Abstract: Mercury (Hg) emission from natural surfaces plays an important role in global Hg cycling. The present estimate of global natural emission has large uncertainty and remains unverified against field data, particularly for terrestrial surfaces. In this study, a mechanistic model is developed for estimating the emission of elemental mercury vapor (Hg^0) from natural surfaces in China. The development implements recent advancements in the understanding of air-soil and air-foilage exchange of Hg^0 and redox chemistry in soil and on surfaces, incorporates the effects of soil characteristics and landuse changes by agricultural activities, and is examined through a systematic set of sensitivity simulations. **Using the model, the net exchange of Hg^0 between the atmosphere and natural surfaces of Mainland China is estimated to be 465.1 Mg yr^{-1} , including 565.5 Mg yr^{-1} from soil surfaces, 9.0 Mg yr^{-1} from water body, and -100.4 Mg yr^{-1} from vegetation.** The air-surface exchange is strongly dependent on the landuse and meteorology, with 9% of net emission from forest ecosystems, 50% from shrubland, and savanna and grassland, 33% from cropland, and 8% from other landuses. Given the large agricultural land area in China, farming activities play an important role on the air-surface exchange over farmland. Particularly, rice field shift from a net sink (3.3 Mg uptake) during April to October (rice planting) to a net source when the farmland is not flooded (November-March). Summing up emissions from each landuse, more than half of the total emission occurs in summer (51%), followed by spring (28%), autumn (13%) and winter (8%). Model verification is accomplished using observational data of air-soil/air-water fluxes and Hg deposition through litterfall for forest ecosystems in China and Monte Carlo simulations. In contrast to the earlier estimate by Shetty et al. (2008) that reported large emission from vegetative surfaces using an evapotranspiration approach, the estimate in this study shows natural emissions are primarily from grassland and dry cropland. Such an emission pattern may alter the current understanding of Hg emission outflow from China as reported by Lin et al. (2010b) because of a substantial natural Hg emission occurs in West China.

39 1. Introduction

40 Accurate inventories of mercury (Hg) emission is the foundation for assessing Hg global
41 biogeochemical cycling (Selin, 2009;Streets et al., 2009;Streets et al., 2011). The inventories of Hg
42 emission include the emission from anthropogenic sources, and the so-called “natural” emission that
43 includes the primary natural release (i.e., from geogenic activities) and the re-emission of legacy Hg stored
44 in the terrestrial and water surfaces. Hg emission from anthropogenic sources has been quantified and
45 updated with reasonable consistency since the 1990s (Streets et al., 2009;Streets et al., 2011;Zhang et al.,
46 2015;Zhang et al., 2016). In particular, the inclusion of the release from commercial products and
47 modifications of Hg emission speciation profiles corresponding to the implementation and upgrade of air
48 pollution control technologies have substantially reduced the uncertainty of anthropogenic Hg emission
49 estimates (Horowitz et al., 2014;Zhang et al., 2016). In contrast, estimates of natural Hg emission are poorly
50 constrained and have large uncertainties ($\pm 2000 \text{ Mg yr}^{-1}$), limiting the understanding of global and regional
51 Hg cycling budgets (Pirrone et al., 2010;Wang et al., 2014b;Song et al., 2015). In light of the control of
52 anthropogenic Hg emission by the legally binding Minamata Convention (Pacyna et al., 2016), a better
53 quantification of natural Hg emission is critical in evaluating the effectiveness of policy actions (Selin,
54 2009;Pirrone et al., 2010;Song et al., 2015).

55 One of the greatest challenges in predicting natural Hg emissions is the limited understanding in the
56 air-surface Hg^0 exchange processes among multiple environmental compartments, such as those in a
57 terrestrial vegetative ecosystem. Estimates from regression-based models derived from the correlations
58 between Hg flux and environmental parameters (e.g., temperature, solar radiation, etc.) may not be
59 representative (Xu et al., 1999;Bash et al., 2004;Lin et al., 2005;Gbor et al., 2006;Shetty et al., 2008;Selin
60 et al., 2008;Smith-Downey et al., 2010) because the relationships between measured fluxed and
61 environmental factors are based on limited field data that are be site-specific, which cannot account for the
62 heterogeneity in soil properties and vegetative coverages. Although the bidirectional resistance schemes
63 describing Hg^0 gas exchange may be appropriate (Bash, 2010;Wang et al., 2014b;Wright and Zhang, 2015),
64 they are limited by the availability of required soil property data and other physicochemical parameters
65 such as Hg^{II} reduction kinetics and characteristics of interfacial exchanges (Bash, 2010;Wang et al., 2014b),

66 leading to inconsistencies between simulated and measured fluxes. Other challenges including acquiring
67 and integrating the meteorology, landuse, and soil property data (Hg content and other characteristics) in a
68 model domain covering China call for further model development to **estimate** natural Hg emission (Wang
69 et al., 2014b).

70 Recent advances in the understanding of Hg^{II} reduction provide new opportunities to build a more
71 physically robust air-soil exchange scheme. These include constrained 10^{-11} to 10^{-10} s⁻¹ pseudo-first-order
72 rate constant of Hg^{II} reduction in soil (Scholtz et al., 2003;Qureshi et al., 2011) and 0.2-1.0 h⁻¹ rate constant
73 in natural water (O'Driscoll et al., 2006;Qureshi et al., 2010). In these reactions, the UV-band of actinic
74 light has been shown to be the primary driver for Hg^{II} photo-reduction in soils and water bodies (Moore
75 and Carpi, 2005;Si and Ariya, 2011); and the role of functional substructures (e.g., -C(O)OH, -SH, -OH) of
76 **DOM (dissolved organic matter)** in the reduction has been determined by kinetic studies using model
77 compounds (He et al., 2012;Si and Ariya, 2011, 2015). Presence of dissolved O₂ has been shown to inhibit
78 most aqueous Hg^{II} reduction but not the photo-reduction of Hg^{II} bound to R-SH (Si and Ariya, 2011). In
79 dry soil, the first-order rate constants of Hg^{II} photo-reduction are 0.007-0.028 h⁻¹ for HgCl₂ coated over
80 sand and 0.003-0.006 h⁻¹ for Hg^{II} in a natural soil (Quinones and Carpi, 2011). In the absence of light, Hg^{II}
81 reduction in soil is also observed at a rate of 0.001-0.002 h⁻¹ at 293 K (Pannu, 2012).

82 Intercontinental transport of Hg emission in China has been suggested to enhance Hg deposition in
83 North America (Jaffe et al., 2005;Strode et al., 2008;Lin et al., 2010b;Chen et al., 2014). However, the
84 natural Hg emission inventory used in earlier modeling studies may not be representative. Wang et al.
85 (2014a) suggested the Hg emissions in China from natural and anthropogenic sources are comparable.
86 Shetty et al. (2008) estimated the natural Hg emission in China to be 462 Mg yr⁻¹ using an outdated model
87 scheme, which was applied for assessing regional Hg budgets in Est Asia (Lin et al., 2010b;Zhu et al.,
88 2015a). The large uncertainty associated with the earlier estimate warrants a re-assessment of these earlier
89 modeling efforts. In addition, the data of soil Hg concentration used in Shetty et al. (2008) are more than 3
90 decades old and requires updates to appropriately represent spatial distribution of soil Hg contents that have
91 been modified due to the rapid industrial development and urbanization occurring in China since 1980s.
92 This data deficiency has been addressed by the National Multi-Purpose Regional Geochemical Survey

93 (NMPRGS) of China completed in 2014 (Li et al., 2014). This database provides soil Hg content for the
94 agricultural and industrialized regions at a resolution of 4 km, which may substantially reduce uncertainty
95 caused by data deficiency. In addition, the **datasets** of terrestrial flux in Mainland China recently reported
96 in the literature allows verification of model results and optimization of model schemes. These field data
97 of Hg⁰ air-surface exchange in China documents the flux characteristics over different landuses including
98 urban-rural-remote differences and effects of crop rotation over agricultural lands (Fu et al., 2008;Fu et al.,
99 2010;Zhu et al., 2011;Fu et al., 2012;Fu et al., 2013a;Sommar et al., 2013a;Sommar et al., 2013b;Zhu et al.,
100 2013;Sommar et al., 2015a;Zhu et al., 2016).

101 Given the scientific advancements and new data availability discussed above, this work develops a
102 state-of-the-science mechanistic model for estimating the natural Hg emission in China. For the first time,
103 the simulated natural emission flux is verified with field measurements over different land surfaces in a
104 modeling effort. The spatial, temporal and seasonal characteristics of the model-estimated emissions over
105 soil, vegetative surface and water are presented and compared to the earlier estimates performed by Shetty
106 et al. (2008). The implications of the new estimate are discussed in terms of chemical transport of Hg
107 emission in China and the need for a re-assessment of mercury emission outflow from China.

108

109 **2. Methods**

110 **2.1 Model description**

111 Compared to the earlier mechanistic schemes (Wang et al., 2014b;Bash, 2010;Scholtz et al.,
112 2003;Zhang et al., 2012b), this model (1) builds a new scheme for estimating the air-soil flux based on the
113 reduction pathways of reactive Hg in soil identified in the literature, (2) develops a scheme for the Hg flux
114 exchange over rice paddy, which is an important landuse feature in China, and (3) updates the scheme for
115 the air-snow interface and chemical parameters for air-foliage flux (Table 1).

116 **2.1.1 Reduction of Hg^{II} in soil**

117 Based on Hg^{II} reduction mechanisms proposed in peer-reviewed literature (Moore and Carpi,
118 2005;Quinones and Carpi, 2011;Si and Ariya, 2011;Pannu, 2012), a new model describing Hg⁰ formation
119 from Hg^{II} reduction in soil is developed using three reaction pathways: (1) photo-reduction of Hg^{II} in soil

120 pore water (Hg_1^0), (2) photo-reduction of Hg^{II} associated with soil particles (Hg_2^0), and (3) Hg^{II} reduction
 121 through non-photochemical pathways (Hg_3^0). The production of Hg^0 in surface soil is calculated as:

$$122 \quad \frac{dHg_1^0}{dt} = K_1 \cdot Hg_{s,m} \quad (1)$$

$$123 \quad \frac{dHg_2^0}{dt} = K_2 \cdot Hg_{p,m} \quad (2)$$

$$124 \quad \frac{dHg_3^0}{dt} = K_3 \cdot Hg_{t,m} \quad (3)$$

125 where K_1 is the photo-reduction rate constant of Hg^{II} in soil pore water (a comprehensive parameter list with
 126 units is shown in Table 1), K_2 is the photo-reduction rate constant of Hg^{II} associated with soil particles, K_3
 127 is the Hg^{II} reduction rate constant in soil through non-photochemical pathways, $Hg_{s,m}$ is the Hg^{II} pool in soil
 128 pore water, $Hg_{p,m}$ is the labile Hg^{II} pool available for reduction on soil particles, $Hg_{t,m}$ is the total reducible
 129 Hg^{II} pool in soil. Based on the Arrhenius equation, K_1 and K_2 are parameterized as a function of solar
 130 irradiance and soil temperature, and K_3 is parameterized as a function of soil temperature and soil moisture:

$$131 \quad K_1 = k_1 \cdot R \cdot \gamma \cdot e^{\frac{T-T_f \cdot E_a}{T_f \cdot T}} \quad (4)$$

$$132 \quad K_2 = k_2 \cdot R_i \cdot \gamma \cdot e^{\frac{T-T_f \cdot E_a}{T_f \cdot T}} \quad (5)$$

$$133 \quad K_3 = k_3 \cdot e^{\frac{T-T_f \cdot E_a}{T_f \cdot T}} \cdot e^{\frac{\theta-\theta_f \cdot E_b}{\theta_f \cdot \theta}} \quad (6)$$

134 where k_1 and k_2 are the photo-reduction rate constants at the reference soil temperature (T_f , Table 1). k_3 is
 135 the dark-reduction rate constant at the reference soil temperature and soil moisture (θ_f , Table 1). R and R_i
 136 are total solar irradiance in the soil profile and under the canopy, respectively. γ is the ratio of UV over
 137 total solar irradiance. An empirical rule suggests that a 10°C temperature increase doubles the rates for
 138 chemical reactions near room temperature (Kissinger, 1957; Hood et al., 1975), which has been shown to
 139 be applicable to Hg^{II} reduction in boreal soil (Pannu et al., 2014). In addition, Hg emission flux from soil
 140 substrate doubles at ~25% increase of soil moisture content (Lin et al., 2010a). Based on these observations,
 141 Equations 4-6 can be simplified as:

$$142 \quad K_1 = k_1 \cdot R \cdot \gamma \cdot 2^{\frac{T-T_f}{10}} \quad (7)$$

$$143 \quad K_2 = k_2 \cdot R_i \cdot \gamma \cdot 2^{\frac{T-T_f}{10}} \quad (8)$$

144 $K_3 = k_3 \cdot 2^{\frac{T-T_f}{10}} \cdot 2^{\frac{\theta-\theta_f}{25\%}}$ (9)

145 R and R_i in Equations 7-8 are calculated based on the Beer-Lambert law:

146 $R_i = R_0 \cdot e^{-K \cdot LAI}$ (10)

147 $R = R_i \cdot \int_0^l e^{-k_r \cdot l} dl$ (11)

148 where R_0 is solar irradiance above the canopy, K is the canopy light extinction coefficient, LAI is leaf area
149 index, k_r is the light extinction coefficient in soil, l is the depth of surface soil.

150 $Hg_{s,m}$ and $Hg_{p,m}$ and $Hg_{t,m}$ are calculated based on Lyon et al. (1997):

151 $Hg_{s,m} = \frac{[Hg_t] \cdot BD}{\theta + kd \cdot BD} \cdot V \cdot \theta \cdot 10^6$ (12)

152 $Hg_{p,m} = \frac{[Hg_t] \cdot BD \cdot kd}{\theta + kd \cdot BD} \cdot BD \cdot V \cdot \varphi$ (13)

153 $Hg_{t,m} = [Hg_t] \cdot BD \cdot V \cdot \varphi$ (14)

154 where $[Hg_t]$ is the total Hg^{II} concentration in soil, BD is the soil bulk density, θ is the soil moisture, and
155 V is the soil volume, φ is the ratio of reducible Hg over total Hg in soil. kd is the soil-water partition
156 coefficient and calculated following Lee et al. (2001) and Sauve et al. (2000):

157 $\log kd = r \cdot pH + s \cdot \log(1000 \cdot foc) + t$ (15)

158 where foc is the fraction of organic carbon in surface soil. The values r , s and t are regression coefficients.

159 Following Obrist et al. (2014), we assume that the Hg^0 emission from soil is controlled by diffusion
160 after Hg^{II} reduction. Basing on the Fick's first law, the observed air-soil flux exchange can be calculated as:

161 $F_{soil} = Hg_1^0 + Hg_2^0 + Hg_3^0 - D_{soil} \frac{GEM}{d/2} \Delta t$ (16)

162 $D_{soil} = 0.66 \cdot (\sigma - \theta) \cdot D_0$ (17)

163 where D_{soil} and D_0 are the diffusivities of Hg^0 vapor in soil and ambient air. GEM is the atmospheric Hg^0
164 concentration, σ is the soil porosity. Hence, during a time period Δt , the soil Hg^0 vapor compensation
165 point used in the bidirectional resistance model can be derived as:

166 $\chi_g = \frac{(Hg_1^0 + Hg_2^0 + Hg_3^0) \cdot d/2}{D_{soil} \cdot \Delta t}$ (18)

167

168 2.1.2 Updates for air-terrestrial exchanges

169 Extending from the two categories (vegetated canopy and bare land) from our earlier work (Wang et
 170 al. (2014b), the terrestrial system is divided into four categories: vegetated surface with unsaturated soil
 171 moisture (e.g., forest, grassland, shrubland, etc.), vegetated surface with saturated soil (i.e., rice paddy),
 172 barren or sparsely vegetated land, and snow/ice surface. The governing equation for calculating Hg^0 air-
 173 surface exchange over vegetated surfaces is:

$$174 \quad F_{cnp} = \frac{\Delta t}{(R_a + R_b)} (\chi_{cnp} - C_{atm}) \quad (19)$$

175 where R_a is the aerodynamic resistance, R_b is the quasi-laminar sub-layer resistance, C_{atm} is the
 176 atmospheric Hg concentration, χ_{cnp} is the overall compensation point. For the canopy biomes with
 177 unsaturated soil, χ_{cnp} is parameterized as in Wang et al. (2014b):

$$178 \quad \chi_{cnp} = \frac{\frac{\chi_c + \chi_s}{R_c + R_s} + \frac{\chi_g}{R_g + R_{ac}} + \frac{C_{atm}}{R_a + R_b}}{\frac{1}{R_c + R_s} + \frac{1}{R_g + R_{ac}} + \frac{1}{R_a + R_b}} \quad (20)$$

179 where χ_c is the cuticular compensation point, χ_s is the stomatal compensation point, R_c is the cuticular
 180 resistance, R_s is the stomatal resistance, R_g is the soil diffusion resistance, R_{ac} is the in-canopy
 181 aerodynamic resistance (Table 1 in details). While for vegetated surface with saturate soil, χ_{cnp} is
 182 parameterized as following:

$$183 \quad \chi_{cnp} = \frac{\frac{\chi_c + \chi_s}{R_c + R_s} + \frac{\chi_w}{R_w + R_{ac}} + \frac{C_{atm}}{R_a + R_b}}{\frac{1}{R_c + R_s} + \frac{1}{R_w + R_{ac}} + \frac{1}{R_a + R_b}} \quad (21)$$

184 where χ_w is the air-water compensation point, R_w is the diffusional resistance on water surface.

185 The governing equation for air-surface exchange in barren or sparsely vegetated land, and over
 186 snow/ice surface is:

$$187 \quad F_{bls} = \frac{\Delta t}{R_a + R_b + R_g} (\chi_g - C_{atm}) \quad (22)$$

188 For bare land, R_g is calculated following Zhang and Lindberg (1999):

$$189 \quad R_g = \frac{d/2}{0.66 \cdot (\sigma - \theta) \cdot D_0} \quad (23)$$

190 For snow/ice surface, R_g is evaluated following Zhang et al. (2012b):

$$191 \quad \frac{1}{R_g} = \frac{\alpha_{Hg^0}}{R_g(O_2)} + \frac{\beta_{Hg^0}}{R_g(O_3)} \quad (24)$$

192 where $R_{g(SO_2)}$ and $R_{g(O_3)}$ are the diffusion resistances of SO_2 and O_3 , α_{Hg^0} is the Hg^0 scaling factor
193 based on SO_2 , β_{Hg^0} is Hg^0 scaling factor based on O_3 . The formulation of $R_{g(SO_2)}$ and $R_{g(O_3)}$ has been
194 described previously (Zhang et al., 2003; Wang et al., 2014b). The χ_g for the air-snow interface is assumed
195 to be 3 ng m^{-3} based on field measurements at air-snow interface (Mann et al., 2015; Lalonde et al.,
196 2003; Fain et al., 2007; Maxwell et al., 2013). Other parameters in Equations 19-24 are described in details
197 in Wang et al. (2014b).

198 **2.2 Model configuration and data**

199 The modeling domain is in Lambert Conformal projection, with 223×149 grid cells at a 36-km spatial
200 resolution. The modeling period is one year (2013). Hourly meteorological data are prepared using the
201 Weather Research and Forecasting (WRF) model Version 3.7. Sensitivity analysis in Wang et al. (2014b)
202 showed that accurate representation of environmental parameters (e.g., temperature, solar irradiance, etc.)
203 greatly improves the flux estimate. To obtain the best physics and dynamics options of WRF for the China
204 domain, a L_{25} (5^6) orthogonal design of experiments is utilized (Supplementary material, Table S1). The
205 best combination of meteorological physics options is selected based on model evaluation metrics R
206 (correlation coefficient) and RMSE (root-mean-square error) between simulated outputs of each
207 combination of options and observed values in 750 meteorological stations. The selected physics options
208 are Thompson (Microphysics Options), Betts-Miller-Janjic (Cumulus Parameterization Options), RRTMG
209 (Radiation Physics Options) and BouLac (PBL Physics Options) based on the results of meteorological
210 model performance evaluation (Figure S1).

211 The datasets for surface soil properties (1 km spatial resolution) containing organic matters contents,
212 pH, bulk density and porosity are adopted from Shangguan et al. (2013). The land cover data (1 km spatial
213 resolution) is obtained from Ran et al. (2012). The land cover map represents the best available datasets
214 and follows the IGBP (International Geosphere-Biosphere Programme) classification system (Figure S2).
215 The ratio of rice planting fields in China during each month are classified following the method used in Liu
216 et al. (2013). The rice planting seasons are April to October in South China (including double rice planting),
217 and May to October in Northeast China (single rice planting). The LAI data, also with a 1 km spatial
218 resolution, are adopted from Yuan et al. (2011). The soil Hg content information utilized by Shetty et al.

219 (2008) is updated and greatly expanded with the comprehensive NMPRGS dataset (Li et al., 2014). These
220 high resolution datasets were re-gridded into the domain specification for each landuse using the spatial
221 tools in ArcGIS 10.1. The soil Hg content in 0-20 cm surface soil varies with landuse types, containing
222 mean concentrations of 119~211, 61~197, 80~82, 80~82 and 31~162 ng g⁻¹ of Hg for forest ecosystems,
223 shrubland, savanna/grassland, cropland, and other landuses, respectively (Table 1). Though the mean Hg
224 concentration in 0-20 cm soil profile could somewhat underestimates Hg concentration in the top soil layer,
225 the dataset is the best available one describing the soil Hg concentration in China. Datasets of Hg
226 concentration in the top soil layer (e.g., 0-5 cm depth) are recommended when they become available.

227 In the simulation, the validated Hg⁰ concentration retrieved from the output of the Hg extension of
228 Community Multi-scale Air Quality modeling system (CMAQ-Hg) version 4.7 for the same modeling
229 period is applied to represent the ambient air concentration of Hg⁰ (Lin et al., 2010b). The simulation does
230 not incorporate the feedback of the air-surface exchange to the air concentration because the feedback of
231 the air-surface exchange to the air concentration does not significantly modify the atmospheric Hg⁰
232 concentration in each grid cell, and the typical variation range of ambient Hg⁰ concentration is not a
233 sensitivity parameter for flux change (Wang et al., 2014b). The model algorithms are coded in FORTRAN
234 90 and Network Common Data Form (NetCDF) version 4.3. The gridded model results are visualized by
235 the Visualization Environmental for Rich Data Interpretation (VERDI) version 1.5.

236

237 **3 Results and discussion**

238 **3.1 Evaluation for soil Hg reduction scheme**

239 Values of all model parameters used in the simulation are showed in Table 1. The value of k_1 is assumed
240 to be $6 \times 10^{-9} \text{ m}^2 \text{ W}^{-1} \text{ s}^{-1}$ based on the relationship between irradiance intensity and apparent photo-reduction
241 rate constant in aerated solution observed by Si and Ariya (2011). Considering the 2 mm maximum
242 photolysis penetration depth in soil (Hebert and Miller, 1990), the measured rate constant in soil particles
243 (depth = 2.07 mm) from Quinones and Carpi (2011) is $2 \times 10^{-3} \text{ m}^2 \text{ W}^{-1} \text{ h}^{-1}$ (k_2) with respect to the pool of
244 labile Hg^{II} available for reduction. The value of k_3 is assumed to be $1.0 \times 10^{-3} \text{ h}^{-1}$ based on the average rate
245 constants for dark (thermal) reduction (Pannu, 2012). The mean ratio of reducible Hg in soil is assumed to

246 be 0.03 for the soil with vegetation based on measurements from Pannu (2012). No data is available for the
247 bare soil. Data from Lindberg et al. (1999) imply that Hg-enriched desert soil (1400-5000 ng g⁻¹ total Hg)
248 produces a nominal Hg⁰ efflux in the range from 40 to 60 ng m⁻² h⁻¹. Derived from back-calculation taking
249 pore diffusion into account, the fraction of reducible Hg is predicted at least 10 times lower (≤ 0.003) than
250 that in the soil with vegetation.

251 Sensitivity analyses using a box model for a typical forest soil are performed to gauge the selected rate
252 coefficients and the results are showed in Figure 2. With $k_1 = 6.0 \times 10^{-9} \text{ m}^2 \text{ W}^{-1} \text{ s}^{-1}$, $k_2 = 2.0 \times 10^{-3} \text{ m}^2 \text{ W}^{-1} \text{ h}^{-1}$,
253 $k_3 = 1.0 \times 10^{-3} \text{ h}^{-1}$, the Hg⁰ vapor concentration in soil porous media is estimated to be 4.5 ng m⁻³, comparable
254 to the measured concentration (4.1±2.0 ng m⁻³) in the surface forest floor (Moore and Castro, 2012). This
255 suggests that the selected empirical constants appropriately represent typical environmental conditions.
256 Generally, the range of Hg⁰ vapor in all simulations is 1.5-6.7 ng m⁻³. Less than 0.1% Hg⁰ vapor is from
257 photo-reduction in soil solution as the Hg pool in soil solution is small ($\leq 0.1\%$ of total Hg concentration).
258 A ~16% fraction of the pore Hg⁰ concentration derives from thermal Hg^{II} reduction, contributing to 0.5-1
259 ng m⁻³ of Hg⁰ vapor present in soil gas. Hg⁰ concentrations in pore gas are typically lower than the 1-2 ng
260 m⁻³ atmospheric Hg concentration in background forest at night (Carpi and Lindberg, 1998; Ericksen and
261 Gustin, 2006; Kuiken et al., 2008a; Kuiken et al., 2008b; Obrist et al., 2014; Fu et al., 2015), suggesting that
262 forest floor acts as a Hg⁰ sink during nighttime. This is consistent with the sign of nocturnal fluxes observed
263 over forest floor (Carpi and Lindberg, 1998; Ericksen et al., 2006; Kuiken et al., 2008a; Kuiken et al., 2008b).
264 Moore and Carpi (2005) reported that the Hg flux under sun-lit condition is 3-5 times higher than the value
265 observed in the dark. The developed model is capable of producing results consistent with the observation
266 that photo-reduction on soil particles dominates the formation of Hg⁰ vapor.

267 Figure 3 illustrates the model response to the model variables at the two experimental levels in Table
268 2. The 2-level factorial design of experiments is meant to gauge the extreme variation of flux caused by the
269 possible range of all parameters. This method is statistically robust, and therefore the synergistic and
270 antagonistic interactions among model parameters can be estimated with indications of statistical
271 significance. On average, increasing soil bulk density from 0.1 to 1.5 g cm⁻³, and Hg content from 10 to
272 400 ng g⁻¹, and soil temperature from 0 to 30 °C, and solar radiation from 0 to 1000 W m⁻², will significantly

273 enhance the flux by 20-30 ng m⁻² h⁻¹. Additional 18-20 ng m⁻² h⁻¹ synergistic effects from the combination
274 of above parameters are also predicted. Filed measurements suggest the combined effects of soil Hg content
275 (from 60 to 590 ng g⁻¹) and soil temperature (from 5 to 30 °C) enhance the flux by ~40 ng m⁻² hr⁻¹ (Fu et
276 al., 2012;Fu et al., 2008). On the other hand, increasing leaf area index (LAI) from 0 to 7 m² m⁻² reduces
277 the flux by 19 ng m⁻² h⁻¹. Furthermore, LAI could offset the positive effects from bulk density, soil Hg
278 concentration, and solar radiation above canopy, leading to an additional -19 to -16 ng m⁻² h⁻¹ decrease,
279 indicating that the canopy shading substantially constrains soil Hg evasion, consistent with the shading
280 could decrease 70-90% fluxes compared to non-shaded soils in filed measurements (Carpi and Lindberg,
281 1998;Zhang et al., 2001;Choi and Holsen, 2009). In reality, since the actual variation of the parameters is
282 much smaller than the possible range, the flux change will also be much milder. To illustrate this, we run
283 the model using the center values of selected parameters (i.e., showing the model results by running the
284 model at half of the experimental level). Using the center values of soil Hg content, LAI, soil bulk density,
285 solar radiation and soil temperature in Table 2 (close to the environmental parameters in a typical forest
286 ecosystem), the air-soil flux is 4.5 ng m⁻² hr⁻¹, similar to the measures fluxes (0.5-9.3 ng m⁻² hr⁻¹) in forest
287 ecosystems of China (Fu et al., 2012;Fu et al., 2008).

288 In the new scheme, the soil organic matter is not incorporated into either K_2 or K_3 , in accordance with
289 the findings of Pannu (2012). While Hg⁰ evasion from substrates coated with HgCl₂ and humic matter is
290 inversely correlated with humic matter content both in the dark and under irradiation, the inhibitory effect
291 from humic matter is not linear to its content (Mauclair et al. (2008). For instance, relatively small
292 differences are observed at humic matter content > 1% (Mauclair et al., 2008). In addition, the effect of soil
293 organic matter type has not been comprehensively investigated (Zhang and Lindberg, 1999;Bash et al.,
294 2007). Further studies that quantify the reduction rate constants associated with different types of soil
295 organic matters (or species) under light, as well as field flux data that relate the observed flux intensity to a
296 given type of organic matter, can improve the present model parameterization.

297

298 3.2 Diurnal variation of natural Hg⁰ emissions in China

299 Table 3 shows the annual mean air-surface fluxes for different landuse types. Annual mean air-foilage
300 fluxes range from -0.2 to -4.5 ng m⁻² h⁻¹, with the highest value over the woody savannas, and the lowest
301 over deciduous forests (Table 3). The diurnal variation for air-foilage flux is displayed in Figure 4. Higher
302 deposition occurs during mid-morning (8:00-10:00) and late-afternoon (16:00-17:00) due to the suitable air
303 temperature and solar irradiance that induces Hg uptake by stomata. The rates of Hg uptake during midday
304 are comparatively weaker due to the stronger irradiance and higher temperature. This bimodal pattern is
305 consistent with field observations (Lindberg et al., 2002;Poissant et al., 2008;Fritsche et al., 2008;Sommar
306 et al., 2015a), suggesting that the model is capable of simulating the diurnal pattern of air-foilage exchange
307 of Hg⁰. Such a diurnal pattern is caused by re-emission of the deposited Hg on the surface foliage through
308 photo-reduction under the strong solar radiation during noontime, and the emissions from underlying soil
309 surfaces. Except for urban lands, the strength of diurnal deposition for the other landuses is controlled by
310 LAI, solar radiation, and air temperature. The elevated atmospheric Hg concentration is an important
311 parameter to induce Hg uptake by growing foliage in urban lands.

312 Simulated mean air-soil fluxes range from 0.1 to 23.3 ng m⁻² h⁻¹, with the lowest flux over barren
313 vegetated lands and the highest over urban lands (Table 3). This suggests that the simulated air-soil fluxes
314 greatly vary over different landuses. There are distinct diurnal variations in terrestrial ecosystems (Figure
315 5). The diurnal pattern is caused by the variation of solar irradiance, close to zero at night and peaking at
316 13:00 to 15:00 (UTC+8). Similar diurnal patterns have been observed during filed measurements for forest,
317 grassland, and cropland in China (Feng et al., 2005;Fu et al., 2008;Fu et al., 2012;Zhu et al., 2013). The
318 degree of diurnal variability for each landuse is highly related to the LAI. Higher LAI gives a more intensive
319 canopy shading and largely inhibits Hg evasion from soil under canopy. This is also the main reason for
320 relative weaker diurnal variation over forest soils compared to shrubland, grassland and cropland (Figure
321 5). The synergistic interactions between low vegetation cover and high soil concentration (Mean=162±83
322 ng g⁻¹) results in the strongest diurnal variation for urban land-types.

323 The simulated annual mean of air-water flux is 3.4 ng m⁻² h⁻¹. The diurnal variability for air-water flux
324 is weaker since wind speed is a more influential driver than irradiance (Wang et al., 2014b), consistent with
325 the diurnal variation observed in field studies that meteorology and photochemical process are the primary

326 factors (Feng et al., 2002;Feng et al., 2003;Wang et al., 2006;Feng et al., 2008;Fu et al., 2010;Fu et al.,
327 2013a;Fu et al., 2013b).

328 Overall, the annual net natural emission in China is 465.1 Mg Hg (Table 3), including 565.5 Mg yr⁻¹
329 from soil, 9.0 Mg yr⁻¹ from water body, and -100.4 Mg yr⁻¹ from the vegetation. The annual quantity of
330 emission from soil is comparable to the estimate (528 Mg yr⁻¹) based on the scale-up calculation using
331 measured air-soil fluxes (Fu et al., 2015a) that suggest emissions from cropland and grassland are the most
332 important contributor. Of the total Hg⁰ emission estimated by the model, 50% is from shrubland, savanna
333 and grassland (C6-C11, 38% total landuse); 33% is from cropland (C12-C13, 22% total landuse); 9% is
334 from forest (C1-C5, 14% total landuse); and 8% is from other landuse types. Forest contributes to 28% of
335 Hg uptake by foliage; shrubland, savanna and grassland contribute to 38%; cropland contributes to 33%;
336 and other landuse types contribute to 1%.

337 Although soil Hg contents in forest ecosystems are 2-4 times higher than that in grassland and cropland,
338 total annual fluxes above the canopy (soil+foliage) of forest ecosystems are 1-6 times lower than the values
339 in other two types of landuses (Table 3). This highlights the importance of canopy cover in natural emission
340 process of Hg⁰. It is noteworthy that the landuse data are based on the survey in 2000 (Ran et al., 2012).
341 From 2000 to 2013, the forested area in China increased from 14.0% to 21.6% (FAO, 2014), benefiting
342 from implementation of governmental Grain for Green Project and stricter natural forest protection actions.
343 Assuming that annual mean air-surface fluxes are at the same level as in this study, the total quantity of
344 natural Hg emission in 2013 is approximately 5% smaller than this estimate because of the increasing forest
345 coverage. Given the forest coverage is projected to be 24 to 26% during 2030-2050 (FAO, 2014), the
346 quantity of natural Hg emission in China would decrease by 9-10% compared to the estimated level of 2013.

347

348 3.3 Spatial distribution of natural Hg emission in China

349 The spatial distribution of annual air-foliage flux can be divided by the well-known geo-demographic
350 demarcation line, “Heihe-Tengchong Line” (Figure 6.1). The vegetation on the east side of the line is much
351 denser than on the west side of the line because of the higher annual precipitation (≥ 800 mm, Figure S2)
352 that leads to stronger Hg⁰ uptake by vegetation (>90% of the grid cells have a flux below -1.0 ng m⁻² h⁻¹ on

353 the east side, compared to >90% of the grid cells has a flux above $-0.5 \text{ ng m}^{-2} \text{ h}^{-1}$ on the west side). There is
354 an enhanced Hg deposition in South China (22°N - 27°N , 105°E - 113°E , Figure 6.1), with the fluxes ranging
355 -3.8 to $-19.1 \text{ ng m}^{-2} \text{ h}^{-1}$. This can be explained by the elevated atmospheric Hg concentrations (2 - 10 ng m^{-3})
356 and dense vegetation (i.e., high LAI, Figure S3) that enhance Hg uptake (Fu et al., 2015;Zhu, 2014).
357 Specifically, evergreen broadleaf forest has the highest LAI compared to other type of forests (Liu et al.,
358 2012) and shows enhanced Hg uptake (up to $-4.5 \text{ ng m}^{-2} \text{ h}^{-1}$ mean flux). Although the direct measurement
359 of Hg deposition flux through vegetative uptake is still not presently feasible, the measured Hg input
360 through litterfall (Fu et al., 2015) suggested the rate of Hg uptake by foliage could be in the range of 4 - 12
361 $\text{ng m}^{-2} \text{ h}^{-1}$, comparable to the simulation results in this study.

362 Figure 6.2 shows the spatial distribution of annual air-soil fluxes. There are three high flux regions
363 (mean flux $\geq 10 \text{ ng m}^{-2} \text{ h}^{-1}$): cropland/grassland in South and Southwest China (mainly in Guangdong,
364 Guangxi, Guizhou, Yunnan, Chongqing and Sichuan provinces), cropland in North China (Heibei, Henan,
365 and Shangdong provinces), and grassland in North China (Inner Mongolia, Shanxi, and Shaanxi, and
366 Xinjiang provinces). Such elevated fluxes in the first two regions have been confirmed in field studies (Feng
367 et al., 2005;Wang et al., 2005;Wang et al., 2006;Fu et al., 2008;Sommar et al., 2015b). The high fluxes in
368 South and Southwest China are attributed to the elevated Hg concentration in soil (85% of grid cells has a
369 soil Hg content $\geq 100 \text{ ng g}^{-1}$, Figure 1). Interestingly, soil Hg content is not the primary factor causing the
370 high fluxes in the other two regions (70% of grid cells has a soil Hg content $\leq 50 \text{ ng g}^{-1}$). Dry deposition of
371 PBM and/or GOM plausibly supply the reducible Hg in soil for gradual reduction and volatilization as Hg^0
372 (Sommar et al., 2015b). The relatively low LAI (Figure S3), strong solar irradiance and high soil
373 temperature (Figure S4-S5) during summer/autumn contribute to the high simulated emissions. The lower
374 simulated fluxes in desert regions compared to fluxes over grassland (Figure 6.2) are caused by the lower
375 fraction of reducible Hg in soils.

376 Since the soil Hg^0 flux is the primary source of natural Hg emission, the spatial distribution of the
377 natural Hg emission is strongly influenced by air-soil flux (Figure 7.1). There is a distinct seasonal variation
378 in the emission quantity: 8% in winter, 28% in spring, 51% in summer, and 13% in autumn (Figure 7.2-
379 7.5). Elevated fluxes mainly cluster in South and Southwest China during winter because of higher soil Hg

380 content (Figure 1), and relatively higher temperature and stronger irradiance. Highest correlation
381 coefficients are found between the flux and soil Hg concentration and soil bulk density (Table 4), suggesting
382 that the soil Hg⁰ pool is a major factor influencing Hg emission in winter. From the cold to warm season,
383 fluxes gradually increase from low latitude to high latitude with the seasonal change of temperature and
384 solar radiation (Figure 7.2-7.4). Under the strong irradiance and temperatures in summer, >65% of the grid
385 cells in the domain has a flux above 10 ng m⁻² h⁻¹ and the effect of soil Hg content is relatively weaker
386 (Table 4). In autumn, higher flux occurs over the cropland of Central and North China, and over the regions
387 with high soil Hg content (Figure 7.6) because of the decreasing temperature and solar irradiance in the
388 south and the influence of soil Hg content in the north. Overall, 72% of natural Hg emission occurs from
389 May to September, with higher emission over grassland and cropland in North China in these months.

390 It is worth noting that parts of regions in South China (23°N-31°N, 110°E-120°E, mainly in Fujian,
391 Jiangxi, Hunan, Hubei, and Anhui provinces) and Northeast China (39°N-51°N, 130°E-134°E, mainly in
392 Liaoning, Jilin and Heilongjiang provinces) have relatively lower fluxes (-6.9~9.0 ng m⁻² h⁻¹) during
393 summer and autumn time (Figure 7.4-7.5). In addition to the impact from the intensive canopy cover in
394 forested area (Figure S2), agricultural activities in these regions also contribute to the smaller fluxes. Based
395 on Liu et al. (2013), 60% croplands in these regions are flooded for rice planting in summer and autumn.
396 Field-scale flux measurement using micrometeorological methods (i.e., aerodynamic gradient method)
397 suggest that a typical oilseeds-rice rotated cropland in Southwest China is a significant source during
398 oilseeds planting seasons with fluxes of 10.1-89.4 ng m⁻² h⁻¹; and a mild sink during rice planting seasons
399 with fluxes of -3.4 to -15.8 ng m⁻² h⁻¹ (Zhu, 2014). The model also successfully simulates such a pattern,
400 with simulated fluxes at 1.1-101.5 ng m⁻² h⁻¹ (Figure 7.2-7.3) during winter and earlier spring when
401 croplands are not flooded and at -3.5 to 1.5 ng m⁻² h⁻¹ during the rice growing season (Figure S6). Overall,
402 3.3 Mg Hg⁰ is predicted to deposit into rice paddies during the rice growing season, with 56% of the
403 deposition occurring in summer, 41% in autumn, and 3% in late spring.

404

405 **3.4 Verification of model estimates**

406 For the first time, the simulated natural Hg emission in China is verified against field observational

407 data in this study. The dataset of Hg deposition through litterfall is utilized for verifying the simulated air-
408 foliage fluxes because of two reasons: (1) it has been shown that Hg deposition through litterfall dominates
409 dry deposition ($\geq 70\%$) in forests of China (Fu et al., 2015); and the annual Hg deposition through litterfall
410 has been used as a surrogate to constrain air-foliage fluxes in forest ecosystems (Risch et al., 2012; Zhang
411 et al., 2012a), and (2) the litterfall data in China comprehensively include different forest types compared
412 to the limited locations where air-foliage flux data are available. For verifying the exchange fluxes over
413 water and soil surfaces, the flux measurements over forest soil, grassland, cropland and water body in China
414 (Table S2) are utilized.

415 To estimate the annual Hg deposition through litterfall in the study domain, Monte Carlo simulation
416 (described in details in SI) is applied for constructing the probability distribution of the Hg deposition
417 through litterfall using litter biomass production and litterfall Hg concentration in China reported in peer-
418 reviewed literature (Figure 8). The sampling locations include 20 sites in Tibetan Plateau, 27 sites for
419 evergreen forests, and 12 sites for deciduous forests. The quality-assured data of litter biomass production
420 (number of replicates ≥ 3 , collector size = 1 m²) are obtained from the China National Knowledge
421 Infrastructure (CNKI). This dataset includes the measurements at 5 sites in Tibetan Plateau, 277 sites for
422 evergreen forests, 74 sites for deciduous forests, and 61 sites for mixed forests.

423 Figure S7 shows the observed Hg concentrations in litter. The Hg concentration for evergreen forest
424 ranges from 17 to 120 ng g⁻¹ with a mean of 52 ± 26 ng g⁻¹. For deciduous forest, the range is 21-62 ng g⁻¹
425 with a mean of 38 ± 12 ng g⁻¹. The difference between the concentrations observed in evergreen forests and
426 in deciduous forests is significant (paired *t* test, $p < 0.05$). The Hg concentration in litter for deciduous forest
427 in China is comparable to the values reported for the same forest type in Europe and North America ($p =$
428 0.101). Hg deposition through litterfall in evergreen broadleaf forest (C2, refer to Table 3 for the landuse
429 type) ranges from 26 to 72 $\mu\text{g m}^{-2} \text{y}^{-1}$ ($n=5$ sites) with a mean of 43 ± 27 $\mu\text{g m}^{-2} \text{y}^{-1}$ (Fu et al., 2015; Ma et al.,
430 2015; Wang et al., 2009), consistent with the Hg deposition estimated by Monte Carlo simulation
431 (mean= 37 ± 19 $\mu\text{g m}^{-2} \text{y}^{-1}$; 95% confidence interval is 4-89 $\mu\text{g m}^{-2} \text{y}^{-1}$). The model-estimated Hg deposition
432 for C1, C3, C4, and C5 is 22 ± 10 , 15 ± 7 , 16 ± 11 , and 17 ± 8 $\mu\text{g m}^{-2} \text{y}^{-1}$, respectively.

433 The measured air-soil flux (Table S2) ranges from -1.4 to 20.7 ng m⁻² h⁻¹ over forest soil ($n=19$; mean=

434 $6.1 \pm 5.1 \text{ ng m}^{-2} \text{ h}^{-1}$), from -18.7 to $114 \text{ ng m}^{-2} \text{ h}^{-1}$ over grassland ($n=14$; mean= $26 \pm 36 \text{ ng m}^{-2} \text{ h}^{-1}$), from -4.1
435 to $135 \text{ ng m}^{-2} \text{ h}^{-1}$ over cropland ($n=33$; mean= $21.3 \pm 36.7 \text{ ng m}^{-2} \text{ h}^{-1}$). For water body ($n=51$), the flux range
436 is 0 - $43.8 \text{ ng m}^{-2} \text{ h}^{-1}$ with a mean of $4.6 \pm 6.6 \text{ ng m}^{-2} \text{ h}^{-1}$ (Table S2). The mean flux from May to October is
437 substantially higher than those from November to April: 3.3 times for water surface ($p=0.004$), 3.2 times
438 higher for forest soil ($p=0.08$), and 1.4 times for cropland ($p=0.50$). A reverse trend is found for grassland,
439 which has higher mean flux in cold seasons (50% higher, $p=0.36$). More measurements in grassland where
440 few data exist will greatly improve the accuracy of the current estimate.

441 Figures S8, S9 and 8.1 compare the model estimates to the mean and variability level predicted by
442 Monte Carlo simulation using field data. The annual Hg uptake simulated by the bidirectional exchange
443 model is not significantly different from the field observations ($p>0.05$, t-test) and the spatial patterns are
444 similar (Figure S8) in coniferous forest ecosystems, demonstrating the model capability for simulating the
445 air-foilage flux. However, the bidirectional exchange model did not capture the spatial distribution of air-
446 foliage flux in broadleaf forest ecosystems (particularly in evergreen broadleaf forest, Figure S9). One
447 possible explanation is that the resistance terms obtained from temperate/boreal forests (Zhang et al., 2012b)
448 may not appropriately represent the value in evergreen broadleaf forests. Field measurements suggests that
449 the leaf stomatal conductance of broadleaf is usually higher than the value of needleleaf (Wang et al.,
450 2015;Ishida et al., 2006;Sobrado, 1991;Eamus, 1999), leading to a larger air-foilage Hg^0 exchange
451 (Graydon et al., 2006). Further studies on the Hg transport and chemical reactions at the air-foilage interface
452 in evergreen broadleaf forests will help constrain the model.

453 Figure 8.2 shows the scatter plot of the measured and model-predicted fluxes over soil and water
454 ($R^2=0.73$). Modeling results for over water surfaces and soil under forest canopy also agree with field data
455 (Figure 8.3-8.4). The model results somewhat underestimates the high fluxes ($\geq 30 \text{ ng m}^{-2} \text{ h}^{-1}$, Figure S9.2)
456 measured over grassland and cropland (Figure 8.4), which be attributed to several possible reasons. One is
457 the bias caused by the comparatively coarser spatial resolution (36 km) of meteorological parameters and
458 soil properties that limit the reproduction of the instantaneously measured fluxes at observational sites. In
459 addition, the limited mechanistic understanding on the re-emission process after Hg dry deposition (Gustin
460 et al., 2015;Lindberg et al., 2007;Gustin et al., 2008b;Ariya et al., 2015) complicates model

461 parameterization. Finally, the uncertainties caused by flux quantification methodology (Lin et al., 2012;Zhu
462 et al., 2015b, c) and the typically short campaign periods (mostly ranging from several days to a couple of
463 weeks) could biased the measurement data (Feng et al., 2005;Fu et al., 2008;Fu et al., 2012;Fu et al.,
464 2015;Zhu et al., 2015b, c). Improvement on flux methods and extended campaign periods at more study
465 sites for cropland/grassland will help constrain the model estimates.

466

467 **3.5 Comparison with earlier estimates and implications on Hg emission outflow in China**

468 Figures **S10** and **S11** show the gridded natural Hg emission in the East Asian Domain reported by
469 Shetty et al. (2008) and Wang et al. (2014a), which have two distinct differences compared to the model
470 estimate in this study. One is the role of vegetation in natural Hg emission, the other is spatial distribution
471 of the emission. Vegetation is clearly an important sink of Hg⁰ with the mechanistic model algorithms
472 implemented in this study; and the shading of vegetation suppress Hg evasion from soil under canopy. In
473 contrast, vegetation is considered a major source, accounting for 76% of total emissions in Shetty et al.
474 (2008) because the model treats Hg evasion as an evapotranspiration process that transports Hg from root
475 zone through vascular tissues in foliage (Gbor et al., 2007;Shetty et al., 2008). Recent experimental
476 evidence using stable Hg isotope tracers points to exclusion of this pathway for cereal plants (Cui et al.,
477 2014). In addition, Hg isotopic signatures observed in air and leaf samples (Demers et al., 2013;Yin et al.,
478 2013) and during air-foliage exchange process (Graydon et al., 2006;Gustin et al., 2008a) indicate uptake
479 of atmospheric Hg by foliage, pointing to vegetation as a Hg⁰ sink. In contrast to the spatial distribution of
480 the emission in this study, the earlier Hg⁰ emission estimates occur mainly in the regions on the east side of
481 the “Heihe-Tengchong Line” (Shetty et al., 2008;Wang et al., 2014a), due to the spatial distribution of
482 vegetation (Shetty et al. (2008) or soil Hg content (Wang et al. (2014a).

483 This study advances upon the earlier estimates (Shetty et al., 2008;Wang et al., 2014a) in three areas.
484 Firstly, the recent soil survey data including soil Hg content and other soil characteristics is a major
485 advantage in this study. The soil Hg data applied in Shetty et al. (2008) is outdated with a coarse spatial
486 resolution; while the data in Wang et al. (2014a) is based on the output of the global terrestrial Hg model in
487 GEOS-Chem, calculated from Hg/C ratios. Secondly, the mechanistic model scheme better describe the air-

488 surface exchange process compared the regression and evapotranspiration in the earlier studies. Finally, the
489 model estimates are verified against the field flux data with generally good agreement, which has not been
490 attempted in earlier works.

491 Although the total quantity of annual natural emission estimated in this study is comparable to earlier
492 estimates (400-600 Mg yr⁻¹) by Shetty et al. (2008) and Wang et al. (2014a), the distinct spatial distribution
493 of natural emissions simulated in this study may alter the current understanding of Hg emission outflow
494 from China assessed by Lin et al. (2010b). The outflow of Hg emissions in China is mainly driven by the
495 prevailing west-wind drift (Lin et al., 2010b; Chen et al., 2014). The predominant natural Hg emission in
496 the west side of model domain results in a longer residence time of evaded Hg, which can be more readily
497 oxidized and deposited within the domain. Furthermore, the dense vegetation in the east side of the domain
498 **can also help capture** the nature Hg⁰ emission, potentially leading to substantially larger domestic deposition
499 and smaller quantity of outflow compared to the estimates by Lin et al. (2010). We are presently to reassess
500 the emission outflow using a regional chemical transport model (e.g., CMAQ-Hg) and a similar mass
501 balance approach by Lin et al. (2010); and will report the model results in a future paper.

502

503 **4. Conclusions**

504 Using a mechanistic model incorporating the present state of understanding in Hg transformation in
505 soils and on foliage surface with up-to-date datasets of soil characteristics and landuse changes, the natural
506 emission of Hg⁰ vapor in China is estimated to be 465.1 Mg yr⁻¹, including 565.5 Mg yr⁻¹ of emission from
507 soils, 9.0 Mg yr⁻¹ of emission from water bodies, and -100.4 Mg yr⁻¹ deposition (uptake) by vegetation. The
508 air-surface exchange is strongly dependent on landuse and meteorology, with 9% of net emission from
509 forest ecosystems, 50% from shrubland, savanna and grassland, 33% from cropland, and 8% from other
510 landuses. Given the large agricultural land area in China, farming activities play an important role on the
511 air-surface exchange. Particularly, rice fields shift from a net sink (3.3 Mg uptake) during the growing
512 season in rice paddy to a net source during the season when the farmland is not flooded. The estimated
513 natural Hg⁰ emission in this study yields similar Hg⁰ evasion quantity but exhibits contrasting spatial
514 distribution compared to the estimate by Shetty et al. (2008). The difference in the spatial patterns may alter
515 the current understanding of Hg emission outflow from China as reported by Lin et al. (2010b) because of

516 a substantial amount of natural Hg⁰ emission occurs in West China, which requires further assessment.

517 For future model improvement, studies focusing on fundamental understanding of Hg^{II} reduction in
518 soil (especially the role of soil organic matter, contribution of photochemical and non-chemical pathways,
519 and radiation transfer in soil) and air-vegetation exchange mechanisms are needed. Continuous updates on
520 the data of soil characteristics and Hg content is also essential. More field data for model performance
521 evaluation is also important for constraining the model. In particular, data of air-foliage flux, and air-soil
522 flux over cropland and grassland in the remote regions of North China is valuable for model calibration.

Table 1 Model variables, constants and rate coefficients used in the model simulation.

Term	Description	Values/units	References/Sources
Hg_1^0	Hg ⁰ formed by photo-reduction in solution	ng m ⁻² h ⁻¹	
Hg_2^0	Hg ⁰ formed by photo-reduction in particles	ng m ⁻² h ⁻¹	
Hg_3^0	Hg ⁰ formed by the dark-reduction in soil	ng m ⁻² h ⁻¹	
K_1	Photo-reduction rate in soil solution	s ⁻¹	
K_2	Photo-reduction rate constant in particles	s ⁻¹	
K_3	Dark-reduction rate constant in soil	s ⁻¹	
$Hg_{s,m}$	Hg ^{II} pool in soil pore water	ng m ⁻²	
$Hg_{p,m}$	Reducible Hg ^{II} pool in soil particles	ng m ⁻²	
$Hg_{t,m}$	Total reducible Hg ^{II} pool in soil	ng m ⁻²	
T	Temperature	K	WRF
θ	Soil moisture	%	WRF
R	Total solar radiation	W m ⁻²	WRF
BD	Soil bulk density	g cm ⁻³	(Shangguan et al., 2013)
LAI	Leaf area index	m ² m ⁻²	WRF (Yuan et al., 2011)
$[Hg_t]$	Total Hg ^{II} concentration in soil	ng g ⁻¹	
V	Soil volume	m ³	
kd	soil-water partition coefficient	L kg ⁻¹	
GEM	Atmospheric Hg ⁰ concentration	ng m ⁻³	(Lin et al., 2010b)
σ	Soil porosity	%	(Shangguan et al., 2013)
D_{soil}	Hg ⁰ vapor diffusion coefficient in soil	m ² s ⁻¹	
D_0	Hg ⁰ vapor diffusion coefficient in ambient air	1.31×10 ⁻⁵ m ² s ⁻¹	(Scholtz et al., 2003)
F_{cnp}	The flux over canopy biomes	ng m ⁻² h ⁻¹	
Δt	Time duration	s	
R_a	Aerodynamic resistance	s m ⁻¹	(Wang et al., 2014b;Zhang et al., 2012b)
R_b	Quasi-laminar sub-layer resistance	s m ⁻¹	Wang et al., 2014b;Zhang et al., 2012b)
C_{atm}	Atmospheric Hg concentration	ng m ⁻³	Wang et al., 2014b;Zhang et al., 2012b)
χ_{cnp}	The total compensation point	ng m ⁻³	Wang et al., 2014b;Zhang et al., 2012b)
χ_c	Cuticular interfaces compensation point	ng m ⁻³	Wang et al., 2014b;Zhang et al., 2012b)
χ_s	Stomatal interfaces compensation point	ng m ⁻³	Wang et al., 2014b;Zhang et al., 2012b)
χ_g	Soil interfaces compensation point	ng m ⁻³	Wang et al., 2014b;Zhang et al., 2012b)
R_c	cuticular resistance	s m ⁻¹	Wang et al., 2014b;Zhang et al., 2012b)
R_s	stomatal resistance	s m ⁻¹	Wang et al., 2014b;Zhang et al., 2012b)
R_g	soil diffusion resistance	s m ⁻¹	Wang et al., 2014b;Zhang et al., 2012b)
R_w	water diffusion resistance	s m ⁻¹	Wang et al., 2014b;Zhang et al., 2012b)
$R_{g(SO_2)}$	SO ₂ soil diffusion resistance	s m ⁻¹	Wang et al., 2014b;Zhang et al., 2012b)
$R_{g(O_3)}$	O ₃ soil diffusion resistance	s m ⁻¹	Wang et al., 2014b;Zhang et al., 2012b)
d	Light penetration into soil column	2.00 mm	(Hebert and Miller, 1990)

γ	Ratio of UV radiation over total radiation	0.08	(Moan, 2001)
K	Canopy light extinction coefficient	0.56	(Zhang et al., 2014)
k_r	Light extinction coefficient in soil	3. mm ⁻¹	(Ciani et al., 2005)
k_1	Photo-reduction rate constant in soil solution	6.0×10 ⁻⁹ m ² W ⁻¹ s ⁻¹	(Si and Ariya, 2011)
k_2	Photo-reduction rate constant in soil particles	2.0×10 ⁻³ m ² W ⁻¹ h ⁻¹	(Quinones and Carpi, 2011)
k_3	Dark-reduction rate constant in soil	1.0×10 ⁻³ h ⁻¹	(Pannu, 2012)
T_f	Reference soil temperature	32°C(Eq.8), 20°C (Eq. 7,9)	(Pannu, 2012;Quinones and Carpi, 2011)
θ_f	Reference soil moisture	25%	(Lin et al., 2010a)
r	Empirical value from regression	0.52	(Lee et al., 2001;Sauve et al., 2000)
s	Empirical value from regression	0.89	(Lee et al., 2001;Sauve et al., 2000)
t	Empirical value from regression	-0.71	(Lee et al., 2001;Sauve et al., 2000)
φ	Ratio of reducible Hg in soil	0.003 (bare), 0.03(others)	(Pannu, 2012)
α_{Hg^0}	Scaling factor of reactivity Hg	0	(Wang et al., 2014b)
β_{Hg^0}	Scaling factor of reactivity Hg	0.1	(Wang et al., 2014b)
Hg_w^{2+}	Hg ^{II} concentration on leaf	3 ng m ⁻² leaf	(Laacouri et al., 2013)

804 Table 2 Examined model variables and the experimental levels of factorial design for air-soil exchange.
 805

Terms	Description	Low level	High level
BD	Soil bulk density (g cm ⁻³)	0.1	1.5
pH	Soil pH (dimensionless)	4	9
P	Soil total porosity (%)	0.05	0.5
T	Soil temperature (°C)	0	35
SMOIS	Soil moisture (%)	0.05	0.5
R0	Solar irradiance above canopy (w m ⁻²)	0	1000
LAI	Leaf area index (dimensionless)	0	7
GEM	Atmospheric Hg0 concentration (ng m ⁻³)	1.5	5
Hgs	Hg concentration in soil (ng g ⁻¹)	10	400
Foc	Soil organic matter content (%)	0.5	30
k1	photo-reduction rates in soil solution (m ² W ⁻¹ s ⁻¹)	3×10 ⁻⁹	9×10 ⁻⁹
k2	photo-reduction rates in soil particles (m ² W ⁻¹ h ⁻¹)	0.7×10 ⁻³	3.0×10 ⁻³
k3	Non-photo-reduction rates (thermal, h ⁻¹)	1.0×10 ⁻³	2.3×10 ⁻³

806

807 Table 3. Mean annual air-surface fluxes, and annual total Hg emissions from individual landuse. SHg is the
 808 Hg content in surface soil (0-10 cm), FF is the Hg⁰ flux over foliage, and FS is the Hg⁰ flux over soil.
 809

Type	Description	Area(%)	SHg (ng g ⁻¹)	FF (ng m ⁻² h ⁻¹)	Leaf(Mg)	FS(ng m ⁻² h ⁻¹)	Soil(Mg)	Tot(Mg)
C1	Evergreen needleleaf forest	5.7	186±74	-2.8	-13.5	6.9	35.2	21.7
C2	Evergreen broadleaf forest	2.6	184±35	-2.6	-6.5	6.2	16.1	9.5
C3	Deciduous needleleaf forest	0.1	119±9	-0.2	-0.03	0.7	0.1	0.1

811

812 Table 4. Pearson correlations between mean total fluxes and major controlling environmental parameters
813 in each season. “***” means $p < 0.01$ and “**” means $p < 0.05$.

814

815

Term	Winter	Spring	Summer	Autumn
LAI	-0.14*	-0.24**	-0.39**	-0.30**
Soil temperature	0.27**	0.35**	0.54**	0.38**
Solar radiation	0.27**	0.32**	0.59**	0.36**
Soil Hg concentration	0.47**	0.13*	0.02	0.39**
Soil bulk density	0.41**	0.16*	0.04	0.32**

816
817 Figure 1. Updated Hg concentrations (ng g^{-1}) in surface soil (0-20 cm) of China. Sampling areas in
818 NMPRGS covers most agriculturally and industrially developed regions of eastern and central China, and
819 is presented in more details in Li et al. (2014).
820

821

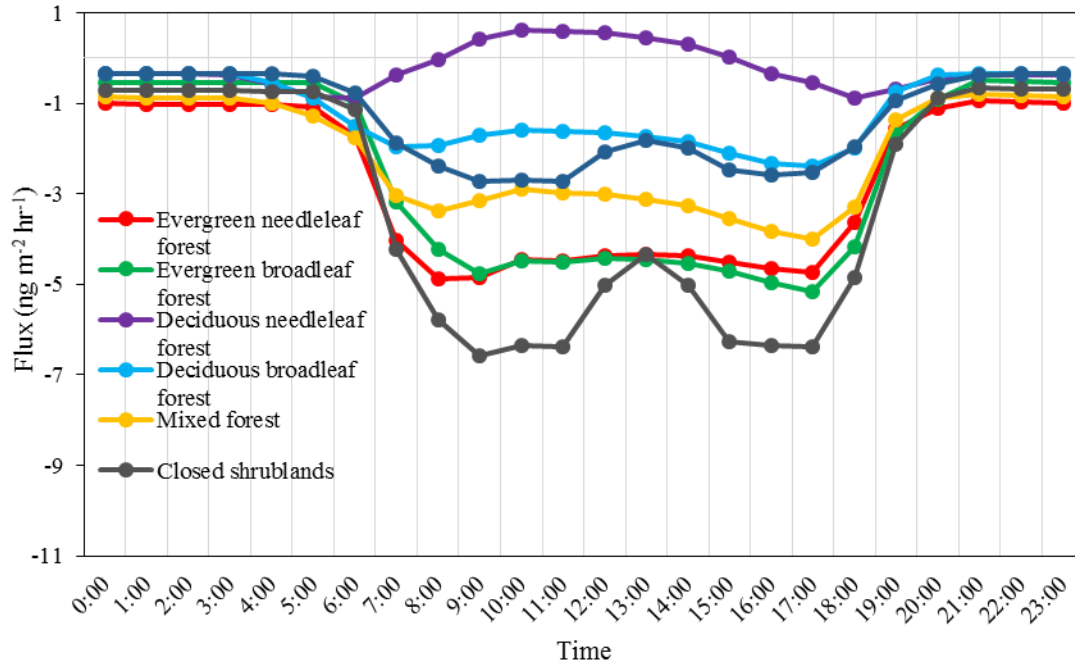

822 Figure 2. Variation of Hg⁰ concentrations (ng m⁻³) in the forest soil pore gas using the typical ranges of
 823 kinetic constants for Hg^{II} reduction in soil (see text for details): $k_1 = 3.0-9.0 \times 10^{-9} \text{ m}^2 \text{ W}^{-1} \text{ s}^{-1}$, $k_2 = 0.7-3.0 \times 10^{-3}$
 824 $\text{ m}^2 \text{ W}^{-1} \text{ h}^{-1}$, $k_3 = 1.0-2.3 \times 10^{-3} \text{ h}^{-1}$, soil Hg content = 150 ng g⁻¹, pH = 4, soil organic content = 20%, soil bulk
 825 density = 0.8 g m⁻³, solar irradiance = 1000 W m⁻², soil temperature = 25 °C, LAI = 5 m² m⁻², soil moisture
 826 content = 20%, and soil soil porosity = 40%. **The environmental conditions are similar to conditions**
 827 **reported by Moore and Castro (2012).**

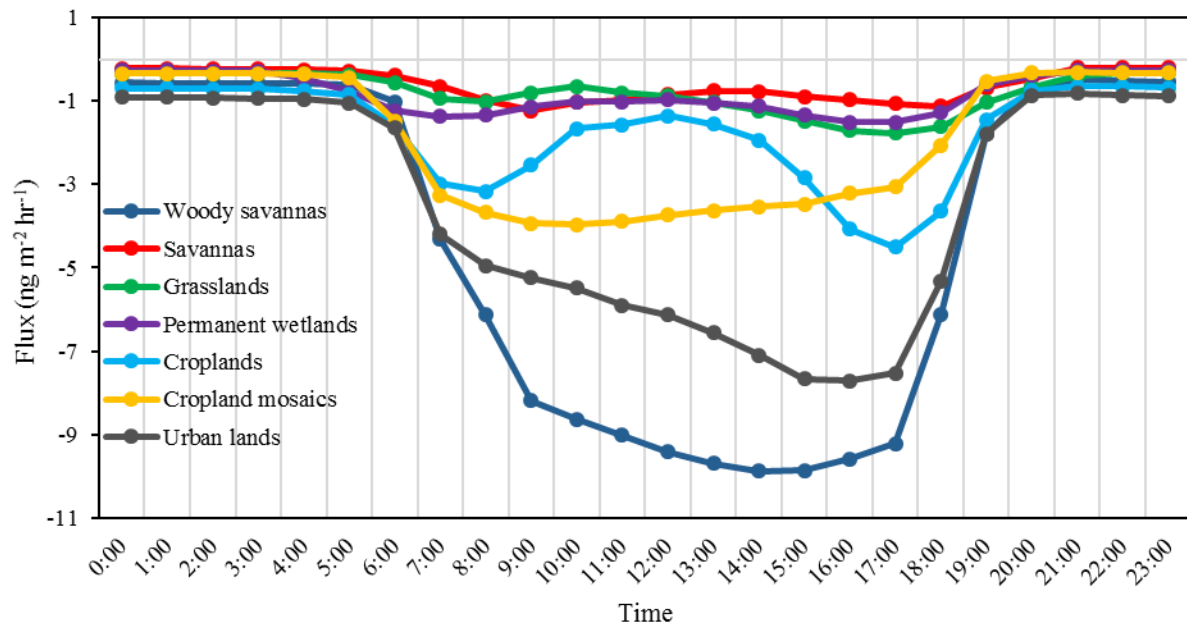

828

829 Figure 3. Sensitivity analysis on model parameters for air-soil exchange using a 2-level factorial design
 830 after pre-screening the model variables shown in Table 2 for the identified significant factors. The effects
 831 shown in the figure are based on a significance level of 95% (i.e., $p < 0.05$).

832

833

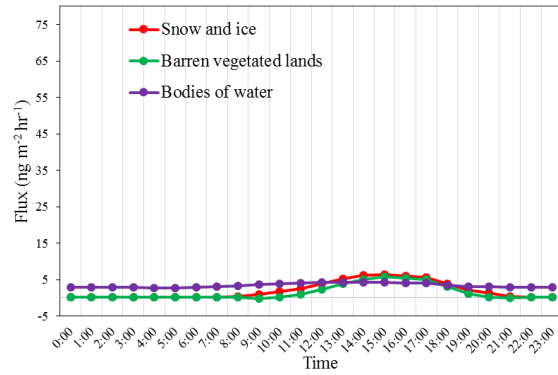

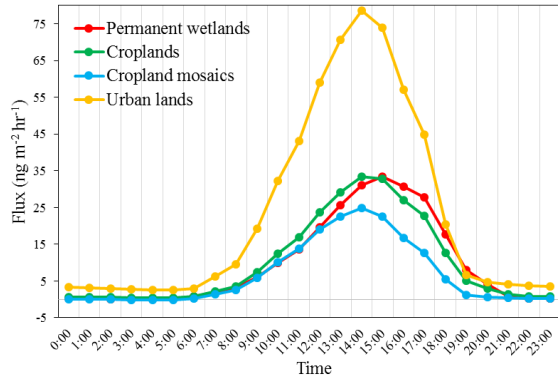

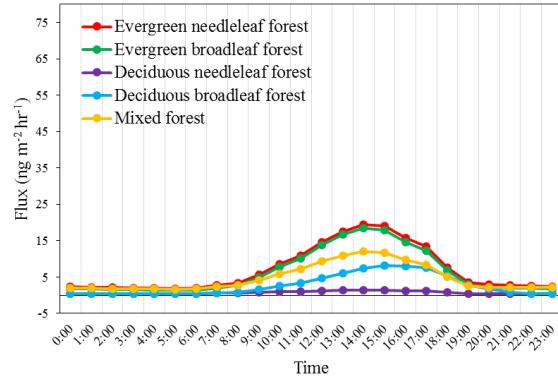

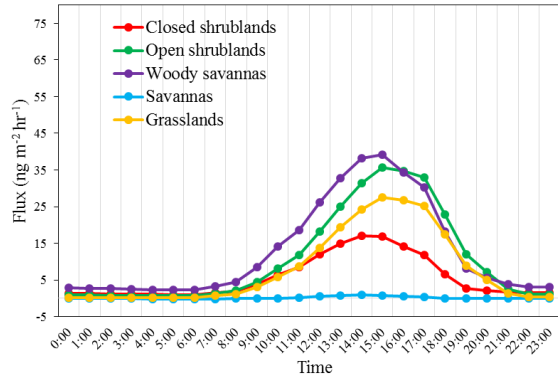

834

835 Figure 4. Diurnal variation of mean simulated exchange fluxes of Hg⁰ over canopy in the model domain
 836 (UTC+8).

837

838

839

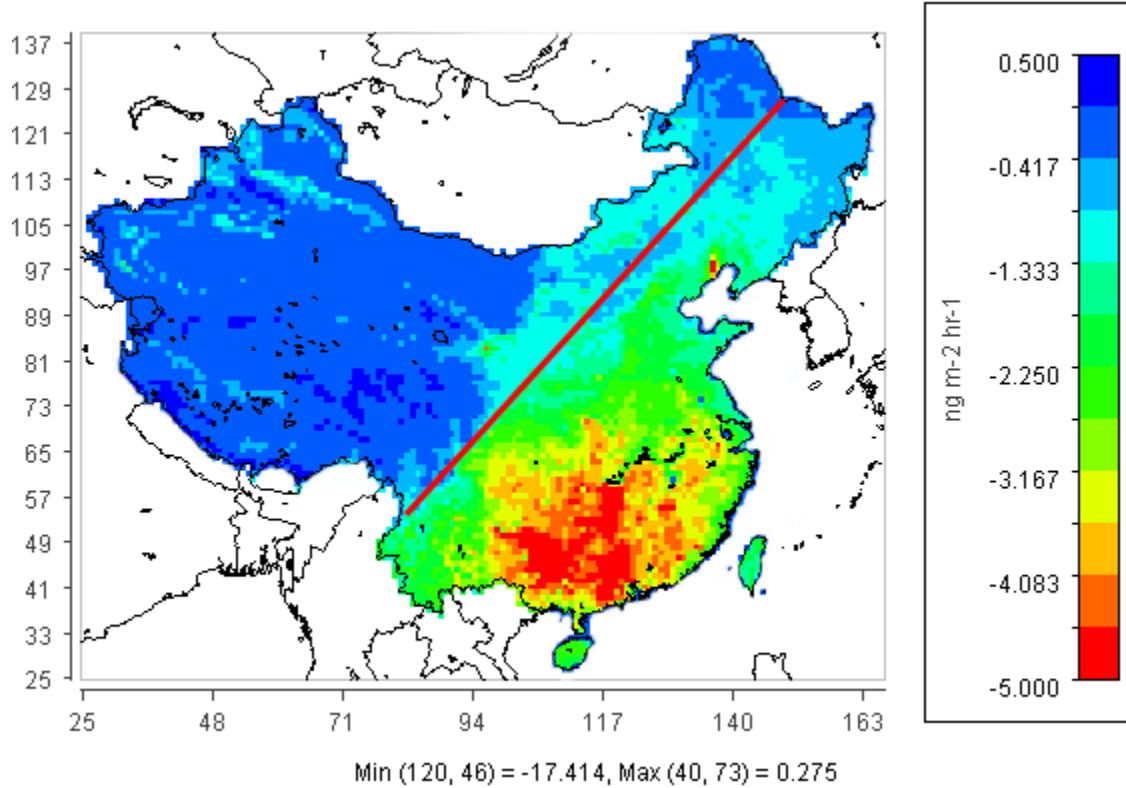

840

841

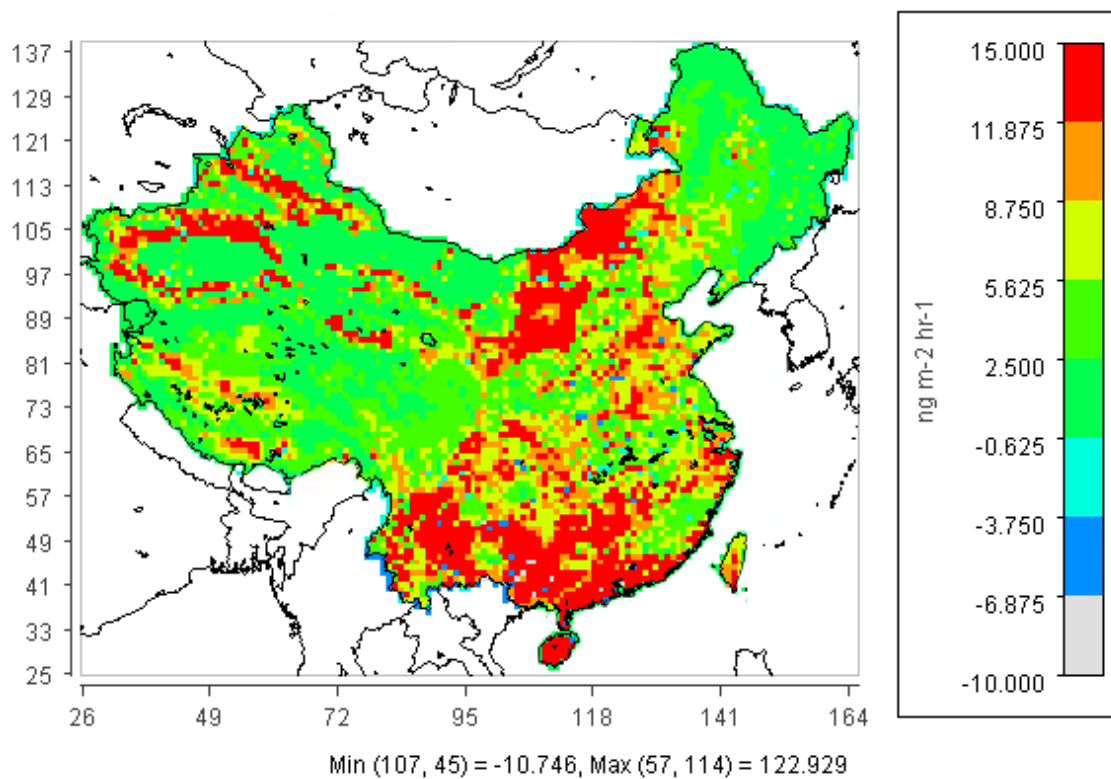

842

843

Figure 5. Diurnal variation of mean simulated exchange fluxes of Hg^0 over soil and water surfaces in the model domain (UTC+8).

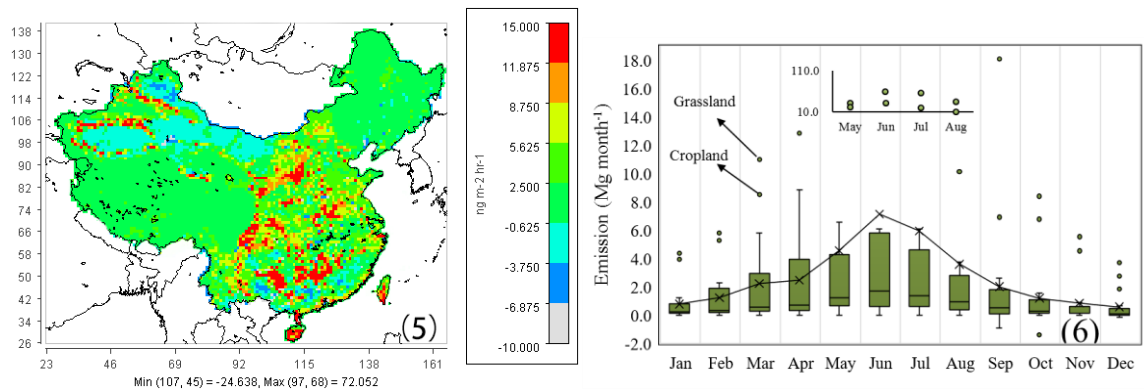

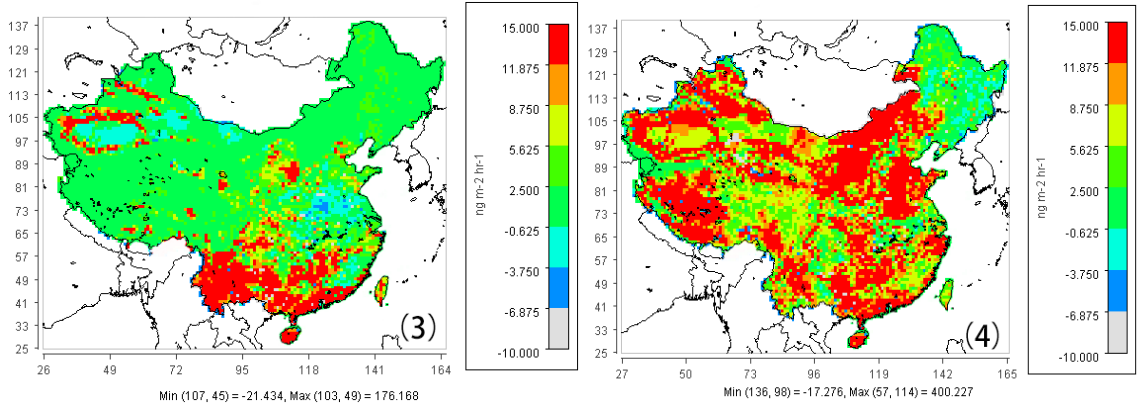

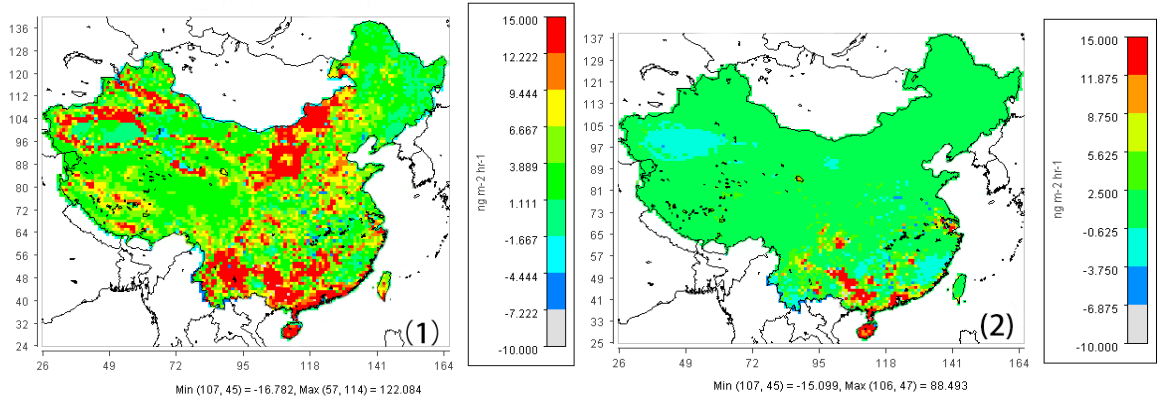

844

845

846 Figure 6. Simulated results of (1) mean annual air-foilage flux, and (2) mean annual air-soil flux in the
 847 study domain.

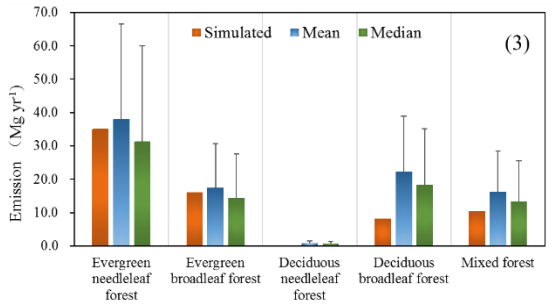

852 Figure 7. Model estimates of (1) annual mean Hg^0 fluxes in the model domain; (2) seasonal mean Hg^0
 853 fluxes in winter, (3) seasonal mean Hg^0 fluxes in spring, (4) seasonal mean Hg^0 fluxes in summer, (5)
 854 seasonal mean Hg^0 fluxes in autumn, and (6) monthly Hg^0 fluxes in the grid cells (box and whisker chart
 855 showing maximum, 75th percentile, mean, median, 25th percentile, and minimum).

856

857

858

859 Figure 8. Model verification: (1) model estimates of Hg⁰ uptake by foliage (which include the uptake by
 860 stoma less the re-emission and from cuticle) and by stoma, compared to the estimate (mean and 95%
 861 confidence interval) of Hg⁰ uptake using Monte Carlo (M-C) simulation of the observational data; (2)
 862 scatter plot of the observed fluxes vs. simulated fluxes for different landuses (the flux observations are
 863 described in detailed in Table S2), (3) comparison between simulated exchange and measured exchange
 864 over soil under canopy, and (4) comparison between simulated exchange and measured exchange over
 865 grasslands, cropland and water surface. The mean and median of Figures 10.3 and 10.4 are based on the
 866 filed data from peer-review literatures (n=19 for forests; n=12 for grasslands; n=42 for croplands; n=51 for
 867 water bodies). Note that the exchange over deciduous needleleaf forests in Figure 8.1 is small because of
 868 the small forest area.
