General comments

This Technical Note provides a compendium of important mineralogic, chemical, physical properties of widely distributed materials (mostly surface soils and aeolian sediments) sampled from re-suspension in the PM2.5 and PM10 size fractions. The primary goal is to provide data that can be used to evaluate the effects of atmospheric dust primarily with respect to radiative forcing and human health. The measurement of radiative properties during re-suspension and comparison with compositional parameters provides important information relating dust mineralogy to optical properties (Fig. 4.5-1). The SEM micrographs and accompanying EDS spectra are of excep-

tional quality and provide a helpful view into typical mineralogic complexity of PM2.5 particles. The comparisons among SSAs, iron, and clay minerals invite collaborative discussions about alternative explanations for the observed relations.

Specific comments.

The manuscript emphasizes the relations among iron, clay minerals, and optical properties. Fe is interpreted to mostly reside in montmorillonite on the basis of correlation of Fe and Al (p. 11). Certainly, some Fe is structurally bound in many of the clay minerals encountered in this study. But how much? A quick scan of literature and text books indicate typical structural Fe concentrations in montmorillonite and illite between $\sim$1 and 7 wt %, expressed as Fe_2O_3. (Of course, chlorite and nontronite by classification and structure contain a lot of Fe – on the order of 8-20+ wt % Fe_2O_3.) Considering the samples that contain primarily rock-derived sediment (i.e., ignoring salt-/carbonate-/diatom-bearing playa samples), the correspondence between Al and Fe could also be attributed to the co-existence of ferric oxide minerals (hematite and goethite) with clay minerals, in varying relative proportions depending on factors of provenance, sorting, and pedogenesis, in some instances.

One reason for my concern (with background in iron oxides but not in clay minerals) stems from the relations illustrated in the scatter plots of Fig. S4-4. The ratios of Fe_2O_3 to Al_2O_3 for most samples (blue markers) seem to be about 0.7. Some sleuthing on chemical analyses of clays, including "standards" used for reflectance spectroscopy (http://speclab.cr.usgs.gov/spectral.lib06/ds231/datatable.html) reveals the following Fe_2O_3/Al_2O_3 ratios: illite: 0.07-0.29 montmorillonite: 0.04-0.28 kaolinite: 0.01-0.04 chlorite: 0.48

These ratios are based on the following analyses for Fe_2O_3 wt %: Illites: 1.6, 6.4, 4.99 Montmorillonite: 5.8, 3.2, 3.5, 1.4, 1.75, 1.2, 3.85 Chlorite 8.3

In many of this study's samples, there seems to be a large excess of chemical Fe_2O_3 that cannot represent structural Fe in clays.

I suggest that the authors reconsider their interpretation that the correspondence between Fe and Al is produced primarily by structural Fe in clay minerals. I suggest instead that – except perhaps for the samples low in Fe and Al – the "excess Fe" is better explained by the presence of the minerals hematite and goethite these sediments, beyond their abundance attributed by the authors. The reason that these ferric oxides have not been commonly noted is that researchers have not looked closely enough for them with specialized instrumentation, which is admittedly difficult to access. These minerals appear to be common in fine-grained, rock-derived sediments worldwide. They are probably ubiquitous in sediments having hues of red, orange, and yellow. Recent work shows these ferric oxides to be commonly nano-sized (<50 nm) and to occur as discrete particles within and on clay minerals and in other occurrences in the same sample. They are revealed by certain magnetic properties and Mössbauer spectroscopy especially at 4.2K (liquid He temperature) because these ultrafine minerals are magnetically ordered at very low temperatures but not at room temperature. The nano-ferric-oxide minerals can be observed (and confirmed as Fe oxide) under very high resolution SEM with EDA beam diameters on the order of a few 10s nm. I suggest that the dust community consider the following: The radiative properties of at least many samples (standards and natural) described as containing Fe-bearing clays are actually strongly controlled by the presence of ferric oxide minerals, many of which are nano-size (Reynolds et al., 2014a, 2014b; Moskowitz, manuscript in review). This distinction is no small matter with respect to modeling the radiative effects of dust in the atmosphere and on surfaces of ice and snow.

The authors similarly attribute the correspondences between Ti - Al and Mn – Ti to residence of Ti and Mn in clays. It appears to me that much of the Ti and Mn are associated with Fe(-Ti) oxide minerals such as ilmenite (usually <5 wt %) and (or) the generally more abundant ferromagnesium silicates, as identified in many samples.

Issues of "long-range transport" [not defined] of dust particles "typically < 9 microns": A body of work indicates the presence of larger particles transported at regional (10s

to many 100s km) and global scales (many 1000s km). A few articles on the topics are: Beltzer et al., 1988; McTainsh et al. 1997; Middleton et al., 2001; Alastuey et al 2005, Chan et al., 2005; Lawrence and Neff, 2009; Neff et al., 2013; van der Does et al., 2015.

Particles >PM10 certainly have important effects on the Earth System through radiative properties (atmospheric and snow/ice melt), infrastructure, health (in the upper respiratory system if not deeper), and fertilization.

Was there any black carbon in any of the samples that might have enhanced measured radiative properties?

P. 2, lines 8-9. Please see Ghio et al., 2014 with respect to medical studies of biologic effects of dust on human lung cells.
