15 **1 DOAS analysis and data screening**

In the DOAS analysis, the slant column densities (SCDs) of the trace gases (TGs) are retrieved from the off-axis spectra using a zenith measurement from the same elevation sequence as the Fraunhofer reference spectrum (FRS). As the latter also contains (usually small) absorptions features, the resulting SCD actually represents the differences between the SCDs of the measured spectrum and the FRS. This difference is usually referred to as the differential SCD (dSCD). The use of a FRS from the same elevation sequence can minimise any effects caused by changes of the properties of the instrument (relevant for long term analyses) and the stratospheric absorptions (relevant for measurements at high solar zenith angle (SZA)). The effect of rotational Raman scattering is considered by including a Ring spectrum (Shefov 1959; Grainger and Ring, 1962; Chance and Spurr, 1997; Solomon et al., 1987; Wagner et al., 2009) computed by the DOASIS software (Kraus, 2006, using a routine from Bussemer 1993). To account for the different wavelength dependencies of the filling-in in clear and cloudy 20 skies, an additional Ring spectrum as described in Wagner et al. (2009) is also included.

For the retrieval of O₄ and NO₂, the wavelength range of 351 to 390 nm is selected, covering two O₄ absorption bands and several NO₂ absorption bands. A 3rd order polynomial is used. Besides the NO₂ cross section at the temperature of 294 K, another cross section at 220 K is also included in the fit to account for the temperature dependence of the NO₂ absorptions. The detailed DOAS settings for the retrieval are listed in Table 1 of the main manuscript. In Fig. S1a and b, the O₄ and NO₂ dSCDs from all measurements are plotted against SZA. NO₂ and O₄ dSCDs show an obvious systematic increase or decrease, 30 respectively, for SZA larger than 75°. For NO₂ this behaviour can be explained by the larger differences of the stratospheric light paths between the measurement and the FRS for large SZA. The opposite dependencies in the morning and evening

(indicated by the different solar azimuth angles) are due to the decrease or increase of the stratospheric light path with time in the morning and evening, respectively. The O_4 behaviour might be related to the interference of the so called intensity offset (see below) and the O_4 absorption. But this hypothesis is still not clearly confirmed.

5 A quite large relative intensity offset (RIO) is found for measurements at large SZAs as indicated in Fig. S1c, which implies a possible interference of the offset corrections and the derived TG dSCDs (see also Coburn et al., 2011). Thus we skip the data for the SZA larger than 75° to avoid the interference with the stratospheric contributions and RIO on the retrieved tropospheric dSCDs.

10 SO_2 dSCDs are retrieved in the wavelength interval from 307.8 nm to 330 nm including O_3 , SO_2 , HCHO cross sections and Ring spectra shown in Table 1 of the main manuscript. Wang et. al (2014) performed sensitivity studies to find the optimum wavelength interval which minimizes both random and systematic uncertainties on the SO_2 retrieval. They found that the wavelength range of 305 to 317.8 nm provides the lowest fitting errors. Below 305 nm, interference with the strong ozone absorption can affect the SO_2 retrieval. At small wavelengths also the signal to noise ratio decreases. Considering the rather low sensitivity of the miniature spectrometer in the UV range used in our study compared to scientific grade spectrometer used in the study of Wang et. al (2014), here we limit the lower wavelength range to 307.8 nm. We also changed the upper wavelength range to 330 nm to minimise the possible interference with other species. The SO_2 , O_3 and Ring dSCDs as well as the intensity offset are plotted against SZAs in Fig. S2. At large SZAs strong changes of all quantities are found indicating the possible interference of the stratospheric ozone absorptions and the intensity offset on the SO_2 retrieval. To avoid these interferences, we screen the SO_2 dSCD data for SZA larger than 75° .

20 HCHO dSCDs are retrieved in the wavelength interval from 324.6 to 359 nm including O_3 , O_4 , SO_2 , HCHO cross sections and Ring spectra shown in Table 1 of the main manuscript. Pinardi et. al (2013) found that the interferences between BrO, Ring spectrum and HCHO can strongly affect the retrieved HCHO dSCDs and they recommended the wavelength range of 336.5 to 359 nm, to minimise the uncertainties of the HCHO retrieval. In the wavelength range below 336.5 nm, the ozone absorption interferes with the HCHO retrieval, like for SO_2 . However this conclusion is only appropriate for the retrieval with the daily noon zenith spectrum as the FRS. In this study, the sequential FRS is used. Because BrO is mostly located in the stratosphere, the difference of the BrO absorptions between the measurement and the FRS is negligible (the differential optical depth of the BrO absorption is typical only 1×10^{-4}) and much lower than using a daily noon FRS (typical 6×10^{-4}). Considering that the BrO absorption signal is too weak to impact the HCHO retrieval, the BrO cross section is not included in the HCHO DOAS fit in this study. Tropospheric BrO is not expected to be found due to large NO_2 concentrations (e.g. Holla et al 2015). Moreover similar to the BrO interference, the effective stratospheric ozone absorption is also much smaller if a sequential FRS is used compared to a daily noon FRS. Thus the wavelength interval can be extended to a shorter wavelength to cover more and stronger absorption bands of HCHO. Moreover a wider wavelength range usually makes the fit more stable, but at shorter wavelengths the interference of the ozone absorption is also stronger. To find the optimal retrieval wavelength interval, the examples of the HCHO retrieval in three different wavelength ranges of 310 to 359 nm, 324.6 to 359 nm and 336.5 to 359 nm are shown in Fig. S3. The measured structure from the DOAS fit in the wavelength

range 310 to 359 nm indicates the strong interference of the ozone absorption. In addition, the HCHO dSCDs and the fitting errors in the three wavelength ranges on two days with low and high HCHO load are shown in Fig. S4. We find that the HCHO dSCDs in the wavelength range of 324.6 to 359 nm are consistent with those in 336.5 to 359 nm, which is recommended by Pinardi, et. al (2013). And both of them are quite different from the values in the wavelength range of 310 to 359 nm, especially on the day with the low HCHO load. The reverse “U” diurnal variation of the HCHO dSCDs in the wavelength range of 310 to 359 nm is an indication for the strong interference of the stratospheric ozone absorption. Moreover the wavelength range of 324.6 to 359 nm has much smaller fitting errors than the wavelength range of 336.5 to 359 nm. Thus we conclude that in general the wavelength range of 324.6 to 359 nm is the optimal wavelength range in which the ozone interference is weak and the fitting error is small. To avoid remaining interferences of the HCHO results with the stratospheric ozone absorption and intensity offset we exclude the HCHO dSCD for $SZA > 75^\circ$ (see. Fig. S5).

After applying these filters, the mean RMS of the residual is 6×10^{-4} for NO_2 , O_4 and HCHO, and 1.3×10^{-3} for SO_2 . The detection limit of the dSCDs (assumed to as two times of the mean RMS) is 3×10^{15} molecules cm^{-2} for NO_2 , 5×10^{41} molecules² cm^{-5} for O_4 , 5×10^{15} molecules cm^{-2} for SO_2 , 5×10^{15} molecules cm^{-2} for HCHO. Only 0.7%, 0.4%, 3.3%, 6.6% of the filtered measurements have results below the respective detection limits for NO_2 , O_4 , SO_2 and HCHO, respectively.

15 2 PriAM inversion algorithm

The profile inversion is based on the fact that the vertical distribution of the light paths depends on the elevation angle of the observation. The vertical trace gas profiles are assumed to be constant for the duration of the elevation angle sequence and also in horizontal dimensions. If the light paths are well-known, vertical trace gas profiles can be derived from a set of dSCDs for the different elevation angles. Besides the observation geometry and sun position, scattering on air molecules (Rayleigh scattering), aerosols and cloud particles (often referred to as Mie scattering) determine the atmospheric light paths. Opposed to the well-known Rayleigh scattering, scattering on aerosols and cloud particles depends on their respective optical properties, which are diverse and depend on a size, shape and composition. Vertical profiles of AEs can be retrieved from a set of O_4 dSCDs for individual elevation sequences using the well-known vertical profile of the O_4 concentration, which is proportional to the square of the concentration of molecular oxygen and thus only depends on temperature and pressure (Hönninger et al., 2004; Wagner et al., 2004; Frieß et al., 2006). Like for other algorithms, a two step inversion procedure is also used in the PriAM algorithm: in the first step the aerosol extinction (AE) profiles and in the second step the profiles of the trace gas VMRs are retrieved. In PriAM we applied the Levenberg-Marquardt modified Gauss-Newton procedure (Rodgers, 2000) to solve the ill-posed inversion problem for AEs (Frieß et al., 2006 and Yilmaz, 2012) through the numerical iteration:

$$30 \quad x_{i+1} = x_i + \left((1 + \gamma_i) S_a^{-1} + K_i^T S_\varepsilon^{-1} K_i \right)^{-1} \left(K_i^T S_\varepsilon^{-1} (y - F(x_i)) - S_a^{-1} (x_i - x_a) \right) \quad (\text{s1})$$

with x_{i+1} and x_i the solutions of atmospheric state at the i and $i+1$ step. x_a is the a-priori profile and y the measurement vector. γ_i is the Levenberg-Marquardt factor, which is multiplied or divided by two to make the minimization of the cost function faster and more stable than for the normal Gauss-Newton algorithm. S_a is the covariance of the error of the a-priori profile and S_ε is the covariance of the errors of the measurements. K_i and $F(x_i)$, which are calculated for each iteration step, are the weighting function and the forward model value at the state of x_i , respectively.

The set of O_4 dSCDs for the m non-zenith elevation angles in each scan (in this study 5° , 10° , 20° and 30°) is the measurement vector to retrieve the AE (σ) in n atmospheric layers. In this study 20 atmospheric layers from the surface to 4 km with height intervals of 0.2 km are used (the same layers are used for the retrievals of the trace gas profiles). Considering the frequent variation of aerosols, very little is known about the expected AE profile. Thus a fixed smoothed box-shaped a-priori AE profile (Boltzmann distribution) is used, as introduced by Yilmaz (2012):

$$\sigma(z) = \frac{\sigma(0)}{1 + \exp\left(\frac{z - \tau}{0.3}\right)} \quad (s2)$$

Here $\sigma(z)$ and $\sigma(0)$ denote the extinction coefficient at the altitude z (km) and at the surface, respectively. τ is the optical depth. In this study, $\sigma(0)$ and τ are 0.15 km^{-1} and 0.3, respectively. The covariance matrix S_a is constructed as follows:

$$S_{a_{ik}} = \sigma_{a_i}^2 \times e^{-\frac{|z_i - z_k|}{\eta}} \quad (s3)$$

With σ_{a_i} the a-priori AE at the atmospheric layer i . z_i and z_k are the heights of the atmospheric layer i and k , respectively. The smoothing factor η is 0.5 km. The covariance matrix of the measurement uncertainties S_ε contains diagonal elements representing the square of the fitting errors of the O_4 dSCDs and off-diagonal elements of zero.

In most previous studies, the optimal linear inverse method (Rodgers, 2000; Friess, 2011) is used to retrieve the vertical profiles of the trace gas VMRs. In PriAM, we use the Gauss-Newton numerical procedure as in eq. (s1) because the use of the safe state of AEs and trace gas VMRs (see below) converts the linear problem into a nonlinear one.

Similar to the retrieval of the AE profiles, the diagonal element of S_ε is the square of the fitting errors of the respective trace gas dSCDs and the off-diagonal elements are zero. The elements of S_a are calculated from eq. s3 but the σ_{a_i} are replaced by the a-priori VMR of the respective trace gas (ρ_{a_i}). One fixed a-priori profile of the VMRs for each trace gas is used. The a-priori profiles of NO_2 and SO_2 are described as an exponential function (similar to Yilmaz, 2012 and Hendrick et al 2014):

$$\rho(z) = \rho(0) \times e^{-\frac{z}{H}} \quad (s4)$$

Here $\rho(z)$ and $\rho(0)$ are the VMR of the trace gases at altitude z (km) and near the surface, respectively. H is the scaling height (in this study fixed to 1km). The ground VMR $\rho(0)$ is set to 4 ppb for NO_2 and 8 ppb for SO_2 .

MAX-DOAS and aircraft measurements in Milano during summer of 2003 indicated that the layer of high HCHO concentration often extends to 1 km or even higher altitudes (Wagner et al., 2011, Junkermann, 2009). Thus for HCHO the same a-priori profile (Boltzmann distribution) as for the AE is used. The surface mixing ratio $\rho(0)$ is set to 4ppb and the VCD to 1.7×10^{16} molecules/cm².

During the profile inversion for aerosols and trace gases, negative values can occur, which are physically invalid. To avoid them, the original atmospheric state vector x is transformed to its corresponding ‘safe state’ x' (Yilmaz, 2012):

$$x' = \ln(x) \quad (s5)$$

After finishing the calculation of x' , x' is transformed back to the original format

$$5 \quad x = e^{x'} \quad (s6)$$

In this way it is ensured that x is always positive.

The averaging kernel (AK) is an important quantity to characterize the vertical resolution of the measurement and the sensitivity of the retrieved state \hat{x} to the true state as a function of altitude. The trace of the averaging kernel matrix yields the degree of freedom (DoF) of the signal, which represents the number of independent pieces of information that can be
10 retrieved. The error of the retrieved state S consists of the smoothing error S_s (due to the limited vertical resolution of the retrieval) and the retrieval noise S_m (due to measurement errors).

2.1 Influence of the choice of the a-priori profiles on the retrieved profiles

We investigate the impact of the choice of the a-priori profiles on the retrieved profiles, VCD (AOD) and near-surface VMR (AE) (from the ground to 200 meters) for two months (July 2011 and February 2012) by either varying the VCD (AOD) by
15 0.5 or 2, or changing the profile shape by replacing the Boltzmann distribution with the exponential distribution (for aerosols and HCHO) or the other way around (for NO_2 and SO_2) (see Fig. S6 in the supplement). We compared the respective differences of the measured dSCDs and modeled dSCDs (results of the forward model) and the retrieved profiles (see Fig. S7), VCDs (AODs) and the near-surface VMRs (AEs) (see Table S1). We found a stronger influence of the a-priori profile for aerosols than for the trace gases. By changing the a-priori profiles, the maximum change of the retrieved VCDs and
20 AODs is on average about 10% and 20%, respectively. The retrieved near-surface VMRs and AEs change by around 2% and 10%, respectively. For both aerosols and trace gases, typically the smallest differences between the measured and modeled dSCDs are found for the standard a-priori profiles (see Fig. S7) indicating that the standard a-priori profiles are the preferred assumptions.

3 Deriving O_4 VCDs from the measured surface temperature and pressure

25 To derive O_4 VCDs from the measured surface temperature and pressure (TP), we first fit 6th order polynomials to the seasonal variations of surface TP (see Fig. 3 in the main manuscript). Second, we calculate height profiles of the temperature assuming a lapse rate of 0.645K / 100m:

$$T_{i+1} = \begin{cases} T_i - 0.645 \times \frac{z_{i+1} - z_i}{0.1} & (0 < z < 12\text{km}) \\ T(z = 12\text{km}) & (z > 12\text{km}) \end{cases} \quad (s7)$$

Here T_i (in unit of kelvin, K) and z_i indicate the temperature and height of the atmospheric layer i , respectively. Above 12 km the temperature is kept constant to represent the temperature inversion around the tropopause. Here it should be noted that this simplification has only negligible influence on the derived O_4 VCD, because most of the O_4 is present at lower altitudes. For the same reason, the TP profiles are only calculated up to an altitude of 20 km.

5 Based on the calculated temperature profile and the surface pressure we calculate the corresponding pressure profile:

$$D_i = 28.9 \times 10^{-3} \times P_i / (T_i \times R) \quad (s8)$$

$$P_{i+1} = P_i - (g \times 100 \times D_i) \quad (s9)$$

Here D (in units of kg/m^3) and P (in unit of hPa) indicate the air density and pressure, respectively. R is the ideal gas constant (8.31 J/mol K), and g is the gravitational constant (9.8 N/kg). Because the O_4 concentration is proportional to the square of the oxygen concentration (which represents 21% of the air density), the profile and VCD of O_4 can be calculated from the assumed air density profile. Fig. 3 in the main manuscript shows the seasonal variation of the O_4 VCD calculated from the measured surface TP in 2012. The O_4 VCD in summer is systematically lower than in winter (by about 2×10^{42} molecules² cm^{-5} , which is about 15% of the annually mean O_4 VCD).

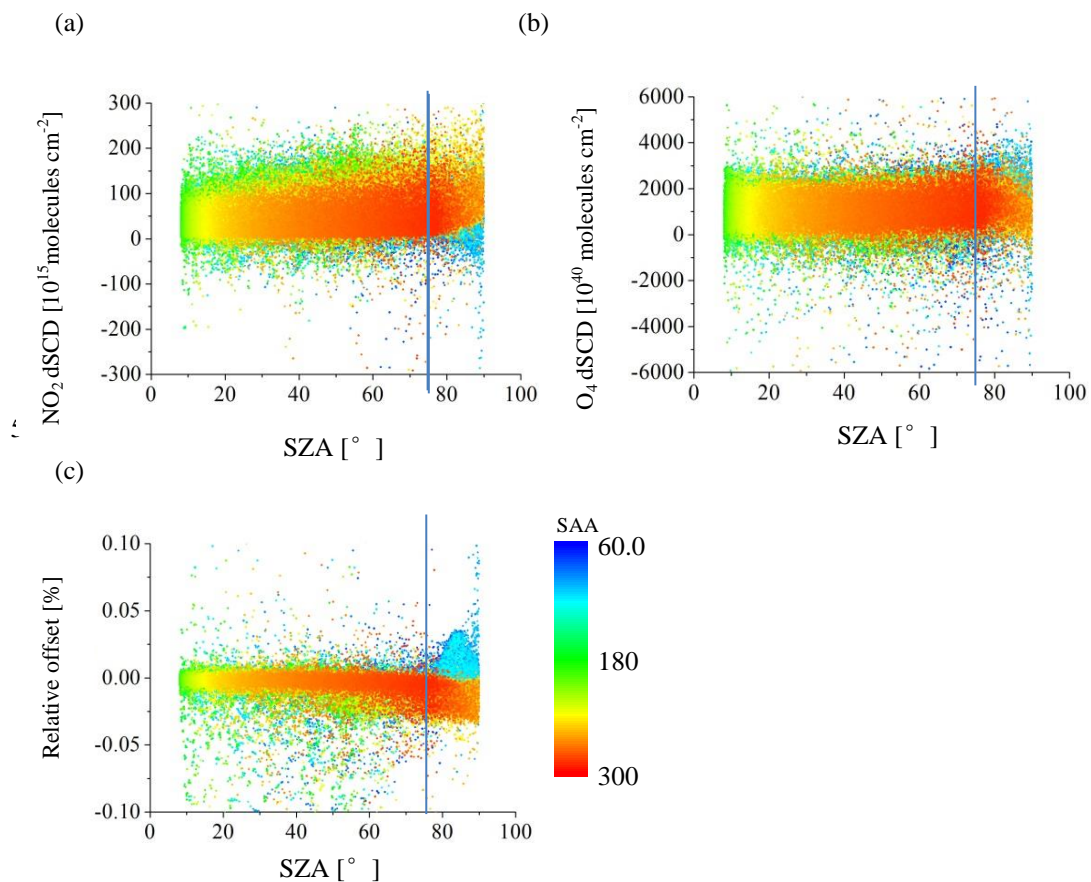

4 Dependencies of the errors of the VCD derived by the geometric approximation and the profile inversion on the aerosol load

In Fig S9, $Diff_{total}$, $Diff_{inversion}$ and $Diff_{geometry}$ for the different TGs are plotted against the for elevation angles of 20° and 30° (for a range of the RAA between 100° to 110°). We found linear relations of $Diff_{geometry}$ against AOD for the three species, especially for 20° elevation angle. The weaker dependence of $Diff_{geometry}$ on AODs for an elevation angle of 30° is due to the lower sensitivity of MAX-DOAS observations on aerosols than for an elevation angle of 20° . Correlation coefficients of the linear regressions of $Diff_{geometry}$ and AODs are largest for HCHO due to its higher layer height compared to the other species. The same reason causes the better correlation for SO_2 than for NO_2 . For relatively large AODs, the relation of $Diff_{total}$ and AOD follows a linear relation of $Diff_{geometry}$ and AODs, but for low AODs, $Diff_{inversion}$ contributes most to $Diff_{total}$. $Diff_{inversion}$ is mostly between $\pm 20\%$ and is randomly distributed around zero. Thus $Diff_{inversion}$ can not be the reason for the systematic bias between the VCD_{geo} and the VCD_{pro} .

(b)

(c)

5 (d)

Figure S19: Mean results of all MAX-DOAS retrievals under different sky conditions. Besides the AOD and AE (a) and the trace gas mixing ratios and VCDs (b to d), also the cost functions and degrees of freedom are shown. The cost functions of all species are higher under cloudy conditions compared to clear sky conditions. The effect of clouds is stronger for aerosols compared to TGs. This is consistent with the larger discrepancy between modelled dSCDs and the measured dSCDs shown in Fig. 13 of the main

10

manuscript. The reason is that clouds are not included in the forward model. The DoF of the inversions strongly depend on the cloud and aerosol load. A large aerosol load leads to an increase of the DoF of the aerosol inversion, but to a decrease of the DoF for the TG inversions. The column densities and near surface TG mixing ratios and AE are found to be quite different for the different sky conditions, probably due to cloud effects on the inversions and the different atmospheric chemistry conditions (photolysis) and dynamics for different cloud conditions.

Table S1 Absolute and relative differences of the retrieved VCDs (and AOD) and near-surface VMRs (AEs) of NO₂, SO₂ and HCHO between either using the three test a-priori profiles or the standard a-priori profile (shown in Fig. S6)

| species | a-priori profile | Absolute difference | | Relative difference | |
|-----------------|------------------|---|---|---------------------|------------------------|
| | | VCD (10^{15} molecules cm^{-2}) or AOD | Near-surface VMR (ppb) or AE (km^{-1}) | VCD or AOD | Near-surface VMR or AE |
| aerosols | Priori 1 | -0.17 | 0.05 | -24% | 10% |
| | Priori 2 | 0.11 | 0.003 | 15% | 0.6% |
| | Priori 3 | -0.16 | 0.67 | 22% | 136% |
| NO ₂ | Priori 1 | -1.7 | -0.29 | -7% | 2.2% |
| | Priori 2 | 2.4 | 0.18 | 10% | 1.3% |
| | Priori 3 | 2.7 | 0.09 | 11% | 0.7% |
| SO ₂ | Priori 1 | -3.1 | -0.21 | -10% | -2% |
| | Priori 2 | 3.9 | 0.10 | 12% | 1% |
| | Priori 3 | 2.3 | -0.17 | 7% | -1% |
| HCHO | Priori 1 | -0.22 | -0.027 | -1% | -0.5% |
| | Priori 2 | 0.85 | 0.049 | 5% | 1% |
| | Priori 3 | -1.1 | -0.025 | -7% | -0.5% |
