14 **Abstract**

15 Laboratory chambers, invaluable in atmospheric chemistry and aerosol formation studies,  
16 are subject to particle and vapor wall deposition, processes that need to be accounted for  
17 in order to accurately determine secondary organic aerosol (SOA) mass yields. Although  
18 particle wall deposition is reasonably well understood and usually accounted for, vapor  
19 wall deposition is less so. The effects of vapor wall deposition on SOA mass yields in  
20 chamber experiments can be constrained experimentally by increasing the seed aerosol  
21 surface area to promote the preferential condensation of SOA-forming vapors onto seed  
22 aerosol. Here, we study the influence of seed aerosol surface area and oxidation rate on  
23 SOA formation in  $\alpha$ -pinene ozonolysis. The observations are analyzed using a coupled  
24 vapor-particle dynamics model to interpret the roles of gas-particle partitioning (quasi-  
25 equilibrium vs. kinetically-limited SOA growth) and  $\alpha$ -pinene oxidation rate in  
26 influencing vapor wall deposition. We find that the SOA growth rate and mass yields are  
27 independent of seed surface area within the range of seed surface area concentrations  
28 used in this study. This behavior arises when the condensation of SOA-forming vapors is  
29 dominated by quasi-equilibrium growth. Faster  $\alpha$ -pinene oxidation rates and higher SOA  
30 mass yields are observed at increasing O<sub>3</sub> concentrations for the same initial  $\alpha$ -pinene  
31 concentration. When the  $\alpha$ -pinene oxidation rate increases relative to vapor wall  
32 deposition, rapidly produced SOA-forming oxidation products condense more readily  
33 onto seed aerosol particles, resulting in higher SOA mass yields. Our results indicate that  
34 the extent to which vapor wall deposition affects SOA mass yields depends on the

35 particular VOC system, and can be mitigated through the use of excess oxidant  
36 concentrations.

### 37 **1. Introduction**

38 Secondary organic aerosol (SOA), formed from the oxidation of volatile and  
39 intermediate volatility organic compounds (VOCs and IVOCs), contributes a significant  
40 fraction of the global organic aerosol burden (Kanakidou et al., 2005; Hallquist et al.,  
41 2009; Tsigaridis et al., 2014). SOA formation studies, which are typically conducted in  
42 laboratory chambers in the presence of seed aerosol particles, provide fundamental data  
43 that can be used to predict the rate of atmospheric SOA formation. An essential  
44 parameter of interest in laboratory chamber studies is the SOA mass yield ( $Y$ ), which is  
45 defined as the ratio of mass concentration of SOA formed to mass concentration of parent  
46 hydrocarbon reacted ( $\Delta\text{HC}$ ),  $Y = \Delta M_o / \Delta\text{HC}$  (Odum et al., 1996; Odum et al., 1997a;  
47 Odum et al., 1997b)). The measured SOA mass yields can subsequently be applied in  
48 atmospheric models to predict regional and global organic aerosol burdens. In order to  
49 obtain accurate SOA mass yields from the evolving aerosol size distribution in chamber  
50 experiments, the loss of both particles and vapors to the chamber walls needs to be  
51 accurately accounted for (Crump and Seinfeld, 1981; McMurry and Grosjean, 1985;  
52 McMurry and Rader, 1985; Cocker et al., 2001a; Weitkamp et al., 2007; Pierce et al.,  
53 2008; Hildebrandt et al., 2009; Loza et al., 2010; Matsunaga and Ziemann, 2010; Loza et  
54 al., 2012; Kokkola et al., 2014; McVay et al., 2014; Yeh and Ziemann, 2014; Zhang et  
55 al., 2014; Yeh and Ziemann, 2015; Zhang et al., 2015a; La et al., 2016).

56 The mechanisms by which particles in chambers deposit on chamber walls are  
57 reasonably well understood. Particles are transported to the boundary layer on the  
58 chamber walls via diffusion, gravitational settling, and electrostatic forces (Crump and  
59 Seinfeld, 1981; McMurry and Grosjean, 1985; McMurry and Rader, 1985; Pierce et al.,  
60 2008). The rate at which particles are transported to the edge of the boundary layer is  
61 dictated primarily by mixing conditions in the chamber. An effective approach for  
62 characterizing particle wall loss involves measuring the size-dependent wall loss rates of  
63 polydisperse inert seed aerosol (e.g. ammonium sulfate particles) injected into the  
64 chamber during seed-only experiments (Keywood et al., 2004; Pierce et al., 2008). The

65 observed particle number concentration decay in each size bin is then fitted to a first-  
66 order exponential decay from which the first-order wall loss coefficients are determined  
67 as a function of particle size. These wall loss coefficients are subsequently used to correct  
68 for size-dependent particle wall loss in actual SOA formation experiments.

69 Vapor-wall deposition mechanisms in chambers are not as well understood or  
70 accounted for as those for particles. The degree to which SOA-forming vapors deposit  
71 onto chamber walls is governed by the rate at which these gas-phase organic molecules  
72 are transported to the walls, the strength of adherence of the organic molecule to the wall,  
73 and the extent of reversible vapor-wall partitioning (Loza et al., 2010; Matsunaga and  
74 Ziemann, 2010; Zhang et al., 2015a). For example, Loza et al. (2010) showed that the  
75 loss of 2,3-epoxy-1,4-butanediol, an isoprene oxidation product analogue, to walls in the  
76 Caltech chamber was essentially irreversible on short time scales but became reversible  
77 on longer time scales. In contrast, glyoxal, a common isoprene oxidation product,  
78 exhibited reversible vapor-wall partitioning over all time scales. Recent studies show that  
79 SOA mass yields measured in chamber experiments can be significantly underestimated  
80 due to wall deposition of SOA-forming vapors that would otherwise contribute to SOA  
81 growth (McVay et al., 2014; Zhang et al., 2014; La et al., 2016). Zhang et al. (2014)  
82 found that chamber-derived SOA mass yields from toluene photooxidation may be  
83 underestimated by as much as a factor of four as a result of vapor wall loss.  
84 Consequently, the use of underestimated chamber-derived SOA mass yields in  
85 atmospheric models will lead to the underprediction of ambient SOA mass concentrations  
86 (Cappa et al., 2016).

87 For the toluene photooxidation system, Zhang et al. (2014) showed that the  
88 measured SOA mass yields increased with increasing seed aerosol surface area,  
89 demonstrating that increasing the seed-to-chamber surface area ratio promoted the  
90 condensation of SOA-forming vapors onto seed aerosol particles. However, increasing  
91 the seed aerosol surface area to promote condensation of SOA-forming vapors onto seed  
92 aerosol particles may not be effective in all VOC oxidation systems. A modeling study by  
93 McVay et al. (2014) showed that the SOA mass yield depends on seed aerosol surface  
94 area only in cases where the condensation of SOA-forming vapors onto seed aerosol

95 particles is kinetically limited (i.e., the timescale for gas-particle equilibrium is  
96 competitive with or greater than the timescale for reaction and vapor-wall deposition). In  
97 addition to the seed aerosol surface area, VOC oxidation rate may also play an important  
98 role in the effect of vapor wall loss on SOA formation. Ng et al. (2007) showed that the  
99 SOA mass yields from *m*-xylene photooxidation are dependent on the oxidation rate, with  
100 higher OH concentrations (hence faster oxidation rates) resulting in higher SOA mass  
101 yields. It was suggested that the “oxidation rate effect” could arise as a result of  
102 competition between growing particles and chamber walls for condensable VOC  
103 oxidation products (Ng et al., 2007). However, McVay et al. (2016) reported similar SOA  
104 growth at low and high OH concentrations in  $\alpha$ -pinene photooxidation. Taken together,  
105 these studies show the importance of understanding how gas-particle partitioning and  
106 VOC oxidation rate impact vapor-wall deposition and SOA mass yields in laboratory  
107 chamber experiments.

108 In this study, we examine the influence of seed aerosol surface area and oxidation  
109 rate on SOA formation in  $\alpha$ -pinene ozonolysis chamber experiments.  $\alpha$ -pinene is the most  
110 abundant monoterpene, with global emissions estimated to be  $\sim 66 \text{ Tg yr}^{-1}$  (Guenther et  
111 al., 2012). Ozonolysis is the major atmospheric oxidation pathway of  $\alpha$ -pinene, and is  
112 estimated to account for reaction of  $\sim 46 \%$  of emitted  $\alpha$ -pinene (Griffin et al., 1999;  
113 Capouet et al., 2008).  $\alpha$ -pinene ozonolysis, a major source of atmospheric SOA on both  
114 regional and global scales (Kanakidou et al., 2005; Hallquist et al., 2009; Carlton et al.,  
115 2010; Pye et al., 2010), has been the subject of numerous studies (Hoffmann et al., 1997;  
116 Griffin et al., 1999; Cocker et al., 2001b; Gao et al., 2004; Presto et al., 2005; Presto and  
117 Donahue, 2006; Pathak et al., 2007a; Pathak et al., 2007b; Song et al., 2007; Shilling et  
118 al., 2008; Henry et al., 2012; Ehn et al., 2014; Kristensen et al., 2014; Zhang et al.,  
119 2015b). Here, we measure the  $\alpha$ -pinene SOA mass yield as a function of seed aerosol  
120 surface area concentration (0 to  $3000 \mu\text{m}^2 \text{ cm}^{-3}$ ) and  $\text{O}_3$  mixing ratio (100 vs. 500 ppb).  
121 These results are analyzed using a coupled vapor-particle dynamics model to evaluate the  
122 roles of gas-particle partitioning and VOC oxidation rate in influencing vapor-wall  
123 deposition effects on the measured SOA mass yields.

## 124 2. Experimental

## 125 2.1. Dark $\alpha$ -pinene ozonolysis experiments

126 Experiments were conducted in the Georgia Tech Environmental Chamber  
127 (GTEC) facility. Details of the dual chamber facility are provided elsewhere (Boyd et al.,  
128 2015). Only one FEP Teflon chamber (volume 13 m<sup>3</sup>) was used for the entirety of this  
129 study. Before each experiment, the chamber is flushed with dried, purified air for at least  
130 36 h until the aerosol number concentration is < 30 cm<sup>-3</sup>. All experiments were conducted  
131 under dry conditions (< 5 % RH) at room temperature (25 °C). NO<sub>x</sub> mixing ratios in these  
132 experiments are < 1 ppb. Experimental conditions are summarized in Table 1.

133 22 ppm of cyclohexane (Sigma Aldrich, ≥ 99.9 %) was first injected into the  
134 chamber to act as an OH scavenger (~440 times the initial  $\alpha$ -pinene concentration). After  
135 the cyclohexane concentration had stabilized in the chamber for 30 min, a known  
136 concentration (~50 ppb in all experiments) of  $\alpha$ -pinene (Sigma Aldrich, > 99 %) was  
137 injected into the chamber, followed by inorganic seed aerosol via atomization of an  
138 aqueous ammonium sulfate (AS) solution (in seeded experiments). To vary the seed  
139 aerosol surface area, different concentrations of AS solutions were used to generate seed  
140 aerosol particles in the seeded experiments. In the “low AS” experiments, a 0.015 M AS  
141 solution was used to generate seed particles, and the resulting initial total AS seed surface  
142 area concentration was ~1000  $\mu\text{m}^2 \text{cm}^{-3}$ . In the “high AS” experiments, a 0.05 M AS  
143 solution was used to generate seed aerosol particles, and the resulting initial total AS seed  
144 surface area concentration was ~3000  $\mu\text{m}^2 \text{cm}^{-3}$ . In selected experiments, no seed aerosol  
145 particles were introduced into the chamber and SOA was formed via nucleation. After the  
146 seed aerosol concentration in the chamber stabilized, O<sub>3</sub> (100 or 500 ppb), which was  
147 generated by passing purified air into a photochemical cell (Jelight 610), was introduced  
148 into the chamber. The start of O<sub>3</sub> injection into the chamber marked the beginning of the  
149 reaction (i.e., reaction time = 0 min). The initial  $\alpha$ -pinene:O<sub>3</sub> molar ratio was fixed at  
150 approximately 1:2 and 1:10 in the 100 and 500 ppb O<sub>3</sub> experiments, respectively. O<sub>3</sub> was  
151 injected into the chamber for 13.5 and 54.25 min in the 100 and 500 ppb O<sub>3</sub> experiments,  
152 respectively, to achieve the desired O<sub>3</sub> concentrations. The O<sub>3</sub> injection times were  
153 established in separate experiments in which only O<sub>3</sub> was injected into the chamber.

154           The  $\alpha$ -pinene and O<sub>3</sub> concentrations were measured by a Gas Chromatograph-  
155 Flame Ionization Detector (GC-FID, Agilent 7890A) and O<sub>3</sub> monitor (Teledyne T400),  
156 respectively. GC-FID measurements were taken 12 min apart. A High Resolution Time-  
157 of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS, Aerodyne Research Inc.) was used  
158 to measure the aerosol elemental composition (DeCarlo et al., 2006; Canagaratna et al.,  
159 2015). Details on the operation of the HR-ToF-AMS and its data analysis are described  
160 elsewhere (Canagaratna et al., 2015). Aerosol size distributions, number and volume  
161 concentrations were measured by a Scanning Mobility Particle Sizer (SMPS, TSI), which  
162 consists of a Differential Mobility Analyzer (DMA, TSI 3081) and a Condensation  
163 Particle Counter (CPC, TSI 3775). For nucleation and low AS experiments, the measured  
164 aerosol size range was set to 14 to 686 nm diameter. For high AS experiments, the  
165 measured aerosol size range was set to 17 to 983 nm. Prior checks were made to confirm  
166 that no particles larger than 686 nm were detected in the nucleation and low AS  
167 experiments. The SOA mass concentrations reported in this study were measured using  
168 the SMPS. The SOA density was calculated from the ratio of the aerosol size  
169 distributions measured by the HR-ToF-AMS and the SMPS during nucleation  
170 experiments (DeCarlo et al., 2004; Bahreini et al., 2005).

## 171   **2.2. Particle wall deposition correction**

172           Particle wall deposition needs to be accounted for to determine the SOA mass  
173 concentration in the chamber. Two limiting assumptions have traditionally been made  
174 regarding interactions between particles deposited on the chamber walls and suspended  
175 vapors when accounting for particle wall loss in the computation of SOA mass yields  
176 (Weitkamp et al., 2007; Hildebrandt et al., 2009; Loza et al., 2012; Zhang et al., 2014).  
177 The first case assumes that particles deposited on the walls cease to interact with  
178 suspended vapors, and therefore the SOA mass present on these deposited particles does  
179 not change after deposition (Loza et al., 2012; Zhang et al., 2014). Adding the SOA mass  
180 present on these deposited particles to that present on the suspended particles provides a  
181 lower bound of the total SOA mass concentration. In the second case, it is assumed that  
182 particles deposited on the walls continue to interact with suspended vapors as if these  
183 particles had remained suspended, and therefore the SOA mass present on these

184 deposited particles increases at the same rate as those suspended (Hildebrandt et al.,  
 185 2009; Weitkamp et al., 2007). Thus, this case provides an upper bound of the total SOA  
 186 mass concentration due to the additional uptake of suspended vapors to wall-deposited  
 187 particles. However, it must be kept in mind that the calculated SOA mass concentration  
 188 can be underestimated even in the upper bound case since the calculation accounts  
 189 neither for differences in the vapor-particle and vapor-wall interaction and transport  
 190 timescales nor for the significantly larger amount of absorbing mass of the chamber walls  
 191 (relative to the deposited particles) for suspended vapors (McVay et al., 2014; Zhang et  
 192 al., 2014; McVay et al., 2016).

193 In this study, we calculate SOA mass yields using the lower bound of the total  
 194 SOA mass concentration obtained from SMPS measurements, which has been described  
 195 in detail previously (Loza et al., 2012), and will be reviewed briefly here. For each  
 196 particle size bin  $i$  at each time increment  $\Delta t$ , the particle number distribution deposited on  
 197 the wall ( $n_{w,i,j}$ ) is:

$$198 \quad n_{w,i,j} = n_{s,i,j} \times (1 - \exp(-\beta_i \Delta t)) \quad (1)$$

199 where  $n_{s,i,j}$  is the suspended particle number distribution in particle size bin  $i$  at time step  
 200  $j$ ,  $\Delta t$  is the difference between time step  $j$  and time step  $j + 1$ , and  $\beta_i$  is the size-dependent  
 201 first-order exponential wall loss rate obtained from seed-only experiments. The particle  
 202 wall loss corrected number distribution ( $n_{total,i,j}$ ) is obtained from the sum of the particle  
 203 number distribution of deposited particles ( $n_{w,i,j}$ ) and suspended particles ( $n_{s,i,j}$ ):

$$204 \quad n_{total,i,j} = n_{s,i,j} + n_{w,i,j} \quad (2)$$

205 Assuming spherical particles, the particle wall loss corrected volume concentration  
 206 ( $V_{total,j}$ ) is:

$$207 \quad V_{total,j} = \sum_{i=1}^m \frac{n_{total,i,j}}{D_{p,i} \ln 10} \times (D_{p,i+} - D_{p,i-}) \times \frac{\pi}{6} D_{p,i}^3 \quad (3)$$

208 where  $m$  is the number of particle size bins,  $D_{p,i+}$  and  $D_{p,i-}$  are the upper and lower limits  
 209 for size bin  $i$ , respectively, and  $D_{p,i}$  is the median particle diameter for size bin  $i$ . The term

210  $D_{p,i} \ln 10$  is needed to convert from a lognormal distribution. Figures S1-S4 and Table S1  
211 show results from the particle wall loss correction. To calculate the SOA mass  
212 concentration ( $\Delta M_{o,j}$ ), the SOA density ( $\rho_{org}$ ) is multiplied by the difference of the  
213 particle wall loss corrected volume concentration ( $V_{total,j}$ ) and the initial seed volume  
214 concentration ( $V_{seed}$ ):

$$215 \quad \Delta M_{o,j} = \rho_{org} \times (V_{total,j} - V_{seed}) \quad (4)$$

216 The measured densities of the  $\alpha$ -pinene SOA are 1.39 and 1.37 g cm<sup>-3</sup> for the 100 and 500  
217 ppb O<sub>3</sub> experiments, respectively, and are within the range (i.e., 1.19 to 1.52 g cm<sup>-3</sup>)  
218 reported in previous  $\alpha$ -pinene ozonolysis studies (Bahreini et al., 2005; Kostenidou et al.,  
219 2007; Song et al., 2007; Shilling et al., 2009).

### 220 **3. Vapor-particle dynamics model**

221 A coupled vapor-particle dynamics model is used to evaluate the influence of seed  
222 aerosol surface area and oxidation rate on SOA formation in the  $\alpha$ -pinene ozonolysis  
223 chamber experiments. This model is similar to that used in McVay et al. (2014), and will  
224 be briefly described here. Parameters from the experimental data (temperature, pressure,  
225 initial  $\alpha$ -pinene concentration) are used as model inputs. The initial size distribution is set  
226 to that measured by the SMPS, with the exception of the two nucleation experiments.  
227 Because nucleation is not explicitly simulated, an approximation is used in which the  
228 smallest diameter bin is initialized with the total number of particles measured at the end  
229 of the experiment (see Table S1). In each simulation, the decay of  $\alpha$ -pinene, the  
230 consumption of O<sub>3</sub>, the SOA mass concentration, and the SOA mass yield are calculated  
231 throughout the duration of the experiment. We assume a linear injection rate of O<sub>3</sub> based  
232 on the time required to inject the desired O<sub>3</sub> concentration. For example, O<sub>3</sub> is injected at  
233 a rate of 500/54.25 ppb min<sup>-1</sup> for the first 54.25 min during the 500 ppb O<sub>3</sub> experiments.  
234 O<sub>3</sub> simultaneously decays by reaction with  $\alpha$ -pinene at a rate constant of  $9.4 \times 10^{-17}$  cm<sup>3</sup>  
235 molec.<sup>-1</sup> s<sup>-1</sup> (Saunders et al., 2003). The O<sub>3</sub>+ $\alpha$ -pinene reaction is assumed to occur in a  
236 well-mixed chamber and produces 5 classes of first-generation products, which are  
237 grouped according to mass saturation concentrations, similar to the volatility basis set  
238 (Donahue et al., 2006): >10<sup>3</sup> (assumed to be completely volatile), 10<sup>2</sup>, 10, 1 and 0.1  $\mu$ g

239  $\text{m}^{-3}$ . Branching ratios between these products are optimized to fit the experimental data.  
 240 These branching ratios cannot be compared directly to previously reported VBS  
 241 parameters for  $\alpha$ -pinene ozonolysis (e.g., Henry et al. (2012)) since VBS parameters are  
 242 typically mass-based, while the branching ratios in the model are mole-based.  
 243 Furthermore, the branching ratios here account for the influence of vapor wall deposition,  
 244 while typical VBS parameters do not. We assume that these 5 classes of products have  
 245 molecular weights 168, 184, 192, 200 and 216  $\text{g mole}^{-1}$  based on the group contribution  
 246 method (Donahue et al., 2011). The first-generation products are assumed not to undergo  
 247 further reaction with  $\text{O}_3$  upon formation.

248 The aerosol dynamics in the chamber obey the aerosol general dynamic equation  
 249 (Seinfeld and Pandis, 2006):

$$250 \quad \left( \frac{\partial n(D_p, t)}{\partial t} \right) = \left( \frac{\partial n(D_p, t)}{\partial t} \right)_{\text{coag}} + \left( \frac{\partial n(D_p, t)}{\partial t} \right)_{\text{cond/evap}} + \left( \frac{\partial n(D_p, t)}{\partial t} \right)_{\text{wall loss}} \quad (5)$$

251 Coagulation is not considered, since an alternative version of the model including  
 252 coagulation showed no change in the predicted  $\alpha$ -pinene ozonolysis SOA mass  
 253 concentrations in simulations with and without coagulation. The change in particle  
 254 number distribution due to particle wall loss is:

$$255 \quad \left( \frac{\partial n(D_p, t)}{\partial t} \right)_{\text{wall loss}} = -\beta_j(D_p)n(D_p, t) \quad (6)$$

256 where, as noted in section 2.2,  $\beta_j(D_p)$  is the size-dependent first-order wall loss rate  
 257 coefficient obtained from fitting seed-only experiments. The rate at which vapor  
 258 condenses onto a spherical aerosol particle is:

$$259 \quad J_i = 2\pi D_p D_i (G_i - G_i^{eq}) F_{FS} \quad (7)$$

260 where  $G_i$  is the concentration of gas-phase species  $i$ ,  $G_i^{eq}$  is the saturation concentration  
 261 of gas-phase species  $i$ ,  $D_i$  is the gas-phase molecular diffusivity (assumed to be  $3 \times 10^{-6}$

262  $\text{m}^2 \text{s}^{-1}$  (McVay et al., 2014)), and  $F_{FS}$  is the Fuchs-Sutugin correction for non-continuum  
 263 gas-phase diffusion:

$$264 \quad F_{FS} = \frac{0.75\alpha_p(1 + \text{Kn})}{\text{Kn}^2 + \text{Kn} + 0.283\text{Kn}\alpha_p + 0.75\alpha_p} \quad (8)$$

265 where  $\alpha_p$  is the vapor-particle mass accommodation coefficient, and Kn is the Knudsen  
 266 number,  $\text{Kn} = 2\lambda_{AB}/D_p$ . The vapor-particle mass accommodation coefficient accounts for  
 267 any resistance to vapor molecule uptake at the particle surface (e.g. surface  
 268 accommodation and particle-phase diffusion limitations).  $\lambda_{AB}$  is the mean free path of the  
 269 gas-phase species, which is:

$$270 \quad \lambda_{AB} = 3D_i \times \sqrt{\frac{\pi M_i}{8RT}} \quad (9)$$

271 where  $R$  is the ideal gas constant,  $T$  is the temperature, and  $M_i$  is the molecular weight of  
 272 diffusing gas-phase molecule  $i$ . For each particle size bin, Eqs. 7-9 are used to compute  
 273 the flux of each gas-phase species to and from an aerosol particle, scaled by the particle  
 274 number concentration in the size bin. The net rate of change for each gas-phase species  
 275 due to evaporation or condensation is obtained from the total flux summed over all the  
 276 particle size bins.

277  $G_i^{eq}$  varies for each particle size bin because it depends on the mass concentration  
 278 of species  $i$  and the total organic mass concentration in the size bin:

$$279 \quad G_i^{eq} = \frac{A_i C_i^*}{\sum_k A_k + M_{mit}} \quad (10)$$

280 where  $A_i$  is the concentration of species  $i$  in the particle phase,  $C_i^*$  is the saturation  
 281 concentration of species  $i$ ,  $\sum_k A_k$  is the sum of all the species concentration in the particle  
 282 phase, and  $M_{mit}$  is the mass concentration of any absorbing organic material initially

283 present in the seed aerosol. To avoid numerical errors in Eq. 10 at the first time step,  $M_{init}$   
 284 is set to  $0.01 \mu\text{g m}^{-3}$ .

285 The oxidation products of  $\alpha$ -pinene ozonolysis are assumed to be subject to  
 286 vapor-wall deposition, which is simulated using a first-order wall-loss coefficient  
 287 (McMurry and Grosjean, 1985):

$$288 \quad k_{wall,on} = \left(\frac{A}{V}\right) \frac{\frac{\alpha_{wall} \bar{c}}{4}}{1 + \frac{\pi}{2} \left(\frac{\alpha_{wall} \bar{c}}{4\sqrt{k_e D_i}}\right)} \quad (11)$$

289 where  $A/V$  is the surface area-to-volume ratio of the chamber (estimated to be  $2.5 \text{ m}^{-1}$ ),  
 290  $\alpha_{wall}$  is the vapor-wall mass accommodation coefficient, and  $k_e$  is the eddy diffusion  
 291 coefficient that describes mixing conditions in the chamber. Based on the measured size-  
 292 dependent particle wall loss rates (method is described in Zhang et al. (2014)),  $k_e$  is  
 293 estimated to be  $0.03 \text{ s}^{-1}$  for the GTEC chamber. Vapor-wall deposition is assumed to be  
 294 reversible, and the rate constant of vapor desorption from the chamber walls is:

$$295 \quad k_{wall,off} = \frac{k_{wall,on}}{K_w C_w} = k_{wall,on} \left(\frac{C_i^* M_w \gamma_w}{C_w M_p \gamma_p}\right) \quad (12)$$

296 where  $C_w$  is the equivalent organic mass concentration in the wall (designated to treat  
 297 gas-wall partitioning in terms of gas-particle partitioning theory and not necessarily  
 298 representative of a physical layer of organic concentration on the wall (Matsunaga and  
 299 Ziemann, 2010)),  $K_w$  is the gas-wall partitioning coefficient,  $M_w$  is the effective molecular  
 300 weight of the wall material,  $\gamma_w$  is the activity coefficient of the species in the wall layer,  
 301  $M_p$  is the average molecular weight of organic species in the particle, and  $\gamma_p$  is the activity  
 302 coefficient of the species in the particle. For simplicity, we assume that  $M_w = M_p$  and  $\gamma_w =$   
 303  $\gamma_p$ .  $C_w$  is set to  $10 \text{ mg m}^{-3}$  based on previous inferences by Matsunaga and Ziemann  
 304 (2010). Sensitivity studies (not shown) show no change in model predictions when  
 305 varying  $C_w$  above  $C_w = 0.1 \text{ mg m}^{-3}$ .

306 In the initial version of the model, after all the  $\alpha$ -pinene is consumed, vapor wall  
307 deposition was assumed to continue to deplete the gas-phase oxidation products and  
308 aerosol mass evaporates to maintain gas-particle equilibrium. SOA evaporation was not  
309 observed experimentally (i.e., the SOA mass concentration does not decrease  
310 significantly over time after peak SOA growth has been achieved in these chamber  
311 experiments (Fig. 2)). In order to represent these observations in the model, a first-order,  
312 particle-phase reaction is introduced by which aerosol species are converted into non-  
313 volatile absorbing organic mass with a timescale of  $\tau_{olig}$ . This mechanism (which is not  
314 included in the model used in McVay et al. (2014)) is similar to that used by the  
315 sequential equilibrium partitioning model, in which aerosol is converted from an  
316 absorbing to non-absorbing, non-volatile phase in order to explain the inhibited diffusion  
317 and evaporation observed in  $\alpha$ -pinene ozonolysis SOA (Cappa and Wilson, 2011).  
318 Although we assume here that the converted non-volatile aerosol mass still participates in  
319 partitioning, either mechanism invokes a particle-phase process to retard SOA  
320 evaporation.

321 Model parameters  $\alpha_w$ ,  $\alpha_p$ ,  $\tau_{olig}$  and the branching ratios between the oxidation  
322 products are optimized to best-fit the predictions with the experimental observations.  
323 Specifically, model predictions are compared to experimental data: SOA mass  
324 concentration vs. reaction time,  $\alpha$ -pinene concentration vs. reaction time, and  $O_3$   
325 concentration vs. reaction time. Figure S6 compares reaction profiles of measured and  
326 modeled  $O_3$  and  $\alpha$ -pinene concentrations for the base model case. Sensitivity tests were  
327 also performed on each model parameter, shown in Figs. S7-S10. Table 2 summarizes the  
328 parameters used. While the optimized parameters provide a good fit to the data, we  
329 caution that the parameters are interconnected, and other fits may also be possible. We  
330 are confident that our conclusions derived using these parameters are robust.

#### 331 4. Results

332 Figure 1 shows the size-dependent particle wall deposition coefficients inferred  
333 from seed-only deposition experiments. The initial total AS seed surface area  
334 concentration in the low AS-seed only and high AS-seed only experiments (which are  
335 conducted using 0.015 M AS and 0.05 M AS solutions, respectively) are similar to those

336 used in the  $\alpha$ -pinene ozonolysis experiments (i.e.,  $\sim 1000$  and  $\sim 3000 \mu\text{m}^2 \text{cm}^{-3}$ ,  
337 respectively). While there are differences in the particle wall deposition coefficients from  
338 the low and high AS-seed only experiments, this difference is likely the result of  
339 uncertainties arising from the low particle number concentrations for the larger particles  
340 in the low AS-seed only experiment. As shown in Fig. 1, both sets of particle wall  
341 deposition coefficients generally fall within the range of those measured in routine  
342 monthly AS-seed only experiments conducted in the chamber.

343         The particle wall deposition corrected number concentration data provide a test of  
344 the appropriateness of the particle wall deposition correction. This is because the  
345 corrected number concentration should level off at a constant value (i.e., the initial  
346 particle number concentration), assuming no significant coagulation, when particle wall  
347 deposition is properly accounted for since the wall-deposited particle number distribution  
348 is added to the suspended particle number distribution during particle wall loss  
349 correction. We account for particle wall deposition in nucleation and low AS experiments  
350 using deposition coefficients determined from the low AS-seed only experiments, while  
351 particle deposition in high AS experiments are accounted for using coefficients  
352 determined from the high AS-seed only experiments. Figures S1 and S2 show the particle  
353 wall deposition-corrected aerosol number and volume concentrations. Over all  
354 experiments, the particle wall deposition-corrected final particle number concentration  
355 (i.e., at the end of the reaction) is 9 to 17 % less than the initial particle number  
356 concentration for the low AS and high AS experiments (Table S1), respectively,  
357 indicating that the particle wall deposition-corrected volume concentrations are slightly  
358 underestimated. It is currently unclear why the particle wall deposition-corrected final  
359 particle number concentrations are somewhat smaller than the initial particle number  
360 concentrations, though this could be due to variations in particle wall deposition rates in  
361 the AS-seed only and  $\alpha$ -pinene ozonolysis experiments. As a sensitivity test, we used the  
362 average of the low AS-seed only and high AS-seed only particle wall deposition  
363 coefficients to account for particle wall deposition in all the experiments (Figs. S3 and  
364 S4). While there is a negligible difference in the particle wall deposition corrected  
365 volume concentrations (Figs. S3 and S4 vs. Figs. S1 and S2), a larger spread (1 to 22 %)  
366 exists in the difference between the initial and final particle number concentrations when

367 the average particle wall deposition coefficients are used (Table S1). Therefore, all  
368 subsequent nucleation and low AS data presented here are particle wall deposition-  
369 corrected using coefficients determined from the low AS-seed only experiments, and all  
370 high AS data are corrected using particle wall deposition coefficients determined from  
371 the high AS-seed only experiments.

372 Figure 2 shows the reaction profiles of the  $\alpha$ -pinene ozonolysis experiments. SOA  
373 growth typically starts within 10 to 20 min of the start of the reaction. At either initial  $O_3$   
374 concentration, the molar ratio of  $O_3$  reacted to  $\alpha$ -pinene reacted is approximately 1:1 (i.e.,  
375 50 ppb  $\alpha$ -pinene reacted with 50 ppb  $O_3$ ), which indicates that  $O_3$  reacts only with  $\alpha$ -  
376 pinene and not its oxidation products. As anticipated, the  $\alpha$ -pinene oxidation rates in the  
377 100 ppb  $O_3$  experiments are significantly slower than those in the 500 ppb  $O_3$   
378 experiments. Figures 2a-c show that peak SOA levels are typically reached at reaction  
379 time  $\sim$ 300 to 350 min in the 100 ppb  $O_3$  experiments, during which  $\geq$  95 % of the  
380 injected  $\alpha$ -pinene has reacted. In contrast, all the  $\alpha$ -pinene reacts within 80 to 90 min of  
381 the start of reaction in the 500 ppb  $O_3$  experiments, and peak SOA levels are achieved at  
382 reaction time  $\sim$ 100 min (Figs. 2d-f). These results indicate that the  $O_3$  concentration  
383 dictates both the rate of  $\alpha$ -pinene oxidation and the time it takes to achieve peak SOA  
384 growth.

385 Figure 3 shows the time-dependent growth curves (SOA mass concentration vs.  
386  $\alpha$ -pinene reacted (Ng et al., 2006)) for the 100 and 500 ppb  $O_3$  experiments. Only SOA  
387 growth data up to SOA peak concentrations are shown. SOA growth essentially stops  
388 once all the  $\alpha$ -pinene has reacted. This is expected, as  $\alpha$ -pinene has only one double  
389 bond; the first step of  $\alpha$ -pinene ozonolysis is rate-limiting and the first-generation  
390 products are condensable (Ng et al., 2006; Chan et al., 2007). The time-dependent SOA  
391 growth curves for experiments corresponding to different seed aerosol concentrations  
392 overlap for both low and high  $O_3$  concentrations. This indicates that the initial AS seed  
393 surface area does not influence the SOA growth rate within the range of AS seed surface  
394 area concentration used. It is important to note that while it appears that the SOA growth  
395 rate is faster in the 100 ppb  $O_3$  relative to the 500 ppb  $O_3$  experiments based on the time-  
396 dependent growth curves shown in Fig. 3, this is not the case. Instead, the observed time-

397 dependent growth curves can be explained by the higher concentration of  $\alpha$ -pinene  
398 having reacted during the 10 to 20 min delay of SOA formation in the 500 ppb O<sub>3</sub>  
399 experiments compared to the 100 ppb O<sub>3</sub> experiments (Fig. 2).

400 Figure 4 shows the time-dependent SOA mass yields as a function of initial total  
401 AS seed surface area for the 100 and 500 ppb O<sub>3</sub> experiments. Regardless of the O<sub>3</sub>  
402 concentration, the SOA mass yields stay roughly constant despite the increase in AS seed  
403 surface area. This indicates that the surface area concentration of AS seed aerosol does  
404 not noticeably influence the partitioning of gas-phase  $\alpha$ -pinene ozonolysis products to the  
405 particle phase within the range of AS seed surface area concentration used. Higher SOA  
406 mass yields are observed in the 500 ppb O<sub>3</sub> experiments, which indicates that the  $\alpha$ -  
407 pinene oxidation rate controls the absolute amount of SOA formed. It is important to note  
408 that these conclusions are robust even when the average of the low AS-seed only and  
409 high AS-seed only particle wall loss coefficients are used to account for particle wall loss  
410 in all the experiments (Fig. S5). The enhancement of SOA mass yields at higher O<sub>3</sub>  
411 concentrations and the lack of a SOA mass yield dependence on AS seed surface area  
412 (within the range of AS seed surface area concentration used in this study) will be  
413 discussed further in Section 5.

414 The  $\alpha$ -pinene ozonolysis SOA mass yields obtained in this study are compared to  
415 those reported in previous studies in Fig. 5. Table S2 lists the experimental conditions  
416 employed in these studies. To facilitate comparison between the different studies, all the  
417 SOA mass yield and concentration data (including this study) are adjusted to an organic  
418 density of 1.0 g cm<sup>-3</sup>. As shown in Fig. 5, the SOA mass yields obtained at peak SOA  
419 growth in this study are generally consistent with those of previous studies where the  
420 chamber was operated in batch mode (that in this study).

421 The competition between the condensation of SOA-forming vapor to aerosol  
422 particles vs. to chamber walls is investigated using the coupled vapor-particle dynamics  
423 model described in Section 3. As noted earlier, optimal model values for  $\alpha_p$ ,  $\alpha_w$ ,  $\tau_{olig}$  and  
424 the branching ratios between the oxidation products were determined for the 100 and 500  
425 ppb O<sub>3</sub> experiments by comparing the observed and best-fit time-dependent SOA,  $\alpha$ -  
426 pinene, and O<sub>3</sub> concentrations profiles (Figs. S6-S10). Sensitivity tests were performed

427 for each parameter to establish that the set of optimal model values provide the best  
428 overall agreement with time-dependent SOA formation profiles observed for all  
429 experiments (Figs. S7-S10). Predictions from the coupled vapor-particle dynamics model  
430 show that the optimal parameters are:  $\alpha_w = 10^{-6}$ ,  $\alpha_p = 1$ ,  $\tau_{olig} = 4$  h, branching ratios = 0.57,  
431 0.35, 0.04, 0.015 and 0.025 for oxidation products with vapor pressures  $>10^3$ ,  $10^2$ , 10, 1  
432 and  $0.1 \mu\text{g m}^{-3}$ , respectively. The best-fit  $\alpha_w = 10^{-6}$  (Fig. S7) corresponds to a first-order  
433 vapor-wall deposition rate constant ( $k_{wall,on}$ ) of  $10^{-4} \text{ s}^{-1}$ . This  $k_{wall,on}$  value is comparable to  
434 that reported by Matsunaga and Ziemann (2010) for a  $8.2 \text{ m}^3$  chamber.

## 435 5. Discussion

436  $\alpha$ -pinene ozonolysis has been carried out at two  $\text{O}_3$  mixing ratios (100 and 500  
437 ppb) under varying AS seed aerosol surface area concentrations (0,  $\sim 1000$  and  $\sim 3000 \mu\text{m}^2$   
438  $\text{cm}^{-3}$ ).

### 439 5.1 Seed aerosol surface area effect

440 Figure 3 shows that the time-dependent SOA growth curves for experiments with  
441 different seed area concentrations overlap at both  $\text{O}_3$  concentrations, which indicates the  
442 AS seed surface area does not affect the rate of SOA growth within the range of AS seed  
443 surface area concentration used in this study. This observation differs from findings by  
444 Pathak et al. (2007b) for the  $\text{O}_3 + \alpha$ -pinene system, who showed that even though the final  
445 SOA mass yields measured in the reaction of 7.3 ppb  $\alpha$ -pinene with 1500 ppb  $\text{O}_3$  were  
446 similar in their seeded and unseeded experiments, SOA growth was considerably slower  
447 in unseeded experiments compared to seeded experiments. The authors suggested that the  
448 slow SOA formation rate in their unseeded experiment was the result of SOA formation  
449 being limited by the mass transfer of semi-volatile oxidation products to newly formed  
450 particles (via nucleation) during the early stages of the experiment. These newly formed  
451 particles have a significantly smaller aerosol surface area for gas-particle partitioning as  
452 compared to that of seed aerosol particles in the seeded experiments. Consequently, the  
453 semi-volatile oxidation products accumulated in the gas phase during the early stages of  
454 the unseeded experiments, resulting in slower SOA growth compared to the seeded  
455 experiments. The observation that the presence of seed aerosol does not influence the

456 SOA growth rate in the present study may be explained by the relatively high  
457 concentrations of  $\alpha$ -pinene reacted and SOA mass loadings obtained. Previous studies  
458 have shown that the delay between the onset of VOC oxidation and SOA formation in  
459 unseeded experiments is most pronounced at low aerosol loadings (Kroll et al., 2007).  
460 We note that the concentrations of  $\alpha$ -pinene reacted and SOA mass loadings obtained in  
461 this study are significantly larger than those reported by Pathak et al. (2007b). Therefore,  
462 it is possible that due to the relatively large concentrations of  $\alpha$ -pinene reacted in this  
463 study, substantial concentrations of gas-phase oxidation products are generated, which  
464 results in rapid partitioning into the particle phase even in the absence of seed aerosol.  
465 This is evident from the large increase in the particle number concentration during the  
466 early stages of the unseeded 100 and 500 ppb O<sub>3</sub> experiments, where the particle number  
467 concentration increased to ~8000 and ~10000 particles/cm<sup>3</sup> during the first 45 min of the  
468 100 and 500 ppb O<sub>3</sub> experiments, respectively (Fig. S1a and S2a). Thus, the SOA growth  
469 rates are not controlled by the presence of AS seed in this study.

470 Figure 4 shows that for both initial O<sub>3</sub> mixing ratios used, the time-dependent  
471 SOA mass yield is similar at any given AS seed surface area (see also Table 1). The  
472 absence of a SOA growth dependence on the AS seed surface area is similar to  
473 observations reported by McVay et al. (2016) for the  $\alpha$ -pinene photooxidation (OH-  
474 driven chemistry) system, but differ from those reported by Zhang et al. (2014) for the  
475 toluene photooxidation system in which the SOA mass yield increased with the surface  
476 area concentration of seed aerosol.

477 The best-fit  $\alpha_p = 1$  (Fig. S8) suggests the absence of significant limitations to  
478 vapor-particle mass transfer in the present  $\alpha$ -pinene ozonolysis study, and that SOA  
479 formation is governed by quasi-equilibrium growth (McVay et al., 2014), which occurs  
480 when SOA-forming vapors are produced at a rate that is significantly slower than that  
481 required to establish gas-particle equilibrium (Shiraiwa and Seinfeld, 2012; Zhang et al.,  
482 2012). Moreover, the characteristic timescale to establish gas-particle equilibrium is less  
483 than those for reaction and vapor-wall deposition. When the vapor and particle phases  
484 maintain equilibrium, gas-particle equilibrium is controlled by the amount of organic  
485 matter in the VOC system. As a result, the rate of condensation of SOA-forming vapors

486 is independent of the seed aerosol surface area (McVay et al., 2014). The best-fit  $\alpha_p = 1$   
487 within the approximate range of  $\alpha_p$  coefficients determined from  $\alpha$ -pinene ozonolysis  
488 SOA thermogravimetric studies ( $\alpha_p = 0.1$ ) (Saleh et al., 2013) and  $\alpha$ -pinene photooxidation  
489 chamber studies ( $\alpha_p = 0.1$  or 1) (McVay et al., 2016). Notably, this result differs markedly  
490 from that for toluene photooxidation (Zhang et al., 2014), where  $\alpha_p$  was determined to be  
491 0.001, and for which, since the SOA mass yield was strongly dependent on the seed  
492 aerosol surface area, the condensation of SOA-forming vapors onto seed aerosol particles  
493 was kinetically limited (McVay et al., 2014). Kinetically-limited SOA growth occurs  
494 when the timescale for gas-particle equilibrium is competitive with or exceeds the  
495 timescale for reaction and vapor wall deposition, and may reflect imperfect  
496 accommodation of gas-phase organics to the particle phase. The markedly different  
497 behavior of the  $\alpha$ -pinene and toluene SOA systems could be due to differences in SOA  
498 volatility and aerosol physical phase state (McVay et al., 2016).

## 499 5.2 Oxidation rate effect

500 At higher  $O_3$  concentrations, the  $\alpha$ -pinene oxidation rate increases, leading to  
501 higher SOA mass yields (the “oxidation rate effect”). This behavior was previously  
502 observed by Ng et al. (2007) for the *m*-xylene photooxidation system, for which the  
503 oxidation rate effect was attributed to the loss of semi-volatile condensable products to  
504 chamber walls in competition with condensation onto seed particles to form SOA.

505 SOA formation from  $\alpha$ -pinene ozonolysis is presumed to be driven by a range of  
506 semi- and low-volatility first-generation products arising from reaction of  $O_3$  with the  
507 single C=C double bond (Ng et al., 2006). These products are subject to two competing  
508 routes: condensation to particles to form SOA or deposition on the chamber walls. Each  
509 process can be represented in terms of a first-order rate constant:  $k_{wall,on}$  and  $k_{particle,on}$  ( $s^{-1}$ ).  
510 The rate of vapor-wall deposition of condensable species A is then  $k_{wall,on} \times [A]$  (molec  
511  $cm^{-3} s^{-1}$ ) and the rate of condensation onto particles is  $k_{particle,on} \times [A]$  (molec  $cm^{-3} s^{-1}$ ).  
512 Increasing the rate of reaction increases the concentration of [A], but the relative rates of  
513 vapor-wall deposition and condensation onto particles will remain the same. In general,  
514 however, both vapor-wall deposition and vapor-particle condensation are reversible

515 processes (McVay et al., 2014; Zhang et al., 2014). The first-order rate constant for  
516 evaporation from the wall can be represented as (Matsunaga and Ziemann, 2010):

$$517 \quad k_{wall,off} = k_{wall,on} \left( \frac{C_i^*}{C_w} \right) \quad (13)$$

518 where  $C_i^*$  is the saturation concentration and  $C_w$  is the assumed equivalent wall organic  
519 concentration. The rate of evaporation from particles is:

$$520 \quad k_{particle,off} = k_{particle,on} \left( \frac{C_i^*}{C_{aer}} \right) \quad (14)$$

521 where  $C_{aer}$  is the organic aerosol concentration ( $C_{aer} = \sum A_k + M_{init}$ ).

522 The difference between  $C_{aer}$  and  $C_w$  is the key to explaining the oxidation rate  
523 effect. At the beginning of the experiment,  $C_{aer}$  is very small because the inorganic seeds  
524 are essentially non-absorbing. Therefore,  $k_{particle,off}$  is large, and the net SOA growth is  
525 small. In contrast,  $C_w$  is considered to be substantial (on the order of  $10 \text{ mg m}^{-3}$ ) and to be  
526 essentially constant throughout the experiment (Matsunaga and Ziemann, 2010; McVay  
527 et al., 2014; Zhang et al., 2014). Model predictions are insensitive to the value of  $C_w$   
528 since, in any event,  $C_w$  is significantly larger than  $C_{aer}$  (Zhang et al., 2014). Therefore,  
529  $k_{wall,off}$  is small at the beginning of the experiment and the net vapor wall loss rate is fast.  
530 As  $C_{aer}$  increases, the net SOA condensation rate increases relative to the net vapor wall  
531 loss rate. When the reaction rate increases corresponding to higher  $\text{O}_3$  concentrations,  $C_{aer}$   
532 grows more quickly because more condensable species are available to form SOA, and  
533 the net condensation rate increases more rapidly. Therefore, the observed oxidation rate  
534 effect is due to vapor wall deposition, and arises because vapor-particle and vapor-wall  
535 condensation are essentially reversible processes. This explanation is consistent with  
536 simulations varying the  $\text{O}_3$  concentration in which all species are non-volatile (i.e., do not  
537 evaporate from the particles or the wall). In this case, no oxidation rate effect is observed  
538 as the  $\text{O}_3$  concentration increases. The growth curves for different  $\text{O}_3$  concentrations  
539 overlap, and the same yield is obtained regardless of  $\text{O}_3$  concentration (Fig. S11).

540           Sensitivity tests were performed to determine the point at which SOA formation is  
541 no longer influenced by the O<sub>3</sub> concentration. In these simulations, the initial  $\alpha$ -pinene  
542 concentration is fixed at 48 ppb, while the O<sub>3</sub> concentration is varied from 75 to 1000  
543 ppb. The rate of O<sub>3</sub> injection is assumed to remain constant as the O<sub>3</sub> concentration is  
544 increased to mimic the experimental protocol (i.e., O<sub>3</sub> injection time is increased to  
545 achieve higher O<sub>3</sub> concentrations). The O<sub>3</sub> injection rate used in these simulations is fixed  
546 at 500/54.25 ppb min<sup>-1</sup>, which is the same as that used to analyze results from the 500  
547 ppb O<sub>3</sub> experiments. Model predictions in Fig. S12 show that the maximum SOA mass  
548 concentration increases with increasing O<sub>3</sub> concentration up to approximately 500 ppb  
549 O<sub>3</sub>. Beyond this O<sub>3</sub> concentration, the SOA growth curves overlap and the maximum  
550 SOA mass concentration does not increase even when more O<sub>3</sub> is added. This plateau  
551 arises due to the lengthening time required to inject increasing amounts of O<sub>3</sub>. More than  
552 1 h is required to inject > 500 ppb of O<sub>3</sub>, and by this time, virtually all of the  $\alpha$ -pinene has  
553 reacted. Increasing the O<sub>3</sub> concentration after all of the  $\alpha$ -pinene has reacted does not lead  
554 to any changes in the SOA mass concentration. However, if a faster injection rate of O<sub>3</sub> is  
555 used, the oxidation rate effect will persist to higher O<sub>3</sub> concentrations (i.e., > 500 ppb O<sub>3</sub>)  
556 (Fig S13). With a faster injection rate, 500 ppb O<sub>3</sub> is injected before all of the  $\alpha$ -pinene  
557 has reacted. Continuing to inject O<sub>3</sub> to a higher concentration (i.e., 750 ppb) will cause  $\alpha$ -  
558 pinene to decay faster and SOA to grow faster than when the O<sub>3</sub> injection stops at 500  
559 ppb. The oxidation rate effect is then apparent at higher O<sub>3</sub> concentrations. If, instead of  
560 using an injection rate of O<sub>3</sub>, simulations are run using fixed initial O<sub>3</sub> (not possible  
561 experimentally), the rate effect persists to even higher O<sub>3</sub> concentrations. The relative  
562 increase in yield with increasing O<sub>3</sub> concentrations slows at very high O<sub>3</sub> concentrations  
563 because the rate of reaction becomes substantially faster than the vapor wall deposition  
564 rate, and there is less marginal effect to increasing the reaction rate.

### 565 **5.3 Interplay of the seed aerosol surface area effect and the oxidation rate effect**

566           In this study, we observe an oxidation rate effect but not a seed aerosol surface  
567 area effect. In Zhang et al. (2014), a seed aerosol surface area effect was observed, but  
568 the variation of the oxidation rate was not studied. A key aspect of vapor wall deposition  
569 is the potential interplay between the seed aerosol surface area effect and the oxidation

570 rate effect. To examine this interplay in the  $\alpha$ -pinene ozonolysis system, simulations were  
571 carried out by varying the seed aerosol surface area and the  $O_3$  concentration  
572 simultaneously, while using the branching ratios, oligomerization rate, and vapor wall  
573 deposition rate parameters obtained in the present study. The initial  $\alpha$ -pinene  
574 concentration was set to 50 ppb, and a fixed  $O_3$  concentration was used in place of a  
575 linear injection.  $\alpha_p$  was varied at 0.001, 0.01, and 1 in these simulations. Figure 6 shows  
576 the SOA mass yield at peak SOA growth as a function of both the seed aerosol surface  
577 area and  $O_3$  concentration for  $\alpha_p = 1$ , 0.01, and 0.001. For  $\alpha_p = 1$ , the oxidation rate  
578 dominates: SOA mass yield increases significantly as  $O_3$  concentration increases while  
579 the seed aerosol surface area has a negligible effect. For  $\alpha_p = 0.01$ , both effects can be  
580 observed in different regions: at low  $O_3$  concentrations and high seed aerosol surface  
581 areas, the oxidation rate effect dominates; at low seed aerosol surface areas and high  $O_3$   
582 concentrations, the seed surface area dominates. At low seed aerosol surface areas and  
583 low  $O_3$  concentrations, both effects are present. For  $\alpha_p = 0.001$ , the seed aerosol surface  
584 area effect dominates except at very high seed aerosol surface areas. These observations  
585 show that the presence of an oxidation rate effect and/or seed aerosol surface area effect  
586 depends on a complex interplay of factors, such as  $\alpha_p$ , the rate of hydrocarbon oxidation,  
587 and the amount of seed surface area present.

## 588 6. Implications

589 In this study, we systematically examine the roles of gas-particle partitioning and  
590 VOC oxidation rate in the presence of vapor-wall deposition in  $\alpha$ -pinene ozonolysis. We  
591 show that despite the presence of vapor-wall deposition, SOA mass yields at peak SOA  
592 growth remain approximately constant regardless the seed aerosol surface area (within  
593 the range of AS seed surface area concentration used in this study). This observation is  
594 consistent with SOA formation in the  $\alpha$ -pinene ozonolysis system being governed by  
595 quasi-equilibrium growth, for which there are no substantial limitations to vapor-particle  
596 mass transfer. This result was demonstrated in a previous modeling study which showed  
597 that increasing the seed-to-chamber surface area ratio will lead to increased SOA growth  
598 only in cases in which the condensation of SOA-forming vapors onto seed aerosol

599 particles is kinetically limited as a result of imperfect accommodation of gas-phase  
600 organics to the particle phase (McVay et al., 2014).

601 An important implication of this study is that diverting vapor-wall deposition in  
602 chamber studies via the addition of ever-increasing quantities of seed aerosol particles is  
603 not effective in VOC systems for which SOA formation is governed by quasi-equilibrium  
604 growth. This study also underscores the importance of accounting for particle wall  
605 deposition appropriately in chamber studies, to avoid erroneous conclusions regarding the  
606 role of gas-particle partitioning (quasi-equilibrium vs. kinetically-limited SOA growth) in  
607 influencing vapor wall loss in the VOC system.

608 We note that the present study shows that the SOA mass yield is independent of  
609 seed aerosol surface area concentration for values ranging from 0 to  $\sim 3000 \mu\text{m}^2 \text{cm}^{-3}$ .  
610 This corresponds to a seed-to-chamber surface area ratio of 0 to  $\sim 1 \times 10^{-3}$ , which is  
611 substantially smaller than the range used by Zhang et al. (2014) to study the influence of  
612 vapor-wall deposition on toluene photooxidation SOA formation in the Caltech chamber  
613 (i.e., 0 to  $\sim 5 \times 10^{-3}$ ). It is possible that a SOA mass yield dependence on the seed surface  
614 area may have become more apparent had a larger range of seed aerosol surface area (i.e.,  
615  $> 3000 \mu\text{m}^2 \text{cm}^{-3}$ ), and hence a larger range of seed-to-chamber surface area ratio, been  
616 used here. One consideration is that coagulation may become increasingly important, and  
617 will need to be accounted for, when higher seed aerosol number concentrations (relative  
618 to those used in this study) are used (Seinfeld and Pandis, 2006; Pierce et al., 2008). A  
619 detailed analysis of the effect of seed aerosol surface area concentrations  $> 3000 \mu\text{m}^2 \text{cm}^{-3}$   
620 on  $\alpha$ -pinene ozonolysis SOA mass yields will be the subject of forthcoming work.

621 Higher SOA mass yields at peak SOA growth are observed in the present study  
622 when  $\text{O}_3$  is increased from 100 to 500 ppb. This is because  $\alpha$ -pinene is oxidized more  
623 quickly, which leads to gas-phase oxidation products being formed more rapidly, and  
624 consequently partitioning more quickly onto AS seed aerosol particles before they are  
625 lost to the chamber walls. Therefore, the oxidation rate effect (i.e., higher SOA mass  
626 yields as a result of faster hydrocarbon oxidation rates) is a consequence of vapor-wall  
627 deposition. An important implication of this study is that SOA mass yields can be  
628 affected by vapor-wall deposition in VOC systems that are not characterized by slow

629 mass accommodation of gas-phase organics to the particle phase (Zhang et al., 2014).  
630 Thus, this work demonstrates that the effect of vapor-wall deposition on SOA mass yields  
631 can be mitigated through the use of excess oxidant concentrations. It should be noted that  
632 the  $\alpha$ -pinene ozonolysis SOA mass yields (absolute values) increased by 5 to 9 % when  
633  $O_3$  is increased from 100 to 500 ppb (for an initial  $\alpha$ -pinene concentration of  $\sim 50$  ppb),  
634 where SOA formation is governed by quasi-equilibrium growth. In the absence of vapor-  
635 wall deposition, SOA mass yields are predicted by the model used here to approximately  
636 double from those observed experimentally. In contrast, Zhang et al. (2014) showed that  
637 the presence of vapor-wall deposition led to underestimation of SOA formation by factors  
638 as much as four in the toluene photooxidation system, where the condensation of SOA-  
639 forming vapors onto seed aerosol is kinetically limited. Taken together, these results  
640 indicate that the magnitude by which vapor-wall deposition affects SOA mass yields  
641 depends on the extent to which the VOC system is governed by kinetically-limited SOA  
642 condensational growth.

643 Given these observations of how gas-particle partitioning can influence the  
644 magnitude by which vapor-wall deposition affects SOA mass yields, an overriding  
645 question is: what controls the gas-particle partitioning behavior of SOA formed in  
646 different VOC systems?  $\alpha_p$  describes the overall mass transfer of vapor molecules into the  
647 particle phase (McVay et al., 2014; Zhang et al., 2014). Thus,  $\alpha_p$  affects the vapor-  
648 particle equilibrium timescale, which, depending on the extent to which it is competitive  
649 with the timescales for reaction and vapor-wall deposition, determines whether SOA  
650 formation is governed by kinetically-limited or quasi-equilibrium growth. Markedly  
651 different  $\alpha_p$  values could arise from the physical phase state of the SOA formed. As  
652 discussed by McVay et al. (2014, 2016), if the SOA formed exists in a semi-solid state  
653 (Vaden et al., 2010; Virtanen et al., 2010; Cappa and Wilson, 2011; Vaden et al., 2011;  
654 Virtanen et al., 2011; Kuwata and Martin, 2012; Perraud et al., 2012; Saukko et al., 2012;  
655 Abramson et al., 2013; Renbaum-Wolff et al., 2013), a low value of  $\alpha_p$  might be expected  
656 owing to retarded surface accommodation and particle-phase diffusion (Zaveri et al.,  
657 2014). Quantification of  $\alpha_p$  is challenging experimentally, and reported  $\alpha_p$  values for the  
658 same system can vary by several orders of magnitude (Grieshop et al., 2007; Stanier et  
659 al., 2007; Vaden et al., 2011; Miles et al., 2012; Saleh et al., 2013). Therefore,  $\alpha_p$  of SOA

660 formed in different VOC systems need to be better constrained through a combination of  
661 experimental and modeling efforts.

662         The SOA mass yield from the ozonolysis of monoterpenes in the GEOS-CHEM  
663 chemical transport model (19 % at  $10 \mu\text{g m}^{-3}$ ) is currently based on that measured in  $\alpha$ -  
664 pinene ozonolysis studies by Shilling et al. (2008) (Pye et al., 2010). Shilling et al. (2008)  
665 measured these SOA mass yields in a teflon chamber operated in continuous-flow mode,  
666 as opposed to batch mode, which is how experiments in the present study and most of  
667 those shown in Fig. 5 and Table S2 were conducted. While it is not possible to directly  
668 compare our results with those of Shilling et al. (2008) due to differences in SOA mass  
669 concentrations, the SOA mass concentrations and yields measured in the current study  
670 are generally consistent with those of previous batch chamber studies. The SOA mass  
671 yields at  $\sim 10 \mu\text{g m}^{-3}$  SOA mass concentration measured by Shilling et al. (2008) are  
672 generally higher than those measured in chambers operated in batch mode (Griffin et al.,  
673 1999; Cocker et al., 2001b; Presto et al., 2005; Presto and Donahue, 2006; Pathak et al.,  
674 2007b) (Fig. 5). One possible explanation for the higher SOA mass yields in the  
675 continuous-flow, steady state, mode is that the SOA-forming vapors are in equilibrium  
676 with the organic mass present on the chamber walls and seed aerosol, hence minimizing  
677 the irreversible loss of SOA-forming vapors to the chamber walls (Shilling et al., 2008).  
678 However, the extent to which SOA mass yields obtained in a continuous-flow reactor are  
679 influenced by vapor wall loss is unclear. Using a continuous-flow reactor, Ehn et al.  
680 (2014) observed  $\alpha$ -pinene ozonolysis SOA mass yields to increase with increasing seed  
681 aerosol surface area but required  $\alpha_p = 1$  to fit the observed SOA growth. The observed  
682 vapor-wall deposition rate constant in their continuous-flow reactor ( $0.011 \text{ s}^{-1}$ ) is two  
683 orders of magnitude larger than that of the GTEC chamber ( $10^{-4} \text{ s}^{-1}$ ). The estimated  
684 timescales for gas-particle and gas-wall partitioning are also approximately equal in their  
685 continuous-flow reactor. This indicates that SOA condensational growth is kinetically  
686 limited in their continuous-flow reactor even at  $\alpha_p = 1$  (Ehn et al., 2014; McVay et al.,  
687 2014), which suggests that SOA mass yields measured in their continuous-flow reactor  
688 may be significantly affected by vapor-wall deposition.

689 Previous studies on SOA formation from the OH and NO<sub>3</sub> oxidation of biogenic  
690 VOCs have similarly reported higher SOA mass yields in the presence of higher oxidant  
691 concentrations. For example, in the NO<sub>3</sub> oxidation of β-pinene, Boyd et al. (2015)  
692 reported SOA mass yields 10 to 30 % higher than those previously reported by Fry et al.  
693 (2009, 2014). In addition to differences in the experimental conditions of the two studies,  
694 Boyd et al. (2015) hypothesized that the higher SOA mass yields could also be a result of  
695 the higher NO<sub>3</sub> concentrations used in their study (which led to faster β-pinene oxidation  
696 rates) compared to those used by Fry et al. (2009, 2014). The oxidation rate effect was  
697 also observed in the *m*-xylene photooxidation system, where Ng et al. (2007) showed that  
698 the SOA mass yields were dependent on the *m*-xylene oxidation rate, with higher OH  
699 concentrations (and hence faster oxidation rates) resulting in higher SOA mass yields  
700 Together, these studies show that faster hydrocarbon oxidation rates can alleviate the  
701 effects of vapor-wall deposition on SOA mass yields in different VOC systems.

702 This gives rise to the question: should chamber SOA experiments on different  
703 VOC systems be performed under as rapid oxidation conditions as possible (i.e., large  
704 oxidant concentrations) to reduce the effects of vapor-wall deposition? A recent study by  
705 McVay et al. (2016) reported similar SOA growth under low and high OH levels for α-  
706 pinene photooxidation. The authors hypothesized that the autoxidation mechanism likely  
707 becomes a more important pathway at low OH levels (Crouse et al., 2013), and thus  
708 contributes substantially to SOA growth. Therefore, it is possible that certain reaction  
709 pathways and mechanisms (which are important in the atmosphere) are biased when  
710 unusually high levels of oxidants are used in chamber experiments (e.g. autoxidation).  
711 Thus, this underscores the need to design chamber experiments that simultaneously  
712 mitigate the magnitude of vapor-wall deposition while ensuring that reaction conditions,  
713 and consequently reaction pathways and oxidation products, are atmospherically relevant.

Experiment	Initial Seed Surface Area ( $\mu\text{m}^2 \text{cm}^{-3}$ )	Initial [ $\alpha$ -pinene] <sup>a</sup> ( $\mu\text{g m}^{-3}$ )	$\Delta M_0$ <sup>b</sup> ( $\mu\text{g m}^{-3}$ )	SOA Mass Yield <sup>c</sup> (%)
100 ppb O <sub>3</sub> nucleation	0	290.2±23.2	62.0±1.2 <sup>d</sup>	22.6±1.9
100 ppb O <sub>3</sub> low AS	1130	280.5±22.4	63.0±0.8 <sup>d</sup>	23.3±1.9
100 ppb O <sub>3</sub> high AS	2700	238.7±19.1	50.6±1.6 <sup>d</sup>	23.3±1.9
500 ppb O <sub>3</sub> nucleation	0	274.4±21.9	87.3±0.3 <sup>e</sup>	31.8±2.5
500 ppb O <sub>3</sub> low AS	1300	264.9±21.2	75.7±0.6 <sup>e</sup>	28.6±2.3
500 ppb O <sub>3</sub> high AS	2720	236.1±18.9	66.3±1.9 <sup>e</sup>	28.1±2.4

 1039 <sup>a</sup>Concentration of  $\alpha$ -pinene injected into the chamber. All the  $\alpha$ -pinene reacted in the 500  
 1040 ppb O<sub>3</sub> experiments, but not the 100 ppb O<sub>3</sub> experiments.

 1041 <sup>b</sup>Uncertainties in the peak SOA mass concentration ( $\Delta M_0$ ) are calculated from one  
 1042 standard deviation of the aerosol volume as measured by the scanning mobility particle  
 1043 sizer.

 1044 <sup>c</sup>SOA mass yields at peak SOA growth are reported.

 1045 <sup>d</sup>The SOA mass concentration is calculated using the density = 1.39 g cm<sup>-3</sup> obtained from  
 1046 the 100 ppb O<sub>3</sub> nucleation experiment.

 1047 <sup>e</sup>The SOA mass concentration is calculated using the density = 1.37 g cm<sup>-3</sup> obtained from  
 1048 the 500 ppb O<sub>3</sub> nucleation experiment.

1061 **Table 2:** Coupled vapor-particle dynamics model parameters

Parameter	Definition	Value
$\alpha_p$	Vapor-particle mass accommodation coefficient	1
$\alpha_w$	Vapor-wall mass accommodation coefficient	$10^{-6}$
$\tau_{olig}$	Timescale of oligomerization	4 h
$C^*$	Saturation vapor pressures and branching ratios of oxidation products	[0.57 ( $>10^3$ ), 0.35 ( $10^2$ ), 0.04 (10), 0.015 (1) and 0.025 (0.1)]
$D_i$	Gas-phase molecular diffusivity	$3 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$
$A/V$	Surface area-to-volume ratio of the chamber	$2.5 \text{ m}^{-1}$
$C_w$	Equivalent organic mass concentration in the wall	$10 \text{ mg m}^{-3}$
$k_e$	Eddy diffusion coefficient	$0.03 \text{ s}^{-1}$
$M_i$	Molecular weight of the diffusing gas-phase molecule $i$	168, 184, 192, 200 and $216 \text{ g mole}^{-1}$
$M_{init}$	Initially absorbing organic material in seed aerosol	$0.01 \text{ } \mu\text{g m}^{-3}$
$P$	Pressure	$1 \times 10^5 \text{ Pa}$
$T$	Temperature	298 K
$\rho_{seed}$	Density of inorganic seed	$1700 \text{ kg m}^{-3}$
$\rho_{org}$	Density of organic material on seed particle	$1300 \text{ kg m}^{-3}$

1070 **Figure 1:** Particle wall deposition coefficients ( $\beta_i$ ) measured during the low AS-seed  
1071 only and high AS-seed only experiments in GTEC. Also shown are the particle wall  
1072 deposition coefficients (labeled “Other”) measured in previous routine monthly AS-seed  
1073 only experiments in the chamber. These previous routine monthly AS-seed only  
1074 experiments were performed using either a 0.008 M AS or a 0.1 M AS solution.

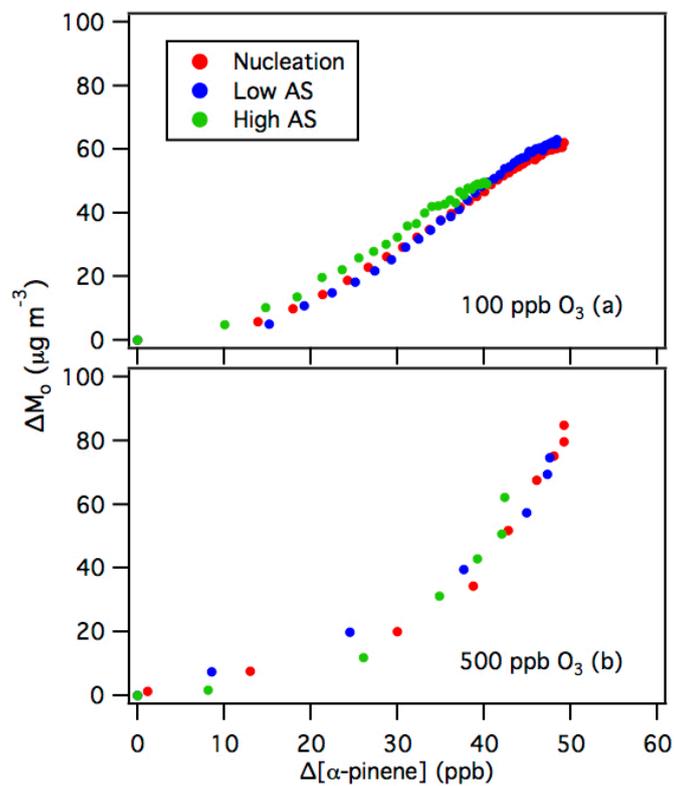

1075

1076

1077 **Figure 2:** Reaction profiles of the  $\alpha$ -pinene ozonolysis experiments. Panels (a), (b) and  
1078 (c) show results from the nucleation, low AS and high AS 100 ppb  $O_3$  experiments,  
1079 respectively. Panels (d), (e) and (f) show results from the nucleation, low AS and high AS  
1080 500 ppb  $O_3$  experiments, respectively. As explained in the main text, the SOA mass  
1081 concentrations ( $\Delta M_o$ ) for the nucleation and low AS experiments are obtained using the  
1082 particle wall rates obtained from the low AS-seed only experiments, while the SOA mass  
1083 concentrations ( $\Delta M_o$ ) for the high AS-seed experiments are obtained using the particle  
1084 wall rates obtained from the high AS-seed only experiments.

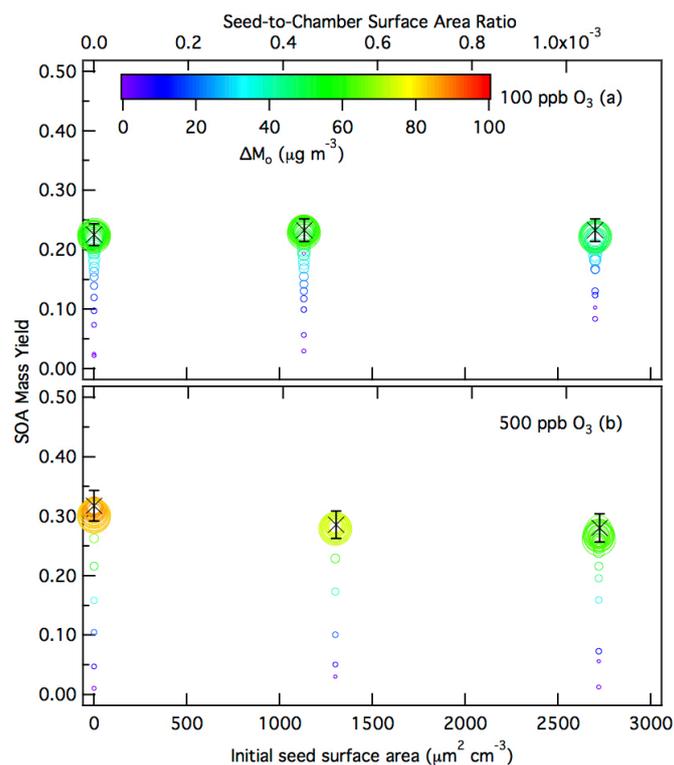

1085

1086

1087 **Figure 3:** Time-dependent SOA growth curves for  $\alpha$ -pinene ozonolysis. Panels (a) and  
1088 (b) show 10 min-averaged results from the 100 ppb and 500 ppb O<sub>3</sub> experiments,  
1089 respectively. Only SOA growth data up to the point of SOA peak growth are shown.

1090

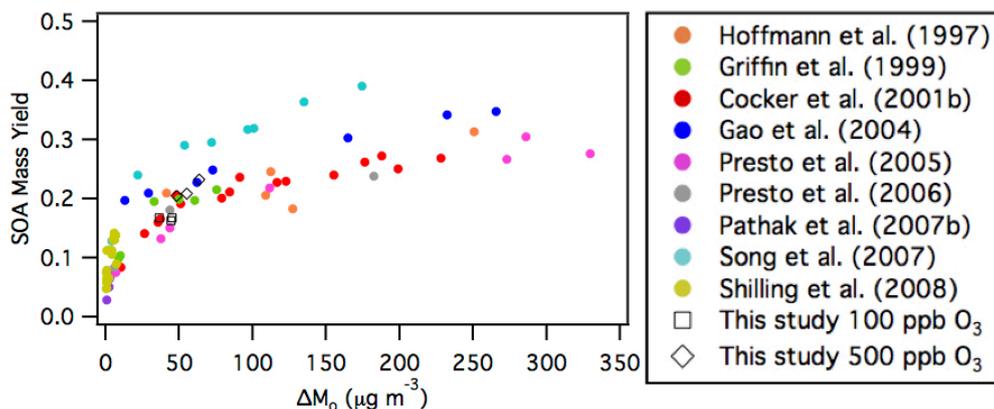

1091

1092 **Figure 4:** 10 min-averaged SOA mass yields over the course of an  $\alpha$ -pinene ozonolysis  
1093 experiment as a function of initial total AS seed surface area concentration for the (a) 100  
1094 ppb  $\text{O}_3$  experiments, and (b) 500 ppb  $\text{O}_3$  experiments. Symbol color indicates the SOA  
1095 mass concentration and symbol size indicates the time after  $\text{O}_3$  is injected into the  
1096 chamber. The  $\times$  symbols are the SOA mass yields at peak SOA growth obtained from  
1097 the experimental data. The y-axis error bars represent the uncertainty in the SOA mass  
1098 yield at peak SOA growth, which originates from the  $\alpha$ -pinene injection and the aerosol  
1099 volume concentration measured by the SMPS at peak SOA growth (one standard  
1100 deviation).

1101

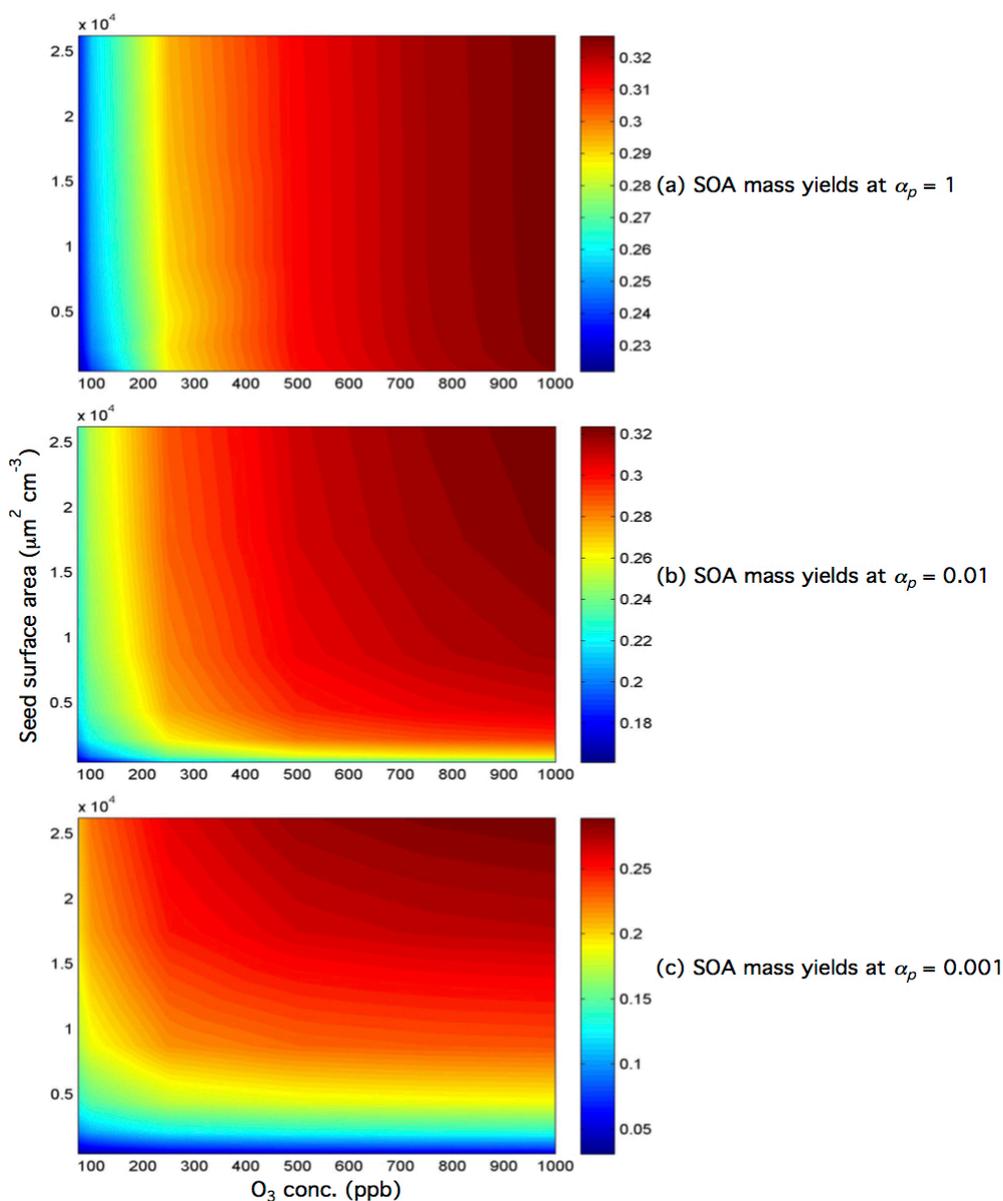

1102

1103

1104 **Figure 5:** Comparison of SOA mass yields obtained in this study to those of previous  
1105 dark  $\alpha$ -pinene ozonolysis studies (Table S2). The SOA mass yields and concentrations of  
1106 majority of these previous studies (Hoffmann et al., 1997; Griffin et al., 1999; Cocker et  
1107 al., 2001b; Gao et al., 2004; Presto et al., 2005; Presto et al. 2006; Pathak et al., 2007b;  
1108 Song et al., 2007) were previously compiled by Shilling et al (2008). Similar to Shilling  
1109 et al. (2008), all the data shown here (including those reported in this study) have been  
1110 adjusted using an organic density of  $1.0 \text{ g cm}^{-3}$ , and to 298 K using a temperature  
1111 correction of 1.6 % per K, as recommended by Pathak et al. (2007b) to facilitate easier  
1112 comparison among the different studies.

1113

1114 **Figure 6:** SOA mass yields at peak SOA growth as a function of both the seed surface  
1115 area and  $\text{O}_3$  concentration for  $\alpha_p = 1$ , 0.01, and 0.001. The SOA mass yields at peak SOA  
1116 growth are indicated by colors and contours. Note that the color bars for panels (a), (b)  
1117 and (c) have different SOA mass yield ranges. Simulations were carried out using the  
1118 branching ratios, oligomerization rate, and vapor wall deposition rate parameters obtained  
1119 in this study. The initial  $\alpha$ -pinene concentration was set to 50 ppb, and a fixed  $\text{O}_3$   
1120 concentration was used in place of a linear injection.
