a NO$_x$ regime based on the H$_2$O$_2$:HNO$_3$ ratio of that

35 simulation. The peak ozone mixing ratios assigned to each NO$_x$ regime at each temperature were averaged, and illustrated in

Fig. 3 for each chemical mechanism and each type of isoprene emissions (temperature independent and temperature dependent). We define the absolute increase in ozone from 20 °C to 40 °C due to faster reaction rates as the difference between ozone mixing ratios from 20 °C to 40 °C when using a temperature-independent source of isoprene emissions. When using a temperature-dependent source of isoprene emissions, the difference in ozone mixing ratios from 20 °C to 40 °C minus the increase due to

5   faster reaction rates, gives the absolute increase in ozone mixing ratios from increased isoprene emissions. These differences are represented graphically in Fig. 3 and summarised in Table 2.

Table 2 shows that the absolute increase in ozone with temperature due to chemistry (i.e. faster reaction rates) is larger than the absolute increase in ozone due to increased isoprene emissions for each chemical mechanism and each NO_x regime. In all cases the absolute increase in ozone with temperature is largest under High-NO_x conditions and lowest with Low-NO_x

10   conditions (Fig. 3 and Table 2). The increase in ozone mixing ratio from 20 °C to 40 °C due to faster reaction rates with High-NO_x conditions is almost double that with Low-NO_x conditions. In the Low-NO_x regime, the increase of ozone with temperature using the reduced chemical mechanisms (CRIv2, MOZART-4, CB05 and RADM2) is similar to that from the MCMv3.2. Larger differences occur in the Maximal-O_3 and High-NO_x regimes.

All reduced chemical mechanisms except RADM2 have similar increases in ozone due to increased isoprene emissions as

15   the MCMv3.2 (Table 2). RADM2 produces 3 ppbv less ozone than the MCMv3.2 due to increased isoprene emissions in each NO_x regime, indicating that this difference is due the representation of isoprene degradation chemistry in RADM2.

Coates and Butler (2015) compared ozone production in different chemical mechanisms to the MCMv3.2 using the TOPP metric (Tagged Ozone Production Potential) as defined in Butler et al. (2011) and showed that less ozone is produced per molecule of isoprene emitted using RADM2 than with MCMv3.2. The degradation of isoprene has been extensively studied

20   and it is well-known that methyl vinyl ketone (MVK) and methacrolein are signatures of isoprene degradation (Atkinson, 2000). All chemical mechanisms in our study except RADM2 explicitly represent MVK and methacrolein (or in the case of CB05, a lumped species representing both these secondary degradation products). RADM2 does not represent methacrolein and the mechanism species representing ketones (KET) is a mixture of acetone and methyl ethyl ketone (MEK) (Stockwell et al., 1990). Thus the secondary degradation of isoprene in RADM2 is unable to represent the ozone production from the

25   further degradation of the signature secondary degradation products of isoprene, MVK and methacrolein. Updated versions of RADM2, RACM (Stockwell et al., 1997) and RACM2 (Goliff et al., 2013), sequentially included methacrolein and MVK and with these updates the ozone production from isoprene oxidation approached that of the MCMv3.2 (Coates and Butler, 2015).

3.2 Ozone Production and Consumption Budgets

Our simulations produced a non-linear relationship between ozone, temperature and NO_x with the absolute increase in ozone

30   with temperature due to temperature-dependent chemistry larger than the increase in ozone with temperature due to temperature-dependent isoprene emissions. These results are consistent between each chemical mechanism, although for the same NO_x and VOC conditions RADM2 and CB05 simulate a more NO_x-sensitive regime at the same temperature than the other chemical mechanisms (MCMv3.2, CRIv2, MOZART-4). In order to understand the temperature dependence of ozone production directly, we examine

~~the modelled day-time~~ determine the chemical processes responsible for the increased ozone with temperature, we analyse the production and consumption budgets of ozone in Sect. 3.2.

3.2 Ozone Production and Consumption Budgets

Since chemical reactions contributing to both production and consumption of O_x ($\equiv O_3 + NO_2 + O(^1D) + O$) ~~normalised~~

5 ~~by the total chemical loss rate of the emitted VOC (~~have temperature-dependent rate constants, we analysed the production and consumption budgets of O_x to determine the temperature-dependent chemical processes controlling the increase of ozone with temperature which was shown in Fig. ~~4b)~~3. The O_x budgets displayed in Fig. 4 are assigned to each NO_x regime for each chemical mechanism and ~~type~~ source of isoprene emissions. The ~~budgets are allocated to the net contribution of major chemical categories, where~~ net production or consumption of O_x is also indicated in Fig. 4.

10 Figure 4 was obtained by determining the chemical reactions producing and consuming O_x and then allocating these reactions to important categories. Reactions of peroxy radicals with NO produce O_x and the peroxy radicals are divided into 'HO2', 'RO2', 'ARO2' ~~represent~~ categories representing the reactions of NO with HO_2, alkyl peroxy radicals and acyl peroxy radicals respectively. ~~'RO2NO2' represents the net effects~~ Thus at each time step the O_x production rate is given by

$$k_{HO_2+NO}[HO_2][NO] + \sum_i k_{RO_2,i+NO}[RO_{2,i}][NO] + \sum_j k_{ARO_2,j+NO}[ARO_{2,j}][NO] \tag{1}$$

15 for each alkyl peroxy radical i and acyl peroxy radical j. The net contributions of peroxy nitrates, ~~which remove when produced and are a source of when they thermally decompose. 'Inorganic' is all other inorganic contributions to production~~ inorganic reactions and any other remaining organic reactions ~~are included in the '~~to the O_x budget are represented by the 'RO2NO2', 'Inorganic' and 'Other Organic' ~~category.Figure 4b also illustrates the net production or consumption of~~ categories in Fig. 4. The net contributions of these categories to the O_x ~~in each case~~budget was calculated by subtracting the consumption rate from

20 the production rate of the reactions contributing to each category. For example, peroxy nitrates produce O_x when thermally decomposing or reacting with OH and consume O_x when produced. Hence, at each time step the net contribution of RO2NO2 to the O_x budget was calculated by

$$\sum_k k_{RO_2NO_2,k}[RO_2NO_{2,k}] + \sum_k k_{RO_2NO_2,k+OH}[RO_2NO_{2,k}][OH] - \sum_k k_{RO_2,k+NO_2}[RO_{2,k}][NO_2] \tag{2}$$

for each peroxy nitrate species k. The cumulative day-time budgets were calculated by summing the net contributions of the

25 reaction rates of each category over the day-time period. The ratio of net ozone to net O_x production was practically constant with temperature in all cases showing that using O_x budgets as a proxy for ozone budgets was suitable at each temperature in our study.

The absolute production and consumption budgets ~~of~~ allocated to the ~~same source categories as~~ major categories are displayed in Fig. ~~4b are included in the supplementary material and further illustrate~~ 4a. Both production and consumption

30 of O_x increase with temperature for each chemical mechanism and each NO_x conditions. The overall net increase of O_x production with temperature (white line in Fig. 4a) is consistent with the increase in ozone mixing ratios for each panel

in Fig. 3. Moreover, the net chemical production of O_x is larger when using a temperature-dependent source of isoprene emissions, again this is consistent with Fig. 3.

In order to determine which temperature-dependent chemical processes are responsible for the overall increase of net O_x production with temperature.

5 , the absolute O_x budgets in Fig. 4a were normalised by the total chemical loss rate of the emitted VOC (Fig. 4b). Thus Fig. 4b gives a measure of the O_x production and consumption efficiency per chemical loss of VOC. The net O_x production efficiency (white line in Fig. 4b) increases from 20 °C to 40 °C by ~ 0.25 molecules of O_x per molecule of VOC oxidised with each NO_x-condition and type of isoprene emissions using the detailed MCMv3.2 chemical mechanism(Fig. 4b). A lower increase in normalised net O_x production efficiency from 20 °C to 40 °C was obtained with the reduced chemical mechanisms

10 (~ 0.2 molecules of O_x per molecule of VOC oxidised with CRIv2, CB05 and RADM2, and ~ 0.1 molecules of O_x per molecule of VOC oxidised using MOZART-4). The increase in net O_x production efficiency is due to the increased contribution with temperature of acyl peroxy radicals (ARO2) reacting with NO and the decreased net contribution with temperature of RO2NO2 (peroxy nitrates) to the normalised O_x budgets.

The increased contribution of ARO2 to O_x production with temperature is linked to the decreased net contribution of

15 RO2NO2 with temperature to O_x budgets as peroxy nitrates are produced from the reactions of acyl peroxy radicals with NO_2. The decomposition rate of peroxy nitrates is strongly temperature dependent and at higher temperatures the faster decomposition rate of RO_2NO_2 leads to faster release of acyl peroxy radicals and NO_2. Thus the equilibrium of RO_2NO_2 shifts towards thermal decomposition with increasing temperature leading to the increased contribution of ARO2 with temperature to O_x production (Fig. 4b). The importance of peroxy nitrate decomposition to the increase of ozone with temperature has

20 been noted by many studies, for example, Dawson et al. (2007) attributed the increase in maximum 8 h ozone mixing ratios with temperature during a modelling study over the eastern US to the decrease in PAN lifetime with temperature. Steiner et al. (2006) also recognised that the decrease in PAN lifetime with temperature contributed to the increase of ozone with temperature concluding that the combined effects of increased oxidation rates of VOC and faster PAN decomposition increased the production of ozone with temperature.

25 When using a temperature-independent source of isoprene emissions, the increased VOC reactivity with temperature is dominated by the increased reactivity of aldehydes at higher temperatures (up to 50 % at 40 °C), alkene and alkane emissions also have large contributions to the total VOC reactivity. The increase in VOC reactivity with temperature is primarily due to the increased emissions of isoprene with temperature in simulations using a temperature-dependent source of isoprene, aldehydes and alkanes also contribute to the total VOC reactivity when using a temperature-dependent source of isoprene.

30 The supplementary material illustrates the contributions of different VOC functional groups to the total reactivity. The large contribution of aldehyde reactivity to total reactivity at higher temperatures is due to the increased production of aldehydes from the secondary degradation of other VOC.

As the production efficiency of O_x remains constant with temperature (~ 2 molecules of O_x per molecule of VOC oxidised, Fig. 4b), the rate of O_x production is controlled by the oxidation rate of VOCs. Faster oxidation of VOCs with temperature

35 speeds up the production of peroxy radicals increasing ozone production when peroxy radicals react with NO to produce NO_2.

The reactivity of VOCs has been linked to ozone production (e.g. Kleinman (2005), Sadanaga et al. (2005)) and the review of Pusede et al. (2015) acknowledged the importance of organic reactivity and radical production to the ozone-temperature relationship. Also, the modelling study of Steiner et al. (2006) noted that the increase in initial oxidation rates of VOCs with temperature leads to increased formaldehyde concentrations and in turn an increase of ozone as formaldehyde is an important source of HO_2 radicals.

Our results indicate that increased VOC reactivity due to faster rate constants for the reaction with OH and the decomposition rate of peroxy nitrates are the temperature-dependent chemical processes leading to increased production of O_x with temperature. Out of these two chemical processes, the increased VOC reactivity with OH with temperature had a larger influence on the increase of O_x production with temperature. These results are consistent between each chemical mechanism and each NO_x condition.

3.3 Comparison to Observations and 3D Model Simulations

This section compares the results from The final step in our study was to compare how well our idealised box model simulations to represent the real-world observations and model output from a 3D model. Using relationship between ozone and temperature. Firstly, we compared the box model simulations to the interpolated observations of the maximum daily 8 h mean (MDA8) of ozone from Schnell et al. (2015) and the meteorological observational data set data of the ERA-Interim re-analysis (Dee et al., 2011). Using this data set, Otero et al. (2016) showed that over the summer (JJA) months, temperature is the main meteorological driver of ozone production during the summer (JJA) months over many regions of central Europe. Model output from the A further test was to compare the box model simulations to the output from a regional 3D model as 3D models include explicit representations of transport and mixing processes which influence ozone production, and which are not well represented in our box model. We used the WRF-Chem regional model using MOZART-4 chemistry 3D model set-up over the European domain for simulations of to simulate ozone production in the year 2007 from using MOZART-4 chemistry, further details are described in Mar et al. (2016)was used to further compare the .

Directly comparing the ozone mixing ratios from our idealised box model simulations to a model including more meteorological processes than the WRF-Chem output is difficult due to significant differences in the setups of the models. For example, WRF-Chem used gas-phase and aerosol chemistry whereas our box model setup used only gas-phase chemistry, also the treatment of photolysis and VOC and NO_x emissions differ between our box model and WRF-Chem. In addition to this, to include the effects of transport and mixing, the box model includes a simple mixing term representing the entrainment of clean free tropospheric air into the growing daytime boundary layer. Stagnant atmospheric conditions are characterised by low wind speeds slowing the transport of ozone and its precursors away from sources and have been correlated with high-ozone episodes in the summer over eastern US (Jacob et al., 1993). Hence, out of the metereological conditions not represented by our box model, stagnation could have the largest influence on the increase of ozone with temperature In order to investigate the sensitivity of ozone production to mixing, further box model simulations were performed without mixing approximating stagnant conditions.

Figure 5 compares the ~~observational~~ ERA-Interim reanalysis and WRF-Chem ~~data~~ output from summer 2007 averaged over central and eastern Germany, where summertime ozone values are driven by temperature (Otero et al., 2016), to the MDA8 values of ozone from the box model simulations for each chemical mechanism with mixing (solid lines) and without mixing (dotted lines). We compare the rate of change of ozone with temperature (m_{O3-T}) between the box model, WRF-Chem and ERA-Interim reanalysis data. This metric has been used to quantify future ozone pollution due to the warmer temperatures predicted by climate change (Dawson et al., 2007; Rasmussen et al., 2013) and is discussed further in the review of Pusede et al. (2015). m_{O3-T} is calculated as the linear slope of the increase of ozone with temperature in ppbv of ozone per °C. Polluted areas have larger m_{O3-T} values than rural areas corresponding to the High-NO_x and Low-NO_x conditions simulated in our study. Table 3 summarises the calculated slopes of the box model simulations displayed in Fig. 5.

The linear slope of the observational data indicates an increase of 2.15 ppbv ozone per °C, this is comparable to the increase of ozone with temperature from other recent studies over urban areas: 2.2 ppbv/°C obtained over the Northeast US (Rasmussen et al., 2013) and Milan, Italy (2.8 ppbv/°C, Baertsch-Ritter et al. (2004)). Despite a high bias in simulated ozone in WRF-Chem, the rate of change of ozone with temperature from the WRF-Chem simulations (2.05 ppbv/°C) is similar to the rate of change of ozone with temperature from the observed data (2.15 ppbv/°C). The differences in ozone production between the different chemical mechanisms with the box model are small compared to the spread of the observational and WRF-Chem data. A temperature-dependent source of isoprene with high-NO_x conditions produces the highest ozone-temperature slope, but is still lower than the observed ozone-temperature slope by a factor of two. In particular, the box model simulations over-predict the ozone values at lower temperatures and under-predict the ozone values at higher temperatures compared to the observed data.

~~In our simulations, we focused on instantaneous production of ozone from a freshly-emitted source of VOC with mixing of clean air from the free troposphere due to a growing boundary layer. This box model setup did not consider stagnant atmospheric conditions characterised by low wind speeds slowing the transport of ozone and its precursors away from sources. Stagnant conditions have been correlated to high-ozone episodes in the summer over eastern US .~~

~~In order to investigate the sensitivity of ozone production to mixing, box model simulations were performed without vertical mixing to approximate stagnant conditions that favour accumulation of secondary VOC oxidation products. The ozone-temperature relationship obtained with each chemical mechanism, using both a temperature-independent and temperature-dependent source of isoprene emissions and the different conditions are displayed in Fig. 5 (dotted lines). Table 3 summarises the slopes (m_{O3-T}) of the linear fits of the box model simulations displayed in Fig. 5 in ppbv of ozone per C determining the rate of increase of ozone with temperature, for both case: with, and without mixing.~~

For all chemical mechanisms, the rate of increase of ozone with temperature increased in the box model simulations without mixing. The m_{O3-T} calculated from the box model simulations without mixing using a temperature-dependent source of isoprene and with Maximal-O_3 conditions (ranging between 2.0 and 2.4 ppbv/°C) are very similar to the slopes of the observational and WRF-Chem results (2.1 and 2.2 ppbv/°C, respectively). The differences in m_{O3-T} when not including mixing in the box model compared to the differences in m_{O3-T} between chemical mechanisms in Table 3 show that the ozone-temperature relationship using our box model setup is more sensitive to mixing than the choice of chemical mechanism.

An analysis Analysis of the O_x budgets, similar to that presented in Fig. 4b shows no appreciable difference between the cases with and without mixing (not shown). The chemical production of Sect. 3.2, shows an increase in absolute net production of O_x in each chemical mechanism when simulating stagnant conditions compared to simulations including mixing (Fig. 4a). Moreover, the O_x budgets normalised by the chemical loss rate of VOC remains unchanged. Furthermore, for the

5   simulations without mixing show no appreciable difference to the simulations including mixing. This analysis is displayed in the supplementary material includes the absolute production and consumption budgets of which also show the increased production with temperature for the simulations performed without mixing. From this and is consistent for each chemical mechanism and each NO_x condition. Thus we conclude that the increased ozone production seen in the box model simulations with reduced mixing is due to enhanced OH reactivity from secondary VOC oxidation products.

10   A slower rate of increase of ozone with temperature with our box model was obtained compared to the rate of increase of ozone with temperature of observational and 3D model simulations. The reason for this discrepancy was that the box model did not represent stagnation conditions which are relevant to real-world conditions. The lack of mixing meant that secondary VOC oxidation products were allowed to accumulate, leading to further degradation and increased production of peroxy radicals compared with simulations including mixing. Thus the chemical processes driving the increase of ozone with temperature

15   determined in Sect.3.2 (faster VOC oxidation and peroxy nitrate decomposition) are not altered by stagnant condition but proceed at a faster rate. ehus during stagnant conditions, stronger reductions in NO_x are required to minimise the impact of increased ozone production at higher temperatures on the urban population.

4   Conclusions

In this study, we determined the effects of temperature on ozone production using a box model over a range of temperatures and

20   NO_x conditions with a temperature-independent and temperature-dependent source of isoprene emissions. These simulations were repeated using reduced chemical mechanism schemes (CRIv2, MOZART-4, CB05 and RADM2) typically used in 3D models and compared to the near-explicit MCMv3.2 chemical mechanism.

Each chemical mechanism produced a non-linear relationship of ozone with temperature and NO_x with the most ozone produced at high temperatures and moderate emissions of NO_x. Conversely, lower NO_x levels led to a minimal increase of

25   ozone with temperature. Thus air quality in a future with higher temperatures would benefit from reductions in NO_x emissions. Simulations of high-NO_x at high temperatures led to the largest differences in ozone mixing ratios predicted by the different chemical mechanisms, future work is needed to address these inter-mechanism differences.

Faster reaction rates at higher temperatures were responsible for a greater absolute increase in ozone than increased isoprene emissions. In our simulations, ozone production was controlled by the increased rate of VOC oxidation with temperature. The

30   net influence of peroxy nitrates increased the net production of O_x per molecule of emitted VOC oxidised with temperature. Currently, chemical mechanisms do not represent the temperature-dependence of alkyl nitrate formation which may lead to discrepancies when simulating temperature-dependent ozone production over certain areas and further work assessing the impact of this missing temperature-dependent chemical process is required.

The rate of increase of ozone with temperature using observational data over Europe was twice as high as the rate of increase of ozone with temperature when using the box model. This was consistent with our box model setup not representing stagnant atmospheric conditions that are inherently included in observational data and models including meteorology, such as WRF-Chem. In model simulations without mixing the rate of increase of ozone with temperature was faster than the simulations including mixing. The simulations without mixing and a maximal ozone production chemical regime led to very similar rates of increase of ozone with temperature to the observational and WRF-Chem data. Furthermore, the ozone-temperature relationship was more sensitive to mixing than the choice of chemical mechanism.

Figure 2. ~~Contours of peak ozone~~ Ozone mixing ratios (ppbv) as a function of ~~the~~ total NO_x emissions and temperature for each chemical mechanism using a temperature-dependent and temperature-independent source of isoprene emissions. ~~The contours can be split into three separate regimes: High-, Maximal-and Low-indicated in the figure.~~

(a) Contours of peak ozone mixing ratios (ppbv) as a function of the total NO_x emissions and temperature. The contours can be split into three separate regimes: High-NO_x, Maximal-O_3 and Low-NO_x indicated in the figure.
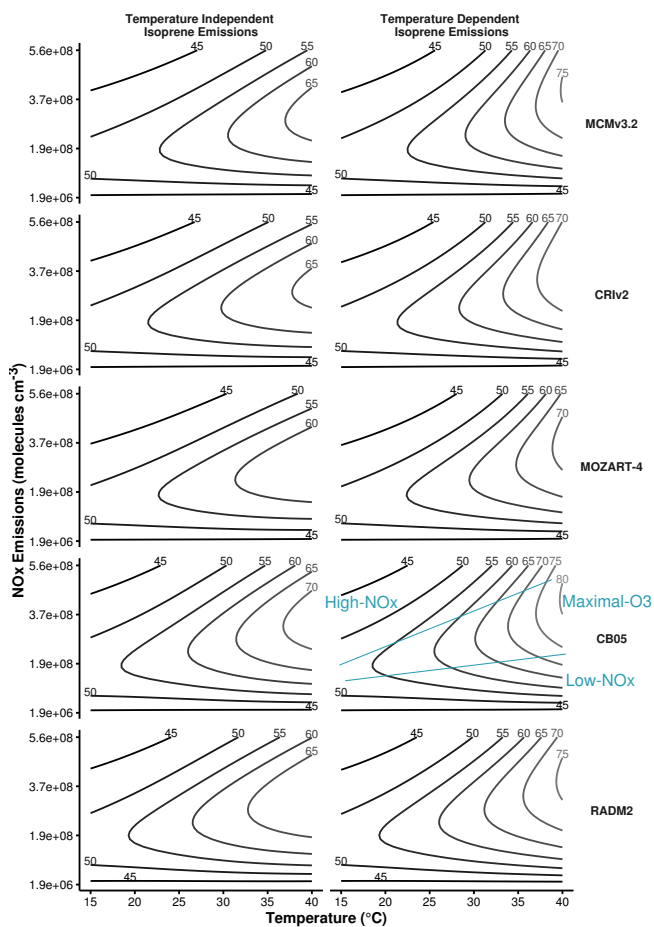

(b) Percent difference in peak ozone from MCMv3.2 at each temperature and NO_x level.

Figure 3. Mean ozone mixing ratios (ppbv) at each temperature after allocation to the different NO_x-regimes of Fig. 2a. The differences in ozone mixing ratios due to chemistry (solid line) and isoprene emissions (dotted line) are represented graphically for MOZART-4 with High-NO_x conditions. Table 2 details the differences for each chemical mechanism and NO_x-condition.

Table 1. Total AVOC emissions in 2011 in tonnes from each anthropogenic source category assigned from TNO-MACC_III emission inventory and temperature-independent BVOC emissions in tonnes from Benelux region assigned from EMEP. The allocation of these emissions to MCMv3.2, CRIv2, CB05, MOZART-4 and RADM2 species are found in the supplementary material.

Source Category	Total Emissions	Source Category	Total Emissions
Public Power	13755	Road Transport: Diesel	6727
Residential Combustion	21251	Road Transport: Others	1433
Industry	62648	Road Transport: Evaporation	2327
Fossil Fuel	15542	Non-road Transport	17158
Solvent Use	100826	Waste	1342
Road Transport: Gasoline	24921	BVOC	10702

Figure 4. Day-time ~~production and consumption~~ budgets of O_x ~~normalised by the total loss rate of emitted VOC~~ in the NO_x-regimes ~~of Fig. 3~~. The white line indicates net production or consumption of O_x. The net contribution of reactions to O_x budgets are allocated to categories of inorganic reactions, peroxy nitrates (RO2NO2), reactions of NO with HO2, alkyl peroxy radicals (RO2) and acyl peroxy radicals (ARO2). All other reactions are allocated to the ~~"~~'Other Organic' category.

(a) O_x production and consumption budgets.
(b) O_x production and consumption budgets normalised by the total loss rate of emitted VOC.

Figure 5. MDA8 values of ozone from the box model simulations allocated to the different NO_x regimes for each chemical mechanism with mixing (solid lines) and without mixing (dashed lines). The slopes of the box model ozone-temperature correlation is compared to the summer 2007 observational data (black circles) and WRF-Chem output (purple boxes) in Table 3.
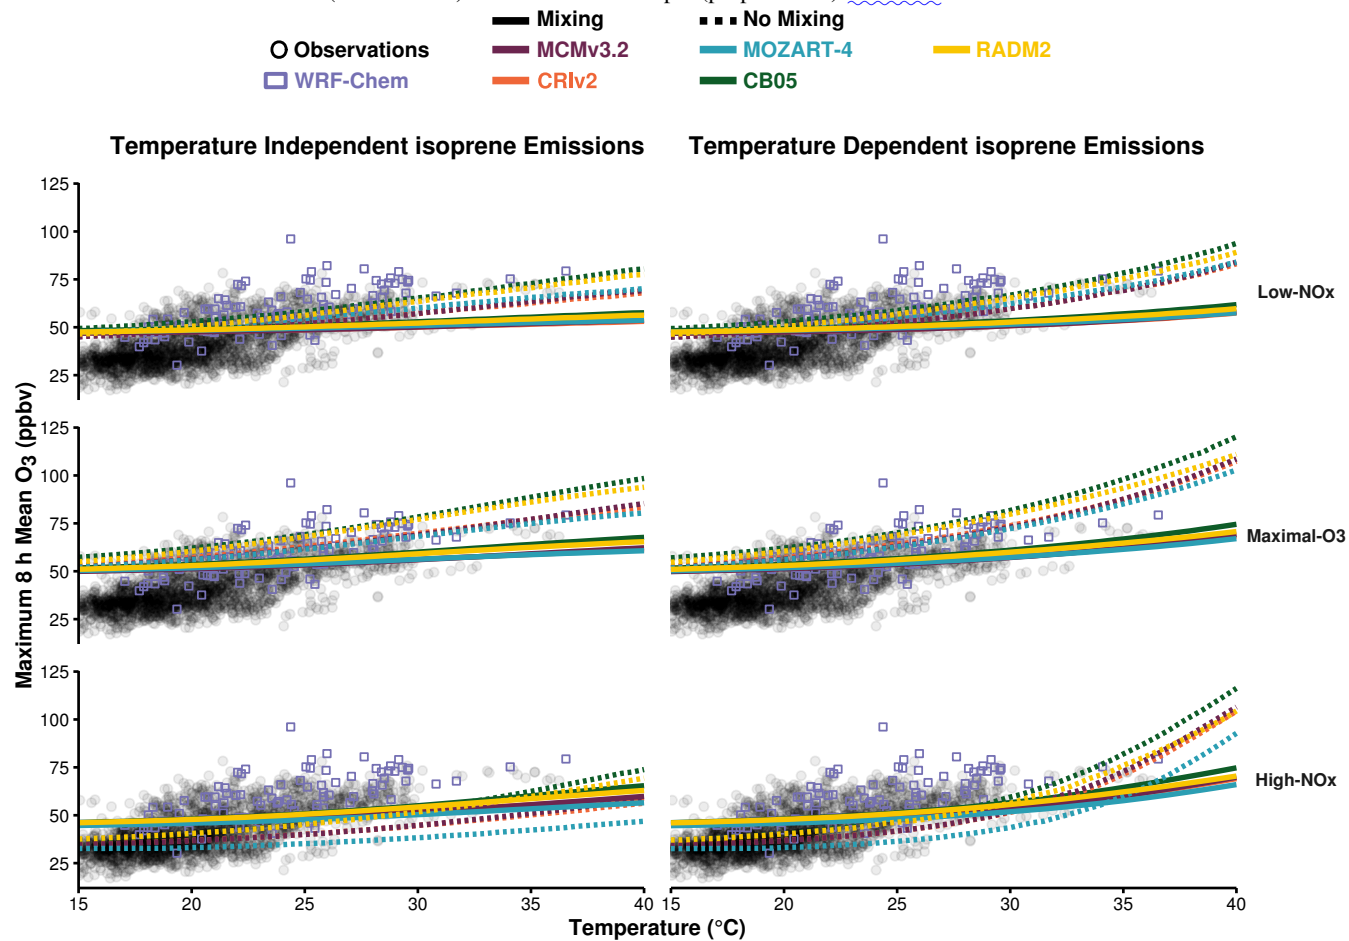

Table 2. Increase in mean ozone mixing ratio (ppbv) due to chemistry (i.e. faster reaction rates) and temperature-dependent isoprene emissions from 20 °C to 40 °C in the NO_x-regimes of Fig. 3.

Chemical Mechanism	Source of Difference	Increase in Ozone from 20 °C to 40 °C (ppbv)		
		Low-NO_x	Maximal-O_3	High-NO_x
MCMv3.2	Isoprene Emissions	4.6	7.7	10.6
	Chemistry	6.8	12.5	15.2
CRIv2	Isoprene Emissions	4.8	7.9	10.8
	Chemistry	6.0	11.1	13.7
MOZART-4	Isoprene Emissions	4.1	6.7	10.0
	Chemistry	6.0	10.2	12.3
CB05	Isoprene Emissions	4.6	7.4	9.8
	Chemistry	9.3	16.0	19.9
RADM2	Isoprene Emissions	3.8	5.7	7.8
	Chemistry	8.6	14.1	17.3

Table 3. Slopes (m_{O3-T}, ppbv per °C) of the linear fit to MDA8 values of ozone and temperature correlations in Fig. 5, indicating the increase of MDA8 in ppbv of ozone per °C. The slope of the observational data is 2.15 ppbv/°C and the slope of the WRF-Chem output is 2.05 ppbv/°C.

Mechanism	Isoprene Emissions	Low-NO_x		Maximal-O_3		High-NO_x	
		Mixing	No Mixing	Mixing	No Mixing	Mixing	No Mixing
MCMv3.2	Temperature Independent	0.28	1.01	0.51	1.36	0.59	0.96
	Temperature Dependent	0.42	1.48	0.74	2.16	0.93	2.63
CRIv2	Temperature Independent	0.25	0.93	0.47	1.27	0.55	0.88
	Temperature Dependent	0.40	1.44	0.71	2.09	0.90	2.52
MOZART-4	Temperature Independent	0.25	0.97	0.44	1.21	0.49	0.59
	Temperature Dependent	0.38	1.43	0.65	1.98	0.81	2.05
CB05	Temperature Independent	0.39	1.30	0.67	1.72	0.79	1.45
	Temperature Dependent	0.52	1.72	0.89	2.44	1.12	2.94
RADM2	Temperature Independent	0.37	1.31	0.61	1.64	0.70	1.28
	Temperature Dependent	0.48	1.68	0.79	2.22	0.97	2.49
