15

16   **Abstract**: Mercury (Hg) emission from natural surfaces plays an important role in global Hg cycling. The

17   present estimate of global natural emission has large uncertainty and remains unverified against field data,

18   particularly for terrestrial surfaces. In this study, a mechanistic model is developed for estimating the

19   emission of elemental mercury vapor (Hg^0) from natural surfaces in China. The development implements

20   recent advancements in the understanding of air-soil and air-foliage exchange of Hg^0 and redox chemistry

21   in soil and on surfaces, incorporates the effects of soil characteristics and landuse changes by agricultural

22   activities, and is examined through a systematic set of sensitivity simulations. Using meteorology simulated

23   by the Weather Research and Forecasting Model (WRF version 3.7), the exchange of Hg^0 between the

24   atmosphere and natural surfaces in Mainland China is estimated to be 465.1 Mg yr^{-1}, including 565.5 Mg

25   yr^{-1} of emission from soils, 9.0 Mg yr^{-1} of emission from water body, and 100.4 Mg yr^{-1} uptake by vegetation.

26   The air-surface exchange is strongly dependent on the landuse and meteorology, with 9% of net emission

27   from forest ecosystems, 50% from shrubland, and savanna and grassland, 33% from cropland, and 8% from

28   other landuses. Given the large agricultural land area in China, farming activities play an important role on

29   the air-surface exchange in farmland. Particularly, rice field shift from a net sink (3.3 Mg uptake) during

30   April to October (rice planting) to a net source when the farmland is not flooded (November-March).

31   Summing up emissions from each landuse, more than half of the total emission occurs in summer (51%),

32   followed by spring (28%), autumn (13%) and winter (8%). Model verification is accomplished using

33   observational data of air-soil/air-water fluxes and Hg deposition through litterfall for forest ecosystems in

34   China and Monte Carlo simulations. In contrast to the earlier estimate by Shetty et al. (2008) that reported

35   large emission from vegetative surfaces using an evapotranspiration approach, the estimate in this study

36   shows natural emissions are primarily from grassland and dry cropland. Such an emission pattern may alter

37   the current understanding of Hg emission outflow from China as reported by Lin et al. (2010b) because of

38   a substantial natural Hg emission occurs in West China.

39

1. Introduction

Accurate inventories of mercury (Hg) emission is the foundation for assessing Hg global biogeochemical cycling (Selin, 2009;Streets et al., 2009;Streets et al., 2011). Hg emission from anthropogenic sources has been quantified and updated with reasonable consistency since the 1990s (Streets et al., 2009;Streets et al., 2011;Zhang et al., 2015;Zhang et al., 2016). In particular, the inclusion of the release from commercial products and modifications of Hg emission speciation profiles dependent on implementation and upgrade of air pollution control technologies have substantially reduced the uncertainty level of anthropogenic Hg emission estimates(Horowitz et al., 2014;Zhang et al., 2016). In contrast, estimates of natural Hg emission are poorly constrained within large uncertainties (± 2000 Mg yr^{-1}), limiting a comprehensive understanding of global/regional Hg cycling budgets (Pirrone et al., 2010;Wang et al., 2014b;Song et al., 2015). In light of the anticipated decrease of Hg emission from anthropogenic sources driven by the legally binding Minamata Convention (De Simone et al., 2015), a better quantification of natural Hg emission is critical in evaluating the effectiveness of policy actions (Selin, 2009;Pirrone et al., 2010;Song et al., 2015).

One of the challenges in predicting natural Hg emissions is to provide physical robust schemes for air-surface Hg^0 exchange. Such gas exchange schemes are complicated and involve not yet well understood processes in multiple environmental compartments, such as in terrestrial vegetative ecosystems. Thus, estimates from regression schemes obtained from correlations between Hg flux and environmental parameters (e.g., temperature, solar radiation, etc.) using limited datasets may not be representative (Xu et al., 1999;Bash et al., 2004;Lin et al., 2005;Gbor et al., 2006;Shetty et al., 2008;Selin et al., 2008;Smith-Downey et al., 2010) because relationship between measured fluxed and environmental parameters are based on limited field data that tend to be site-specific, which cannot account for the heterogeneity in soil properties and vegetative coverages. Although the bidirectional resistance schemes applied to describe the Hg^0 gas exchange may appropriate (Bash, 2010;Wang et al., 2014b;Wright and Zhang, 2015), they are limited by the availability of comprehensive soil property data and other physicochemical parameters such as Hg^{II} reduction kinetics and physical characteristics of interfacial exchanges(Bash, 2010;Wang et al., 2014b), leading to inconsistences between simulated and measured fluxes. Other challenges including

Atmospheric

EGU

68   acquiring and assimilating meteorology, landuse, and soil Hg and moisture content data into the model

69   scheme over a large geospatial coverage in China warrant for further model development to estimating

70   natural Hg emission (Wang et al., 2014b).

71   Advances in the fundamental understanding of Hg^{II} reduction provide new opportunities to build a

72   more physically robust air-soil exchange scheme. These include constrained pseudo-first-order reduction

73   rate constant of Hg^{II} in soil (10^{-11} to 10^{-10} s^{-1}, (Scholtz et al., 2003;Qureshi et al., 2011) and in natural water

74   (0.2-1.0 h^{-1}, O'Driscoll et al., 2006;Qureshi et al., 2010), where the UV-band of actinic light is a primary

75   driver for Hg^{II} photo-reduction in soils and water bodies rather than its visible part (Moore and Carpi,

76   2005;Si and Ariya, 2011). Besides constrained effective rate constants, the role of specific substructures

77   (e.g. functional groups such as -C(O)OH, -SH, -OH,) of DOM in the reduction mechanism has been

78   pinpointed by kinetic studies of various model compounds(He et al., 2012;Si and Ariya, 2011, 2015). In

79   some of these specific reactions, the presence of molecular oxygen shows an inhibiting role in the reduction

80   to Hg^0 whereas e.g. the photo-reduction of HgII bound to R-SH compounds proceeds to Hg^0 irrespective of

81   dissolved O_2 (Si and Ariya, 2011). For the photo-reduction in dry soil, the first-order rate constants are

82   0.007-0.028 h^{-1} for $HgCl_2$ coated over sand and 0.003-0.006 h^{-1} for Hg^{II} in a natural soil (Quinones and

83   Carpi, 2011). In the dark condition at room temperature (293 K), reduction rate constants of the reducible

84   Hg in soil are 0.001-0.002 h^{-1} (Pannu, 2012).

85   The intercontinental transport of Hg from China has been considered to significantly contribute to Hg

86   deposition in North America (Jaffe et al., 2005;Strode et al., 2008;Lin et al., 2010b;Chen et al., 2014). Wang

87   et al. (2014a) suggested the Hg emissions from natural and anthropogenic sources were comparable. Using

88   an outdated model scheme, Shetty et al. (2008) estimated 462 Mg yr^{-1} of Hg emitting into atmosphere in

89   China. This natural emission inventory has been used in East Asia CMAQ simulations to assess regional

90   Hg budgets (Lin et al., 2010b;Zhu et al., 2015a). However, the large uncertainty on the estimate of natural

91   Hg emission warrants a re-assessment of these earlier modeling efforts. In addition, the dataset of soil Hg

92   concentration in Shetty et al. (2008) is more than 3 decades old and requires updates to appropriately

93   represent spatially-resolved soil Hg contents that have been modified due to the rapid industrial

94   development and urbanization occurring in China since 1980s. In the meantime, the National Multi-Purpose

Atmospheric
Chemistry
and Physics
Discussions

95   Regional Geochemical Survey (NMPRGS) of China has been completed in 2014 (Li et al., 2014). This

96   database provides soil Hg content for the agricultural and industrialized regions at resolution of 4 km, which

97   forms a basis of greatly reducing the uncertainty of Hg natural emission previously hampered by data

98   deficiency. In addition, a recent datasets of terrestrial flux in Mainland China reported in the literature

99   allows verification of model results and optimization of model schemes. In particular, recent field

100   measurements of Hg^0 air-surface exchange in China documented the flux characteristics over different land-

101   uses including urban-rural-remote differences and effects of crop rotation over agricultural lands (Fu et al.,

102   2008;Fu et al., 2010;Zhu et al., 2011;Fu et al., 2012;Fu et al., 2013a;Sommar et al., 2013a;Sommar et al.,

103   2013b;Zhu et al., 2013;Sommar et al., 2015a;Zhu et al., 2016).

104   In light of the scientific advancements and renewed data availability discussed above, this work

105   develops a state-of-the-science mechanistic model for estimating the natural Hg emission in China. For the

106   first time, the simulated natural emission flux is verified with field measurements over different land

107   surfaces in this modeling effort. The spatial, temporal and seasonal characteristics of the model-estimated

108   emissions over soil, vegetative surface and water are presented and compared to the estimates performed

109   by Shetty et al. (2008). The implications of the new natural emission estimate are discussed in terms of

110   chemical transport of Hg emission in China and the need for a re-assessment of mercury emission outflow

111   in China.

112

113   **2. Methods**

114   **2.1 Model description**

115   **2.1.1 Reduction of Hg^{II} in soil**

116   Based on Hg^{II} reduction mechanisms proposed in peer-reviewed literature (Moore and Carpi,

117   2005;Quinones and Carpi, 2011;Si and Ariya, 2011;Pannu, 2012), a new model scheme describing Hg^0

118   formation from Hg^{II} reduction in soil is developed using three reaction pathways: (1) photo-reduction of

119   Hg^{II} in soil pore water (Hg_1^0), (2) photo-reduction Hg^{II} associated with soil particles (Hg_2^0), and (3) Hg^{II}

120   reduction through non-photochemical pathways (Hg_3^0). The production of Hg^0 in surface soil is calculated

121   as:

Atmospheric
Chemistry
and Physics
Discussions

122    $\frac{dHg_1^0}{dt} = K_1 \cdot Hg_{s,m}$ (1)

123    $\frac{dHg_2^0}{dt} = K_2 \cdot Hg_{p,m}$ (2)

124    $\frac{dHg_3^0}{dt} = K_3 \cdot Hg_{t,m}$ (3)

125   where K_1 is the photo-reduction rate constant of Hg^{II} in soil pore water (a comprehensive parameter list with

126   units is shown in Table 1), K_2 is the photo-reduction rate constant of Hg^{II} associated with soil particles, K_3

127   is the Hg^{II} reduction rate constant in soil through non-photochemical pathways, $Hg_{s,m}$ is the Hg^{II} pool in soil

128   pore water, $Hg_{p,m}$ is the labile Hg^{II} pool available for reduction in soil particles, $Hg_{t,m}$ is the total reducible

129   Hg^{II} pool in soil. Based on the Arrhenius equation, K_1 and K_2 are parameterized as a function of solar

130   irradiance and soil temperature, and K_3 is parameterized as the function of soil temperature and soil moisture:

131    $K_1 = k_1 \cdot R \cdot \gamma \cdot e^{\frac{T-T_f}{T_f}\frac{E_a}{T}}$ (4)

132    $K_2 = k_2 \cdot R_i \cdot \gamma \cdot e^{\frac{T-T_f}{T_f}\frac{E_a}{T}}$ (5)

133    $K_3 = k_3 \cdot e^{\frac{T-T_f}{T_f}\frac{E_a}{T}} \cdot e^{\frac{\theta-\theta_f}{\theta_f}\frac{E_b}{\theta}}$ (6)

134   where k_1 and k_2 are the photo-reduction rate constants at the reference soil temperature (T_f, Table 1). k_3 is

135   the dark-reduction rate constant at the reference soil temperature and soil moisture (θ_f, Table 1). R and R_i

136   are total solar radiation in the soil profile and under the canopy, respectively. γ is the ratio of UV over total

137   solar radiation. An empirical rule suggests that a 10°C temperature rise doubles reaction rates for many

138   chemical reactions near room temperature (Kissinger, 1957;Hood et al., 1975), which has been evinced to

139   apply for Hg^{II} reduction in boreal soil (Pannu et al., 2014). In addition, Hg emission flux from soil substrate

140   doubles in the dark for a 25% increase of soil moisture content (Lin et al., 2010a). Based on these

141   observations, Equations 4-6 can be simplified as:

142    $K_1 = k_1 \cdot R \cdot \gamma \cdot 2^{\frac{T-T_f}{10}}$ (7)

143    $K_2 = k_2 \cdot R_i \cdot \gamma \cdot 2^{\frac{T-T_f}{10}}$ (8)

144    $K_3 = k_3 \cdot 2^{\frac{T-T_f}{10}} \cdot 2^{\frac{\theta-\theta_f}{25\%}}$ (9)

145   R and R_i in Equations 7-8 are calculated based on the Beer-Lambert law:

Atmospheric
Chemistry
and Physics
Discussions

Open Access

146     $R_i = R_0 \cdot e^{-K \cdot LAI}$ (10)

147     $R = R_i \cdot \int_0^l e^{-k_r \cdot l} dl$ (11)

148   where R_0 is solar irradiance above the canopy, K is the canopy light extinction coefficient, LAI is leaf area

149   index, k_r is the light extinction coefficient in soil, l is the depth of surface soil.

150     $Hg_{s,m}$ and $Hg_{p,m}$ and $Hg_{t,m}$ are calculated based on Lyon et al. (1997):

151     $Hg_{s,m} = \frac{[Hg_t] \cdot BD}{\theta + kd \cdot BD} \cdot V \cdot \theta \cdot 10^6$ (12)

152     $Hg_{p,m} = \frac{[Hg_t] \cdot BD \cdot kd}{\theta + kd \cdot BD} \cdot BD \cdot V \cdot \varphi$ (13)

153     $Hg_{t,m} = [Hg_t] \cdot BD \cdot V \cdot \varphi$ (14)

154   where $[Hg_t]$ is the total Hg^{II} concentration in soil, BD is the soil bulk density, θ is the soil moisture, and

155   V is the soil volume, φ is the ratio of reducible Hg over total Hg in soil. kd is the soil-water partition

156   coefficient and calculated following Lee et al. (2001) and Sauve et al. (2000):

157     $\log kd = r \cdot pH + s \cdot \log(1000 \cdot foc) + t$ (15)

158   where f_{oc} is the fraction of organic carbon in surface soil. The values r, s and t are regression coefficients.

159   Following Obrist et al. (2014), we assume that the Hg^0 emission from soil is controlled by diffusion

160   process after Hg^{II} reduction. Basing on the Fick's first law, the observed air-soil flux exchange can be

161   calculated as:

162     $F_{soil} = Hg_1^0 + Hg_2^0 + Hg_3^0 - D_{soil} \frac{GEM}{d/2} \Delta t$ (16)

163     $D_{soil} = 0.66 \cdot (\sigma - \theta) \cdot D_0$ (17)

164   where D_{soil} and D_0 are the Hg^0 vapor diffusion coefficient in soil and ambient air. GEM is the atmospheric

165   Hg^0 concentration, σ is the soil porosity. Hence, during a time period Δt, the soil Hg^0 vapor compensation

166   point used in bidirectional resistance model can be derived as:

167     $\chi_g = \frac{(Hg_1^0 + Hg_2^0 + Hg_3^0) \cdot d/2}{D_{soil} \cdot \Delta t}$ (18)

168

169   **2.1.2 Updates for air-terrestrial exchanges**

170   Extending from the two categories (vegetated surface canopy and bare land) considered in Wang et al.

171   (2014b), the terrestrial system is divided into four categories: vegetated surface with unsaturated soil

Atmospheric
Chemistry
and Physics
Discussions

172 moisture (e.g., forest, grassland, shrubland, etc.), vegetated surface with saturated soil (i.e., rice paddy),

173 barren or sparsely vegetated land, and snow/ice surface. The governing equation for calculating Hg^0 air-

174 surface exchange over vegetated surfaces is:

175 $$F_{cnp} = \frac{\Delta t}{(R_a + R_b)}(\chi_{cnp} - C_{atm}) \qquad (19)$$

176 where R_a is the aerodynamic resistance, R_b is the quasi-laminar sub-layer resistance, C_{atm} is the

177 atmospheric Hg concentration, χ_{cnp} is the overall compensation point. For the canopy biomes with

178 unsaturated soil, χ_{cnp} is parameterized as Wang et al. (2014b):

179 $$\chi_{cnp} = \frac{\frac{\chi_c}{R_c} + \frac{\chi_s}{R_s} + \frac{\chi_g}{R_g + R_{ac}} + \frac{C_{atm}}{R_a + R_b}}{\frac{1}{R_c} + \frac{1}{R_s} + \frac{1}{R_g + R_{ac}} + \frac{1}{R_a + R_b}} \qquad (20)$$

180 where χ_c is the cuticular compensation point, χ_s is the stomatal compensation point, R_c is the cuticular

181 resistance, R_s is the stomatal resistance, R_g is the soil diffusion resistance, R_{ac} is the in-canopy

182 aerodynamic resistance (Table 1 in details). While for vegetated surface with saturate soil, χ_{cnp} is

183 parameterized as following:

184 $$\chi_{cnp} = \frac{\frac{\chi_c}{R_c} + \frac{\chi_s}{R_s} + \frac{\chi_w}{R_w + R_{ac}} + \frac{C_{atm}}{R_a + R_b}}{\frac{1}{R_c} + \frac{1}{R_s} + \frac{1}{R_w + R_{ac}} + \frac{1}{R_a + R_b}} \qquad (21)$$

185 where χ_w is the soil compensation point, R_w is the water diffusion resistance.

186 The governing equation for air-surface exchange in barren or sparsely vegetated land, and snow/ice

187 surface is:

188 $$F_{bls} = \frac{\Delta t}{R_a + R_b + R_g}(\chi_g - C_{atm}) \qquad (22)$$

189 For bare land, R_g is calculated following Zhang and Lindberg (1999):

190 $$R_g = \frac{d/2}{0.66 \cdot (\sigma - \theta) \cdot D_0} \qquad (23)$$

191 For snow/ice surface, R_g is evaluated following Zhang et al. (2012b):

192 $$\frac{1}{R_g} = \frac{\alpha_{Hg^0}}{R_{g(SO_2)}} + \frac{\beta_{Hg^0}}{R_{g(O_3)}} \qquad (24)$$

193 where $R_{g(SO_2)}$ and $R_{g(O_3)}$ are the diffusion resistances of SO_2 and O_3, α_{Hg^0} is the Hg^0 scaling factor

194 based on SO_2, β_{Hg^0} is Hg^0 scaling factor based on O_3. The formulation of $R_{g(SO_2)}$ and $R_{g(O_3)}$ has been

195 described previously (Zhang et al., 2003;Wang et al., 2014b). χ_g is assumed to be 3 ng m^{-3} based on field

Atmospheric
Chemistry
and Physics
Discussions

196 measurements at air-snow interface (Mann et al., 2015;Lalonde et al., 2003;Fain et al., 2007;Maxwell et al.,

197 2013). Other parameters in Equations 19-24 are described in details in Wang et al. (2014b).

2.2 Model configuration and data

199 The modeling domain is in Lambert Conformal projection, with 223×149 grid cells at 36-km spatial

200 resolution. The modeling period is one year (2013). Hourly meteorological data are prepared using the

201 Weather Research and Forecasting (WRF) model Version 3.7. Sensitivity analysis in Wang et al. (2014b)

202 showed that accurate model representation of environmental parameters (e.g., temperature, solar irradiance,

203 etc.) greatly improves the flux estimate. To obtain the best physics and dynamics options of WRF for the

204 China domain, a L_{25} (5^6) orthogonal design of experiments is utilized (Supplementary material, Table **S1**).

205 The best combination of meteorological physics options is selected based on model evaluation metrics R

206 (correlation coefficient) and RMSE (root-mean-square error) between simulated outputs of each

207 combination of options and observed values in 750 meteorological stations. The selected physics options

208 are Thompson (Microphysics Options), Betts-Miller-Janjic (Cumulus Parameterization Options), RRTMG

209 (Radiation Physics Options) and BouLac (PBL Physics Options) based on the results of meteorological

210 model performance evaluation (Figure **S1**).

211 The datasets for surface soil properties (1 km spatial resolution) containing organic matters contents,

212 pH, bulk density and porosity are adopted from Shangguan et al. (2013). The land cover data (1 km spatial

213 resolution) is obtained from Ran et al. (2012). The land cover map represents the best available datasets

214 and follows the IGBP (International Geosphere-Biosphere Programme) classification system (Figure **S2**).

215 The ratio of rice planting fields in China during each month are classified following the method used in Liu

216 et al. (2013). The rice planting seasons are April to October in South China (including double rice planting),

217 and May to October in Northeast China (single rice planting). The LAI data, also with a 1 km spatial

218 resolution, are adopted from Yuan et al. (2011). The soil Hg content information utilized by Shetty et al.

219 (2008) is updated and greatly expanded with the comprehensive NMPRGS dataset (Li et al., 2014). These

220 high resolution datasets were re-gridded into the domain specification for each landuse using the spatial

221 tools in ArcGIS 10.1. The soil Hg content varies with landuse types, containing 119±9~211±83, 61±33 ~

222   197±96, 80±59~82±74, 80±59~82±74 and 31±15~162±83 of Hg for forest ecosystems, shrubland,

223   savanna/grassland, cropland, and other landuses, respectively (Table 1).

224   In the simulation, the Hg^0 concentration retrieved from the output of the Hg extension of Community

225   Multi-scale Air Quality modeling system (CMAQ-Hg) version 4.7 for the same modeling period is applied

226   to represent the ambient air concentration of Hg^0 (Lin et al., 2010b). The simulation does not incorporate

227   the feedback of the air-surface exchange to the air concentration because the feedback of the air-surface

228   exchange to the air concentration does not significantly modify the atmospheric Hg^0 concentration, and the

229   typical variation range of ambient Hg^0 concentration is not a sensitivity parameter for flux change (Wang

230   et al., 2014b). The model algorithms are coded in FORTRAN 90 and Network Common Data Form

231   (NetCDF) version 4.3. The gridded model results are visualized by the Visualization Environmental for

232   Rich Data Interpretation (VERDI) version 1.5.

233

234   **3 Results and discussion**

235   **3.1 Verification for soil Hg reduction scheme**

236   Values of all model parameters used in the simulation are showed in Table 1. The value of k_1 is assumed

237   to be 6×10^{-9} m^2 W^{-1} s^{-1} based on the relationship between radiant intensity and apparent photo-reduction

238   rate constant in aerated solution observed by Si and Ariya (2011). Considering the 2 mm maximum

239   photolysis penetration depth in soil (Hebert and Miller, 1990), the measured rate constant in soil particles

240   (depth = 2.07 mm) from Quinones and Carpi (2011) is 2×10^{-3} m^2 W^{-1} h^{-1} (k_2) with respect to the pool of

241   labile Hg^{II} available for reduction. The value of k_3 is assumed to be 1.0×10^{-3} h^{-1} based on the average rate

242   constants for dark (thermal) reduction (Pannu, 2012). The mean ratio of reducible Hg in soil is assumed to

243   be 0.03 for the soil with vegetation based on measurements from Pannu (2012). No data is available for the

244   bare soil. Data from Lindberg et al. (1999) hints that Hg enriched desert soil (1400-5000 ng g^{-1} total Hg)

245   produces a nominal Hg^0 efflux in the range from 40 to 60 ng m^{-2} h^{-1}. Derived from back-calculation taking

246   pore diffusion into account, the fraction of reducible Hg is predicted at least 10 times lower (≤ 0.003) than

247   that in the soil with vegetation.

Atmospheric
Chemistry
and Physics
Discussions

248   Sensitivity analyses using a box model for a typical forest soil are performed to gauge the selected rate

249   coefficients and the results are showed in Figure 2. With $k_1 = 6.0 \times 10^{-9}$ m^2 W^{-1} s^{-1}, $k_2 = 2 \times 10^{-3}$ m^2 W^{-1} h^{-1}, k_3

250    $= 1.0 \times 10^{-3}$ h^{-1}, the Hg^0 vapor concentration in soil porous media is estimated to be 4.5 ng m^{-3}, comparable

251   to the measured concentration (4.1±2.0 ng m^{-3}) in the surface forest floor (Moore and Castro, 2012),

252   suggesting that the selected values for the empirical constants appropriately represent environmental

253   condition. Generally, the range of Hg^0 vapor in all simulations is 1.5-6.7 ng m^{-3}. Less than 0.1% Hg^0 vapor

254   is from photo-reduction in soil solution as the Hg pool in soil solution is small ($\leqslant$ 0.1% of total Hg

255   concentration). A ~16% fraction of the pore Hg^0 concentration derives from thermal Hg^{II} reduction,

256   contributing to 0.5-1 ng m^{-3} of Hg^0 vapor present in soil gas. Hg^0 soil gas concentrations are typically lower

257   than atmospheric Hg concentration (1-2 ng m^{-3}) in forest ecosystems (Carpi and Lindberg, 1998;Ericksen

258   and Gustin, 2006;Kuiken et al., 2008a;Kuiken et al., 2008b;Obrist et al., 2014;Fu et al., 2015) and suggest

259   forest floor acting as a sink at night. This is consistent with the sign of nocturnal fluxes observed over forest

260   floor settings (Carpi and Lindberg, 1998;Ericksen et al., 2006;Kuiken et al., 2008a;Kuiken et al., 2008b).

261   Moore and Carpi (2005) reported that the Hg flux under sun-lit condition is 3-5 times higher than the value

262   under dark condition. This developed model is capable of simulating such observation that the photo-

263   reduction in soil particles dominates the formation of Hg^0 vapor.

264   Figure 3 illustrates the model response to the model variables at the two experimental levels in Table

265   2. Noting that the two experimental levels represent the typical endpoints of environmental parameter

266   ranges and therefore the range of flux response to the possible variation of environmental factors can be

267   measured. On average, increasing soil bulk density from 0.1 to 1.5 g cm^{-3}, and Hg content from 50 to 1000

268   ng g^{-1}, and soil temperature from 0 to 30 ˚C, and solar radiation from 0 to 1000 W m^{-2}, will significantly

269   enhance the flux by 112-135 ng m^{-2} h^{-1}. Additional 112-128 ng m^{-2} h^{-1} synergistic effects from the

270   combination of above parameters are also predicted. On the other hand, increasing leaf area index (LAI)

271   from 0 to 7 m^2 m^{-2} reduces the flux by 131 ng m^{-2} h^{-1}. In addition, LAI could offset the positive effects from

272   bulk density, soil Hg concentration, and solar radiation above canopy, leading to an additional -114 to -131

273   ng m^{-2} h^{-1} decrease, indicating that the canopy shading substantially constrains soil Hg evasion, consistent

274 with the shading could decrease 70-90% fluxes compared to non-shaded soils in filed measurements (Carpi

275 and Lindberg, 1998;Zhang et al., 2001;Choi and Holsen, 2009).

276 Compared to the earlier sensitivity analysis in Wang et al. (2014b), the soil organic matter content

277 appear not to considerably influence the simulated flux (p = 0.915). In the new scheme, the soil organic

278 matter is not incorporated into either K_2 or K_3, in accordance with the findings of Pannu (2012). While Hg^0

279 evasion from substrates coated with $HgCl_2$ and humic matter is inversely correlated with humic matter

280 content both in the dark and under irradiation, the inhibitory effect from humic matter is not linear to its

281 content (Mauclair et al. (2008). For instance, relatively small differences are observed at humic matter

282 content > 1% (Mauclair et al., 2008). Additionally, the effect of soil organic matter type has not been

283 comprehensively investigated (Zhang and Lindberg, 1999;Bash et al., 2007). Further study to quantify the

284 corresponding reduction rate constants associated with different types of soil organic matters (or species)

285 and solar radiation, as well as field flux data that relate the observed flux intensity to a given type of organic

286 matter, can further improve the present model parameterization.

287

288 **3.2 Diurnal variation of natural Hg^0 emissions in China**

289 Table 3 shows the annual mean air-surface fluxes for different landuse types. Annual mean air-foliage

290 fluxes range from -0.2 to -4.5 ng m^{-2} h^{-1}, with the highest value over the woody savannas, and the lowest

291 over deciduous forests (Table 3). The diurnal variation for air-foliage flux is displayed in Figure 4. Higher

292 deposition occurs during early morning (8:00-10:00) and later afternoon (16:00-17:00) due to the suitable

293 air temperature and solar irradiance that induces Hg uptake by stomata. The rates of Hg uptake during

294 midday are comparatively weaker due to the stronger irradiance and higher temperature. This bimodal

295 pattern is consistent with field observations (Lindberg et al., 2002;Poissant et al., 2008;Fritsche et al.,

296 2008;Sommar et al., 2015a), suggesting that the model is capable of simulating the diurnal pattern of air-

297 foliage exchange of Hg^0. Such pattern in the modelling is caused by re-emission of the deposited Hg on the

298 surface foliage through photo-reduction under the strong solar radiation during noontime, and also the offset

299 effect from emissions from underlying soils. Except for urban lands, the strength of diurnal deposition for

Atmospheric
Chemistry
and Physics
Discussions

300   the other landuse is controlled by LAI, solar radiation, and air temperature. The elevated atmospheric Hg

301   concentration is the important parameter to induce Hg uptake by growing foliage in urban lands.

302   Simulated mean air-soil fluxes range from 0.1 to 23.3 ng m^{-2} h^{-1}, with the lowest flux over barren

303   vegetated lands and the highest over urban lands (Table 3). This suggests that the simulated air-soil fluxes

304   greatly vary over different landuses. There are distinct diurnal variations in terrestrial ecosystems (Figure

305   5). Such diurnal pattern is caused by the variation of solar radiation, close to zero at night and peaking at

306   13:00 to 15:00 (UTC+8). Similar diurnal patterns have been observed during filed measurements for forest,

307   grassland, and cropland in China (Feng et al., 2005;Fu et al., 2008;Fu et al., 2012;Zhu et al., 2013). The

308   degree of diurnal variability for each landuse in terrestrial ecosystems is highly related to the LAI. Higher

309   LAI gives a more intensive canopy shading and largely inhibits Hg evasion from soil under canopy. This is

310   also the main reason for relative weaker diurnal variation over forest soils compared to shrubland, grassland

311   and cropland (Figure 5). The synergistic interactions between low vegetation cover and high soil

312   concentration (Mean=162±83 ng g^{-1}) results in the strongest diurnal variation for urban land-types.

313   The simulated annual mean air-water flux is 3.4 ng m^{-2} h^{-1}. The diurnal variability for air-water flux is

314   weaker since wind speed is a more influential driver than sun-light (Wang et al., 2014b), consistent with

315   the diurnal variation observed in field studies that meteorology and photochemical process are the primary

316   factors(Feng et al., 2002;Feng et al., 2003;Wang et al., 2006;Feng et al., 2008;Fu et al., 2010;Fu et al.,

317   2013a;Fu et al., 2013b).

318   Overall, the annual net natural emission in China is 465.1 Mg Hg (Table 3), including 565.5 Mg yr^{-1}

319   of emission from soil, 9.0 Mg yr^{-1} of emission from water body, and 100.4 Mg yr^{-1} deposition (uptake) on

320   vegetated landscapes. The annual quantity of emission from soil is comparable to the estimate (528 Mg yr^{-1}

321    $^{-1}$) based on the scale-up calculation using measured air-soil fluxes (Fu et al., 2015a) that suggest emissions

322   from cropland and grassland are the most important contributor. Of the total Hg^0 emission estimated by the

323   model, 50% is from shrubland, savanna and grassland (C6-C11, 38% total landuse); 33% is from cropland

324   (C12-C13, 22% total landuse); 9% is from forest (C1-C5, 14% total landuse); and 8% is from other landuse

325   types. The forest contributes to 28% of Hg uptake by foliage; shrubland, savanna and grassland contribute

326   to 38%; cropland contributes to 33%; and other landuse types contribute to 1%.

Atmospheric
Chemistry
and Physics
Discussions

327   Although soil Hg contents in forest ecosystems are 2-4 times higher than that in grassland and cropland,

328   total annual fluxes above the canopy (soil+foliage) of forest ecosystems are 1-6 times lower than the values

329   in other two types of landuses (Table 3). This highlights the importance of canopy cover in natural emission

330   process of Hg^0. It is noteworthy that the landuse data are based on the survey in 2000 (Ran et al., 2012).

331   During last 15 years, the forested area in China increased from 14.0% to 21.6% (FAO, 2014), benefiting

332   from implementation of governmental Grain for Green Project and stricter natural forest protection actions.

333   Assuming that annual mean air-surface fluxes are at the same level as in this study, the total quantity of

334   natural Hg emission in 2014 is approximately 5% smaller than this estimate because of the increasing forest

335   coverage. Given the forest coverage is projected to be 24% in 2030, and 26% in 2050 (FAO, 2014), the

336   total quantity of natural Hg emission in China during 2030-2050 would decrease 9-10 %.

337

3.3 Spatial distribution of natural Hg emission in China

339   The annual spatial distribution of air-foliage flux can be divided by the well-known geo-demographic

340   demarcation line, "Heihe-Tengchong Line" (Figure 6.1). The vegetation on the east side of the line is much

341   denser than on the west side of the line because of abundant annual precipitation ($\geqslant$ 800 mm, Figure **S2**),

342   which leads to much stronger Hg^0 uptake by vegetation (>90% of the grid cells have a flux below -1.0 ng

343     $m^{-2} h^{-1}$ on the east side, compared to >90% of the grid cells has a flux above -0.5 ng $m^{-2} h^{-1}$ on the west side).

344   There is an enhanced Hg deposition in South China (22°N-27°N,105°E-113°E, Figure 6.1) where fluxes

345   ranging -3.8 to -19.1 ng $m^{-2} h^{-1}$. This can be explained by an elevation in atmospheric Hg concentrations

346   and a more intense vegetative Hg^0 uptake. Field measurements suggest that this region has dense vegetation

347   (i.e., high LAI, Figure **S3**) and elevated (2-10 ng m^{-3}) atmospheric Hg concentration (Fu et al., 2015;Zhu,

348   2014), which enhances Hg uptake by foliage. Specifically, evergreen broadleaf forest has the highest LAI

349   compared to other type of forests (Liu et al., 2012) and shows enhanced Hg uptake (up to -4.5 ng $m^{-2} h^{-1}$

350   mean flux). Although the direct measurement of Hg deposition flux through vegetative uptake is still not

351   feasible presently, the measured Hg input through litterfall (Fu et al., 2015) suggested the rate of Hg uptake

352   by foliage could up to 4-12 ng $m^{-2} h^{-1}$, comparable to the simulation results in this study.

Atmospheric
Chemistry
and Physics
Discussions

353   Figure 6.2 shows the spatial distribution of annual air-soil fluxes. There are three high flux regions

354   (mean flux $\geq$ 10 ng m^{-2} h^{-1}): cropland/grassland in South and Southwest China (mainly in Guangdong,

355   Guangxi, Guizhou, Yunnan, Chongqing and Sichuan provinces), cropland in North China (Heibei, Henan,

356   and Shangdong provinces), and grassland in North China (Inner Mongolia, Shanxi, and Shaanxi, and

357   Xinjiang provinces). Such elevated fluxes in first two regions have been confirmed in field

358   observations(Feng et al., 2005;Wang et al., 2005;Wang et al., 2006;Fu et al., 2008;Sommar et al., 2015b).

359   Elevated fluxes in South and Southwest China are attributed to the elevated Hg concentration in soil (85%

360   of grid cells has a soil Hg content $\geq$100 ng g-1, Figure 1). Interestingly, soil Hg content is not the primary

361   factor causing the high fluxes in the other two regions (70% of grid cells has a soil Hg content $\leq$50 ng g^{-}

362   ^{1}). Dry deposition of PBM and/or GOM plausibly supply to the reducible Hg in soil for gradual reduction

363   and volatilization as Hg^{0} (Sommar et al., 2015b). The relatively low LAI (Figure S3), strong solar irradiance

364   and high soil temperature (Figure **S4-S5**) during summer/autumn contribute to the high simulated emissions.

365   The lower simulated fluxes in desert regions compared to fluxes over grassland (Figure 6.2) are caused by

366   the lower fraction of reducible Hg in soils.

367   Since the soil Hg^{0} efflux is the primary source of natural Hg emission, the spatial distribution of the

368   natural Hg emission is strongly influenced by air-soil flux (Figure 7.1). There is a distinct seasonal variation

369   in the emission quantity: 8% in winter, 28% in spring, 51% in summer, and 13% in autumn (Figure 7.2-

370   7.5). Elevated fluxes mainly cluster in South and Southwest China in winter because of higher soil Hg

371   content (Figure 1), and relatively higher temperature and stronger irradiance. Highest correlation

372   coefficients are found between the flux and soil Hg concentration and soil bulk density (Table 4), suggesting

373   that the soil Hg^{0} pool is a major factor influencing Hg emission in winter. From the cold to warm season,

374   fluxes gradually increase from low latitude to high latitude with the seasonal change of temperature and

375   solar radiation (Figure 7.2-7.4). Under the strong irradiance and temperatures during summer, >65% of the

376   grid cells in the domain has a flux above 10 ng m^{-2} h^{-1} and the effect of soil Hg content becomes weaker

377   (Table 4). In autumn, high flux occurs over the cropland of Central and North China, and over the regions

378   with high soil Hg content (Figure 7.6) because of the decreasing temperature and solar irradiance. Overall,

Atmospheric
Chemistry
and Physics
Discussions

379   72% of natural Hg emission occurs from May to September, with higher emission over grassland and

380   cropland in North China in these months.

381   It is worth noting that parts of regions in South China (23˚N-31˚N, 110˚E-120˚E, mainly in Fujian,

382   Jiangxi, Hunan, Hubei, and Anhui provinces) and Northeast China (39˚N-51˚N, 130˚E-134˚E, mainly in

383   Liaoning, Jilin and Heilongjiang provinces) have relatively lower fluxes (-6.9~9.0 ng m^{-2} h^{-1}) during

384   summer and autumn time (Figure 7.4-7.5). In addition to the impact from the intensive canopy cover in

385   forests (Figure **S2**), the agricultural activities in these regions also contribute to the smaller fluxes. Based

386   on Liu et al. (2013), 60% croplands in these regions are flooded for rice planting in summer and autumn.

387   Field-scale flux measurement using micrometeorological methods (i.e., aerodynamic gradient method)

388   suggest that a typical oilseeds-rice rotated cropland in Southwest China is a significant source during

389   oilseeds planting seasons with fluxes of 10.1-89.4 ng m^{-2} h^{-1}; and a mild sink during rice planting seasons

390   with fluxes of -3.4 to -15.8 ng m^{-2} h^{-1} (Zhu, 2014). The model also successfully simulates such a pattern,

391   with simulated fluxes at 1.1-101.5 ng m^{-2} h^{-1} (Figure 7.2-7.3) during winter and earlier spring when

392   croplands are not flooded and -3.5 to 1.5 ng m^{-2} h^{-1} during the rice growing season (Figure S6). Overall, 3.3

393   Mg Hg^0 is predicted to deposit into rice paddies during the rice growing season, with 56% of the deposition

394   occurring in summer, 41% in autumn, and 3% in late spring.

395

396   **3.4 Verification of model estimates**

397   For the first time, the simulated natural Hg emission in China is verified against field observational

398   data in this study. The dataset of Hg deposition through litterfall is utilized for verifying the simulated air-

399   foliage fluxes because of two reasons: (1) it has been shown that Hg deposition through litterfall dominates

400   dry deposition (≥70%) in forests of China (Fu et al., 2015); and the annual Hg deposition through litterfall

401   has been used as a surrogate to constrain air-foliage fluxes in forest ecosystems (Risch et al., 2012;Zhang

402   et al., 2012a), and (2) the litterfall data in China have are more comprehensive for different forest types

403   compared to the air-foliage flux measured by enclosure methods. For verifying the exchange fluxes over

404   water and soil surfaces, the flux measurements over forest soil, grassland, cropland and water body in China

405   (Table **S2**) are utilized.

406   To estimate the annual Hg deposition through litterfall in the study domain, Monte Carlo simulation

407   (described in details in SI) is applied for constructing the probability distribution of the litterfall deposition

408   based on litter biomass production and litterfall Hg concentration in China reported in peer-reviewed

409   literature (Figure 8). The sampling locations include 20 sites in Tibetan Plateau, 27 sites for evergreen

410   forests, and 12 sites for deciduous forests. The quality-assured data of litter biomass production (number of

411   replicates $\geqslant$ 3, collector size = 1 m^2) are obtained from the China National Knowledge Infrastructure

412   (CNKI). This dataset includes the measurements at 5 sites in Tibetan Plateau, 277 sites for evergreen forests,

413   74 sites for deciduous forests, and 61 sites for mixed forests.

414   Figure 8 shows the dataset of Hg concentration in litterfall. The Hg concentration for evergreen forest

415   ranges from 17 to 120 ng g^{-1} with a mean of 52±26 ng g^{-1}. For deciduous forest, the range is 21-62 ng g^{-1}

416   with a mean of 38±12 ng g^{-1}. The difference between the concentration observed in evergreen forests and

417   in deciduous forests is significant (paired t test, $p < 0.05$). The Hg concentration in litters for deciduous

418   forest in China is compared to the values reported for the same forest type in Europe and North America (p

419   = 0.101). Hg deposition through litterfall in evergreen broadleaf forest (C2) range from 26 to 72 μg m^{-2} y^{-1}

420   (n=5 sites) with a mean of 43±27 μg m^{-2} y^{-1} (Fu et al., 2015;Ma et al., 2015;Wang et al., 2009), consistent

421   with the Hg deposition estimated by Monte Carlo simulation (mean=37±19 μg m^{-2} y^{-1}; 95% confidence

422   interval is 4-89 μg m^{-2} y^{-1}). The model-estimated Hg deposition for C1, C3, C4, and C5 is 22±10, 15±7,

423   16±11, and 17±8 μg m^{-2} y^{-1}, respectively.

424   The measured air-soil flux (Table **S2**) ranges from -1.4 to 20.7 ng m^{-2} h^{-1} over forest soil (n=19; mean=

425   6.1±5.1 ng m^{-2} h^{-1}), from -18.7 to 114 ng m^{-2} h^{-1} over grassland (n=14; mean= 26±36 ng m^{-2} h^{-1}), from -4.1

426   to 135 ng m^{-2} h^{-1} over cropland (n=33; mean= 21.3±36.7 ng m^{-2} h^{-1}). For water body (n=51), the flux range

427   is 0-43.8 ng m^{-2} h^{-1} with a mean of 4.6±6.6 ng m^{-2} h^{-1} (Table **S2**). The mean flux in the warm season (May

428   to October) is substantially higher than those in the cold seasons: 3.3 times for water surface (p=0.004), 3.2

429   times higher for forest soil (p=0.08), and 1.4 times for cropland (p=0.50). A reverse trend is found for

430   grassland, which has higher mean flux in cold seasons (50% higher, p=0.36).

431   Figure 9.1 compares the model estimate and the mean and uncertainty level estimated by Monte Carlo

432   simulation using field data. The annual Hg uptake simulated by the bidirectional exchange model is not

Atmospheric
Chemistry
and Physics
Discussions

433   significantly different from the field observations (p>0.05, t-test), demonstrating the model capability for

434   simulating the air-foliage flux. Figure 9.2 shows the scatter plot of the measured versus model predicted

435   flux over soil and water (R^2=0.73). Modeling results for soil/water surfaces and over soil under forest

436   canopy also agree with filed measurements (Figure 9.3-9.4). The simulation somewhat underestimates the

437   high fluxes ($\geq$ 30 ng m^{-2} h^{-1}, Figure 9.2) measured over grassland and cropland (Figure 9.4).

438   The underestimated fluxes over grassland and cropland can be attributed to several possible reasons.

439   One is the bias caused by the comparatively coarser spatial resolution (36 km) of meteorological parameters

440   and soil properties that limit the reproduction of the instantaneously measured fluxes at observational sites.

441   In addition, the kinetic constants observed by laboratory study are used in the simulation for grassland and

442   cropland and potentially introduce uncertainty. Further studies focusing on in-situ measurement of Hg^{II}

443   reduction rate in soil can help constrain the model simulation result. Furthermore, limited mechanistic

444   understanding on Hg dry deposition (Gustin et al., 2015) and on the fate of deposited Hg (Lindberg et al.,

445   2007;Gustin et al., 2008b;Gustin et al., 2015;Ariya et al., 2015) complicates quantifying the contribution

446   of dry deposition to Hg emission from soil. Finally, the uncertainties caused by flux quantification

447   methodology (Lin et al., 2012;Zhu et al., 2015b, c) and the typically short transient campaign periods

448   (mostly ranging from several days to a couple of weeks) can also be a factor(Feng et al., 2005;Fu et al.,

449   2008;Fu et al., 2012;Fu et al., 2015;Zhu et al., 2015b, c). Improvement on flux methods and extended

450   campaign periods at more study sites for cropland/grassland will improve the model estimates.

451

452   **3.5 Comparison with earlier estimates and implications on Hg emission outflow in China**

453   Figures **S7** and **S8** show the gridded natural Hg emission in the East Asian Domain reported by Shetty

454   et al. (2008) and Wang et al. (2014a), which have two distinct differences compared to the new model

455   estimate in this study. One is regarding the role of vegetation in natural Hg emission, the other is spatial

456   distribution of the emission. Vegetation is clearly assigned as a substantial sink of Hg^0 based on the

457   mechanistic model algorithms in this study; and the shading of vegetation suppress Hg evasion from soil

458   under canopy. In contrast, vegetation is considered a major source, accounting for 76% total emissions in

459   Shetty et al. (2008) because earlier models treat Hg evasion similar to the evapotranspiration process that

460 transport Hg from root zone through vascular tissues in foliage (Gbor et al., 2007;Shetty et al., 2008).

461 However, recent experimental evidence using stable Hg isotope tracers points to exclusion of this pathway

462 for cereal plants (Cui et al., 2014). In addition, Hg isotopic signatures in air and foliage samples (Demers

463 et al., 2013;Yin et al., 2013) and during air-foliage exchange process (Graydon et al., 2006;Gustin et al.,

464 2008a) indicate uptake of atmospheric Hg by foliage, pointing to vegetation as a Hg^0 sink. Also in contrast

465 to the spatial distribution of the emission in this study, earlier Hg^0 emission estimates occur mainly in the

466 regions on the east side of the "Heihe-Tengchong Line" (Shetty et al., 2008;Wang et al., 2014a). Such spatial

467 distribution in Shetty et al. (2008) is caused by spatial distribution of vegetation as the vegetation is the

468 most important contributor for Hg emission, and in Wang et al. (2014a) is caused by spatial distribution of

469 soil Hg concentration as soil Hg concentration shapes natural Hg emission in simple regression schemes.

470 Furthermore, this study advances upon the earlier estimates (Shetty et al., 2008;Wang et al., 2014a) in

471 two fronts. Firstly, the recent soil survey data including soil Hg content and other soil characteristics is a

472 major advantage in this study. The soil Hg data applied in Shetty et al. (2008) is outdated with a coarse

473 spatial resolution; while the data in Wang et al. (2014a) is based on the output of the global terrestrial Hg

474 model in GEOS-Chem, calculated from Hg/C ratios. In addition, the mechanistic model scheme that

475 comprehensively treats the meteorological parameters and physicochemical properties of soil represents the

476 air-surface exchange more appropriately compared to the earlier, undeveloped regression schemes (Shetty

477 et al., 2008;Wang et al., 2014a). With the model results verified against the field flux measurements, the

478 natural emission quantity and spatial distribution in this study represent the state of science estimate of air-

479 surface exchange of Hg^0 in China.

480 Although the total quantity of annual natural emission estimated by the new model developed in this

481 study is comparable to in earlier estimates (400-600 Mg yr^{-1}) by Shetty et al. (2008) and Wang et al. (2014a) ,

482 the distinct spatial distribution of natural emissions simulated in this study may alter the current

483 understanding of Hg emission outflow from China as reported by Lin et al. (2010b). The outflow of Hg

484 emissions in China is mainly driven by the prevailing west-wind drift (Lin et al., 2010b;Chen et al., 2014).

485 The larger natural Hg emission in the west side of model domain results in a longer residence time of evaded

486 Hg, which can be more readily oxidized and then deposited within the domain. Furthermore, the dense

Atmospheric
Chemistry
and Physics
Discussions

487 vegetation in the east side of the domain also enhance the uptake of atmospheric Hg^0. Such a spatial pattern

488 may lead to substantially larger domestic deposition and smaller quantity of outflow compared to the modes

489 estimates by Lin et al. (2010). We are presently to reassess the emission outflow using a regional chemical

490 transport model (e.g., CMAQ-Hg) and a similar mass balance approach by Lin et al. (2010); and will report

491 the model results in a future paper.

492

493 **4. Conclusions**

494 Using a mechanistic model incorporating the present state of understanding in Hg transformation in

495 soils and on foliage surface with up-to-date datasets of soil characteristics and landuse changes, the natural

496 emission of elemental mercury vapor in China is estimated to be 465.1 Mg yr^{-1}, including 565.5 Mg yr^{-1} of

497 emission from soils, 9.0 Mg yr^{-1} of emission from water bodies, and -100.4 Mg yr^{-1} deposition (uptake) by

498 vegetation. The air-surface exchange is strongly dependent on landuse and meteorology, with 9% of net

499 emission from forest ecosystems, 50% from shrubland, savanna and grassland, 33% from cropland, and 8%

500 from other landuses. Given the large agricultural land area in China, farming activities play an important

501 role on the air-surface exchange. Particularly, rice fields shift from a net sink (3.3 Mg uptake) during the

502 growing season in rice paddy to a net source during the season when the farmland is not flooded. The

503 estimated natural Hg^0 emission in this study yields similar Hg^0 evasion quantity but exhibits contrasting

504 spatial distribution compared to the estimate by Shetty et al. (2008). The difference in the spatial emission

505 patterns may alter the current understanding of Hg emission outflow from China as reported by Lin et al.

506 (2010b) because of a substantial amount of natural Hg^0 emission occurs in West China.

507 For future model improvement, studies focusing on fundamental understanding of Hg^{II} reduction in

508 soil (especially the role of soil organic matter, contribution of photochemical and non-chemical pathways,

509 and radiation transfer in soil) and air-vegetation exchange mechanisms are needed. Continuous

510 improvement on the data quality of soil characteristics and Hg content is also essential. Availability of field

511 data for modeling performance evaluation is also important for constraining the model. In particular, data

512 of air-foliage flux, and air-soil flux over cropland and grassland in the remote regions of North China is

513 also valuable for model calibration.

803   Table 1 Model variables, constants and rate coefficients used in the model simulation.

804

Term	Description	Values/units	References/Sources
Hg_1^0	Hg^0 formed by photo-reduction in solution	ng m^{-2} h^{-1}	
Hg_2^0	Hg^0 formed by photo-reduction in particles	ng m^{-2} h^{-1}	
Hg_3^0	Hg^0 formed by the dark-reduction in soil	ng m^{-2} h^{-1}	
K_1	Photo-reduction rate in soil solution	s^{-1}	
K_2	Photo-reduction rate constant in particles	s^{-1}	
K_3	Dark-reduction rate constant in soil	s^{-1}	
$Hg_{s,m}$	Hg^{II} pool in soil pore water	ng m^{-2}	
$Hg_{p,m}$	Reducible Hg^{II} pool in soil particles	ng m^{-2}	
$Hg_{t,m}$	Total reducible Hg^{II} pool in soil	ng m^{-2}	
T	Temperature	K	WRF
θ	Soil moisture	%	WRF
R	Total solar radiation	W m^{-2}	WRF
BD	Soil bulk density	g cm^{-3}	(Shangguan et al., 2013)
LAI	Leaf area index	m^2 m^{-2}	WRF (Yuan et al., 2011)
$[Hg_t]$	Total Hg^{II} concentration in soil	ng g^{-1}	
V	Soil volume	m^3	
kd	soil-water partition coefficient	L kg^{-1}	
GEM	Atmospheric Hg^0 concentration	ng m^{-3}	(Lin et al., 2010b)
σ	Soil porosity	%	(Shangguan et al., 2013)
D_{soil}	Hg^0 vapor diffusion coefficient in soil	m^2 s^{-1}	
D_0	Hg^0 vapor diffusion coefficient in ambient air	1.31×10^{-5} m^2 s^{-1}	(Scholtz et al., 2003)
F_{cnp}	The flux over canopy biomes	ng m^{-2} h^{-1}	
Δt	Time duration	s	
R_a	Aerodynamic resistance	s m^{-1}	(Wang et al., 2014b;Zhang et al., 2012b)
R_b	Quasi-laminar sub-layer resistance	s m^{-1}	Wang et al., 2014b;Zhang et al., 2012b
C_{atm}	Atmospheric Hg concentration	ng m^{-3}	Wang et al., 2014b;Zhang et al., 2012b
χ_{cnp}	The total compensation point	ng m^{-3}	Wang et al., 2014b;Zhang et al., 2012b
χ_c	Cuticular interfaces compensation point	ng m^{-3}	Wang et al., 2014b;Zhang et al., 2012b
χ_s	Stomatal interfaces compensation point	ng m^{-3}	Wang et al., 2014b;Zhang et al., 2012b
χ_g	Soil interfaces compensation point	ng m^{-3}	Wang et al., 2014b;Zhang et al., 2012b
R_c	cuticular resistance	s m^{-1}	Wang et al., 2014b;Zhang et al., 2012b
R_s	stomatal resistance	s m^{-1}	Wang et al., 2014b;Zhang et al., 2012b
R_g	soil diffusion resistance	s m^{-1}	Wang et al., 2014b;Zhang et al., 2012b
R_w	water diffusion resistance	s m^{-1}	Wang et al., 2014b;Zhang et al., 2012b
$R_{g(SO_2)}$	SO$_2$ soil diffusion resistance	s m^{-1}	Wang et al., 2014b;Zhang et al., 2012b
$R_{g(O_3)}$	O$_3$ soil diffusion resistance	s m^{-1}	Wang et al., 2014b;Zhang et al., 2012b
d	Light penetration into soil column	2 mm	(Hebert and Miller, 1990)

γ	Ratio of UV radiation over total radiation	0.08	(Moan, 2001)
K	Canopy light extinction coefficient	0.56	(Zhang et al., 2014)
k_r	Light extinction coefficient in soil	3 mm^{-1}	(Ciani et al., 2005)
k_1	Photo-reduction rate constant in soil solution	6×10^{-9} m^2 W^{-1} s^{-1}	(Si and Ariya, 2011)
k_2	Photo-reduction rate constant in soil particles	2×10^{-3} m^2 W^{-1} h^{-1}	(Quinones and Carpi, 2011)
k_3	Dark-reduction rate constant in soil	1.0×10^{-3} h^{-1}	(Pannu, 2012)
T_f	Reference soil temperature	32°C(Eq.8), 20°C (Eq. 7,9)	(Pannu, 2012;Quinones and Carpi, 2011)
θ_f	Reference soil moisture	25%	(Lin et al., 2010a)
r	Empirical value from regression	0.52	(Lee et al., 2001;Sauve et al., 2000)
s	Empirical value from regression	0.89	(Lee et al., 2001;Sauve et al., 2000)
t	Empirical value from regression	-0.71	(Lee et al., 2001;Sauve et al., 2000)
φ	Ratio of reducible Hg in soil	0.003 (bare), 0.03(others)	(Pannu, 2012)
α_{Hg^0}	Scaling factor of reactivity Hg	0	(Wang et al., 2014b)
β_{Hg^0}	Scaling factor of reactivity Hg	0.1	(Wang et al., 2014b)
Hg_w^{2+}	Hg^{II} concentration on leaf	3 ng m^{-2} leaf	(Laacouri et al., 2013)

Figure 9. Model verification: (1) model estimates of Hg^0 uptake by foliage (which include the uptake by stoma less the re-emission and from cuticle) and by stoma, compared to the estimate (mean and 95% confidence interval) of Hg^0 uptake using Monte Carlo (M-C) simulation of the observational data; (2) scatter plot of the observed fluxes vs. simulated fluxes for different landuses (the flux observations are described in detailed in Table S2), (3) comparison between simulated exchange and measured exchange over soil under canopy, and (4) comparison between simulated exchange and measured exchange over grasslands, cropland and water surface. The mean and median of Figure 9.3 and 9.4 are based on the filed data from peer-review literatures (n=19 for forests; n=12 for grasslands; n=42 for croplands; n=51 for water bodies). Note that the exchange over deciduous forests in Figure 9.1 is small because of the small forest area.
