16 **Abstract**

17 Despite recent advances in global Earth System Models (ESMs), the current global mean
18 aerosol direct and indirect radiative effects remain uncertain, as does their future role in climate
19 forcing and regional manifestations. Reasons for this uncertainty include the high spatio-
20 temporal variability of aerosol populations. Thus, limited area (regional) models applied at
21 higher resolution over specific regions of interest are generally expected to ‘add value’, i.e.
22 improve the fidelity of the physical-dynamical-chemical processes that induce extreme events
23 and dictate climate forcing, via more realistic representation of spatio-temporal variability.
24 However, added value is not inevitable, and there remains a need to optimize use of numerical
25 resources, and to quantify the impact on simulation fidelity that derives from increased
26 resolution. Here we quantify the value added by enhanced spatial resolution in simulations of
27 the drivers of aerosol direct radiative forcing by applying the Weather Research and
28 Forecasting model with coupled Chemistry (WRF-Chem) over eastern North America at
29 different resolutions. Using Brier Skill Scores and other statistical metrics it is shown that
30 enhanced resolution (from 60 to 12 km) improves model performance for all of the
31 meteorological parameters and gas phase concentrations considered, in addition to both mean
32 and extreme Aerosol Optical Depth (AOD) in three wavelengths in the visible relative to
33 satellite observations, principally via increase of potential skill. Some of the enhanced model
34 performance for AOD appears to be attributable to improved simulation of specific humidity
35 and the resulting impact on aerosol hygroscopic growth/hysteresis.

36

37 **Keywords:** added value, high-resolution WRF-Chem simulations, aerosol optical properties,
38 extreme AOD

39 **1 Motivation and Objectives**

40 Aerosols alter Earth's radiation balance primarily by scattering or absorbing incoming solar
41 radiation (direct effect, dominated by accumulation mode (diameters \sim wavelength (λ), where
42 total extinction is often quantified using AOD), or regulating cloud formation/properties by
43 acting as cloud condensation nuclei (CCN) (indirect effect, dominated by diameters \geq 100 nm,
44 magnitude = $f(\text{composition})$). Most aerosols (excluding black carbon) have a larger scattering
45 cross-section than absorption cross-section, and act as CCN thus enhancing cloud albedo and
46 lifetimes. Hence increased aerosol concentrations are generally (but not uniformly) associated
47 with surface cooling (offsetting a fraction of greenhouse gas warming) (Boucher, 2013; Myhre
48 et al., 2013b) to a degree that is principally dictated by the aerosol concentration, size and
49 composition, in addition to the underlying surface and height of the aerosol layer (McComiskey
50 et al., 2008). Despite major advances in measurement and modeling, both the current global
51 mean aerosol direct effect (possible range: -0.77 to $+0.23 \text{ W m}^{-2}$) and the indirect effect
52 (possible range: -1.33 to -0.06 W m^{-2}) remain uncertain (Stocker, 2013), as does their future
53 role in climate forcing (Rockel et al., 2008) and regional manifestations (Myhre et al., 2013a).
54 Specific to our current study region (eastern N. America), one analysis using the NASA GISS
55 global model found that the "regional radiative forcing from US anthropogenic aerosols elicits
56 a strong regional climate response, cooling the central and eastern US by $0.5\text{--}1.0 \text{ }^\circ\text{C}$ on average
57 during 1970–1990, with the strongest effects on maximum daytime temperatures in summer
58 and autumn. Aerosol cooling reflects comparable contributions from direct and indirect
59 radiative effects" (Leibensperger et al., 2012). A recent comparison of multiple global models
60 conducted under the AEROCOM-project indicated this is also a region that exhibits very large
61 model-to-model variability in simulated AOD ($\langle \text{AOD} \rangle \sim 0.5$, $\sigma(\text{AOD}) \sim 1$) (Myhre et al.,
62 2013a).

63 Major reasons why aerosol radiative forcing on both the global and regional scales remains
64 uncertain include short atmospheric residence times and high spatio-temporal variability of
65 aerosol populations, and the complexity of the processes that dictate aerosol concentrations,
66 composition and size distributions (Seinfeld and Pandis, 2016). Although aerosol processes
67 and properties are increasingly being treated in the global Earth System Models (ESMs) (Long
68 et al., 2015; Tilmes et al., 2015) being applied in Coupled Model Intercomparison Project Phase
69 6 (CMIP-6) (Meehl et al., 2014), the scales on which such models are applied remain much
70 coarser than those on which aerosol population properties are known to vary (Anderson et al.,
71 2003). Therefore, limited area atmospheric models (regional models) applied at higher

72 resolution over specific regions of interest are expected to ‘add value’ (i.e. improve the fidelity)
73 of the physical-dynamical-chemical processes that induce extreme events and dictate climate
74 forcing. There is empirical evidence to suggest strong resolution dependence in simulated
75 aerosol particle properties. For example, WRF-Chem simulations with spatial resolution
76 enhanced from 75 km to 3 km exhibited higher correlations and lower bias relative to
77 observations of aerosol optical properties over Mexico likely due to more accurate description
78 of emissions, meteorology and of the physicochemical processes that convert trace gases to
79 particles (Gustafson et al., 2011; Qian et al., 2010). This improvement in the simulation of
80 aerosol optical properties implies, a reduction of the uncertainty in associated aerosol radiative
81 forcing (Gustafson et al., 2011). Further, WRF-Chem run over the United Kingdom and
82 Northern France at multiple resolutions in the range of 40-160 km, underestimated AOD by
83 10-16% and overestimated CCN by 18-36% relative to a high resolution run at 10 km, partly
84 as a result of scale dependence of the gas-phase chemistry and differences in the aerosol uptake
85 of water (Weigum et al., 2016).

86 However, debate remains regarding how to objectively evaluate model performance, quantify
87 the value added by enhanced resolution (Di Luca et al., 2015; Rockel et al., 2008) and on
88 possible limits to the improvement of climate representation in light of errors in the driving
89 “imperfect lateral boundary conditions” (Diaconescu and Laprise, 2013). Nevertheless,
90 although “it is unrealistic to expect a vast amount of added values since models already
91 performs rather decently” (Di Luca et al., 2015) and global ESMs are now run at much higher
92 resolution than in the past, it is generally assumed that high resolution regional models will add
93 value via more realistic representation of spatio-temporal variability than global coarser-
94 resolution simulations. Further, “the main added value of a regional climate model is provided
95 by its small scales and its skill to simulate extreme events, particularly for precipitation”
96 (Diaconescu and Laprise, 2013).

97 Here we quantify the value added by enhanced resolution in the description of the drivers of
98 aerosol direct radiative forcing using year-long simulations from WRF-Chem over eastern
99 North America. The primary performance evaluation focuses on AOD at different wavelengths
100 ($\lambda = 470, 550$ and 660 nm, where the AOD at different λ is used as a proxy of the aerosol size
101 distribution (Tomasi et al., 1983), see details in Sect. 2.1) and is measured relative to
102 observations from satellite-borne instrumentation. Thus the term “value added” is used here to
103 refer to an improvement of model performance in simulation of wavelength specific AOD as
104 measured by the MODerate resolution Imaging Spectroradiometer (MODIS) instrument

105 aboard the polar-orbiting Terra satellite. We begin by quantifying the performance of WRF-
106 Chem when applied over eastern North America at a resolution of 60 km (WRF60) (~ finest
107 resolution likely to be employed in CMIP-6 global simulations) and then compare the results
108 to those from simulations conducted at 12 km (WRF12) (simulation details are given in Table
109 1). Quantification of model skill is undertaken by mapping the WRF12 output to the WRF60
110 grid (WRF12-remap) and computing Brier Skill Scores (BSS) using MODIS as the target,
111 WRF60 as the reference forecast and WRF12-remap as the forecast to be evaluated. We also
112 evaluate the impact of simulation resolution on extreme AOD values that are associated with
113 enhanced impacts on climate and human health. This analysis uses both *Accuracy* and *Hit Rate*
114 as the performance metrics and focuses on the co-occurrence of extreme values in space from
115 the model output and MODIS.

116 Our final analysis focuses on evaluation of the value-added by enhanced resolution in terms of
117 key meteorological and gas-phase drivers of aerosol concentrations and composition and is
118 conducted relative to the MERRA-2 reanalysis product for the physical variables and columnar
119 gas concentrations from satellite observations (see details of the precise data sets used given
120 below). The meteorological parameters considered are air temperature at 2 m (T_{2m}), total
121 monthly precipitation (PPT), planetary boundary-layer height ($PBLH$) and specific humidity
122 in the boundary layer (Q_{PBL}). The gas phase concentrations considered are: sulfur dioxide
123 (SO_2), ammonia (NH_3), nitrogen dioxide (NO_2) and formaldehyde (HCHO).

124 **2 Materials and Methods**

125 **2.1 Spectral dependence of AOD**

126 Three properties dictate the actual aerosol direct radiative forcing: AOD, single scattering
127 albedo and asymmetry factor, all of which are a function of the wavelength (λ) of incident
128 radiation. The first property is related to the total columnar mass loading, typically dominates
129 the variability of direct aerosol effect (Chin et al., 2009) and is the focus of the current research.
130 The relationship between the aerosol size distribution and spectral dependence of AOD is
131 described by a power law function:

$$132 \quad \beta(\lambda_1) = \beta(\lambda_2) \times \frac{\lambda_1^{-\alpha}}{\lambda_2^{-\alpha}} \quad (1)$$

133 where β is the particle extinction coefficient at a specific wavelength λ and α is the Ångström

134 exponent (Ångström, 1964) which describes the wavelength dependence of AOD (and is
 135 inversely proportional to the average aerosol diameter):

$$136 \quad \alpha = \frac{\ln \frac{AOD(\lambda_1)}{AOD(\lambda_2)}}{\frac{\lambda_2}{\lambda_1}} \quad (2)$$

137 The aerosol volume distribution (and thus also its size distribution) usually conforms to a multi-
 138 lognormal function with n modes:

$$139 \quad \frac{dV(r)}{d \ln r} = \sum_{i=1}^n \frac{C_i}{\sqrt{2\pi\sigma_i}} \exp\left[-\frac{(\ln r - \ln R_i)^2}{2\sigma_i^2}\right] \quad (3)$$

140 where C_i is the particle volume concentration in the mode i , R_i is the geometric mean radius
 141 and σ_i is the geometric standard deviation, thus we have:

142

$$143 \quad AOD(\lambda) = \int \frac{3\beta(m, r, \lambda)}{4r} \frac{dV(r)}{d \ln r} d \ln r dZ \quad (4)$$

144 As indicated in (Schuster, 2006), “the spectral variability of extinction diminishes for particles
 145 larger than the incident wavelength”, thus fine mode particles contribute more to AOD in the
 146 visible ($\lambda \sim 0.5 \mu\text{m}$) than at longer wavelengths, whereas coarse mode particles provide a similar
 147 AOD both at short and long wavelengths. This is reflected in the Ångström parameter which
 148 can be thus used as a proxy for the fine mode fraction or fine mode radius (Schuster, 2006).

149 **2.2 WRF-Chem simulations**

150 WRF-Chem (version 3.6.1) simulations were performed for the calendar year 2008 over eastern
 151 North America, in a domain centered over southern Indiana (86°W, 39°N) at two resolutions,
 152 one close to the finest resolution designed for CMIP-6 global model runs (i.e. 60 km, WRF60)
 153 and the other one at much higher resolution (12 km, WRF12). Simulation settings are identical
 154 for the two runs except for the time-step used for the physics (Table 1). Physical and chemical
 155 parameterizations were chosen to match previous work using WRF-Chem at 12 km on the same
 156 region which showed good performance relative to observations and the year 2008 was selected
 157 because representative of average climate and aerosol conditions during 2000 - 2014 (Crippa
 158 et al., 2016). More specifically the simulations adopted the RADM2 chemical mechanism
 159 (Stockwell et al., 1990) and a modal representation of the aerosol size distribution

160 (MADE/SORGAM, (Ackermann et al., 1998;Schell et al., 2001)) with three lognormal modes
161 and fixed geometric standard deviations (i.e. 1.7, 2 and 2.5 for Aitken, accumulation and coarse
162 mode, respectively (Ackermann et al., 1998;Grell et al., 2005)). Aerosol direct feedback was
163 turned on and coupled to the Goddard shortwave scheme (Fast et al., 2006). A telescoping
164 vertical grid with 32 model layers from the surface to 50 hPa and 10 layers up to 800 hPa was
165 selected. Meteorological initial and boundary conditions from the North American Mesoscale
166 Model at 12 km resolution are applied every 6 hours, while initial and chemical boundary
167 conditions are taken from MOZART-4 (Model for Ozone and Related chemical Tracers,
168 version 4) with meteorology from NCEP/NCAR-reanalysis (Emmons et al., 2010).
169 Anthropogenic emissions are specified for both WRF60 and WRF12 from the US National
170 Emission Inventory 2005 (NEI-05) (US-EPA, 2009) which provides hourly point and area
171 emissions at 4 km on 19 vertical levels. The simulation settings and specifically the use of a
172 modal representation of the aerosol size distribution were selected to retain computational
173 tractability. Accordingly, the 60 km simulations for the year 2008 completed in 6.4 hours
174 whereas the 12 km simulations completed in 9.5 days (230 hours) on the Cray XE6/XK7
175 supercomputer (Big Red II) owned by Indiana University, using 256 processors distributed on
176 8 nodes.

177 Value added is quantified by degrading (averaging) hourly output from the 12 km resolution
178 simulation to 60 km (hereafter WRF12-remap) as follows: the 12 km domain is resized
179 excluding 2 grid cells at the border to exactly match the 60 km resolution domain. Each coarse
180 grid cell thus includes 5×5 12 km resolution cells and its value is the mean of all valid 12 km
181 grid cells inside it if at least half of those cells contain valid AOD (i.e. no cloud cover),
182 otherwise the whole coarse cell is treated as missing. In all comparisons only cells with
183 simultaneous (i.e. model and MODIS) clear sky conditions are considered. A daily value from
184 WRF-Chem is computed as an instantaneous value for the hour nearest to the satellite overpass
185 time. When the comparison is done on a monthly basis, a monthly mean value is computed
186 from the daily values obtained under clear sky conditions, only if there are at least five valid
187 observations in the month.

188 **2.3 Observations**

189 Model aerosol optical properties are evaluated relative to the MODIS Collection 6 dark-target
190 land aerosol product from aboard the Terra satellite (~1030 overpass local solar time (LST))
191 (Levy et al., 2013). To provide a consistent assessment of model skill, the evaluation of AOD

192 is conducted only on land areas since the MODIS dark-target ocean aerosol product is based
193 on a retrieval algorithm different from the one over land (Levy et al., 2013). Trace gas
194 concentrations are evaluated relative to measurements from the Ozone Monitoring Instrument
195 (OMI; version 3) (Chance, 2002) and the Infrared Atmospheric Sounding Interferometer (IASI;
196 NN version 1) (Whitburn, 2016) aboard the Aura (~1345 LST) and MetOp satellites (~0930
197 LST), respectively. MODIS retrieves AOD at multiple λ including 470, 550, and 660 nm, and
198 the MODIS algorithm removes cloud-contaminated pixels prior to spatial averaging over $10 \times$
199 10 km (at nadir). OMI and IASI have nadir resolutions of 13×24 km and 12 km (circular
200 footprint), respectively, and have been filtered to remove retrievals with cloud fractions > 0.3
201 (Fioletov et al., 2011; McLinden et al., 2014; Vinken et al., 2014) and OMI pixels affected by
202 the row anomalies. MODIS, OMI, and IASI provide near daily global coverage, although the
203 row anomalies render portions of the OMI viewing swath unusable. Uncertainty in AOD from
204 MODIS is spatially and temporally variable. It has been estimated as $\pm (0.05 + 15\%)$ for AOD
205 over land (Levy et al., 2013), and prior research has reported 71% of MODIS Collection 5
206 retrievals fall within $0.05 \pm 20\%$ for AOD relative to AERONET in the study domain (Hyer et
207 al., 2011). The accuracy of OMI (“root sum of the square of all errors, including forward model,
208 inverse model, and instrument errors” (Brinkma, 2003)) is 1.1 DU or 50% for SO_2 , 2×10^{14}
209 $\text{cm}^{-2}/30\%$ for background/polluted NO_2 conditions, and 35% for HCHO. This uncertainty is
210 typically reduced by spatial and temporal averaging, as employed herein (Fioletov et al.,
211 2011; Krotkov et al., 2008). IASI NH_3 retrievals do not use an a priori assumption of emissions,
212 vertical distribution, or lifetime of NH_3 (i.e. no averaging kernel); therefore, NH_3 accuracy is
213 variable, and thus only retrievals with uncertainty lower than the retrieved concentrations are
214 used (Whitburn, 2016).

215 For the model evaluation, satellite observations for each day are regridded to the WRF-Chem
216 discretization. This is done by averaging all valid retrievals within: 0.1° and 0.35° of the WRF-
217 Chem grid-cell center for the 12×12 km and 60×60 km resolutions, respectively for MODIS;
218 $0.125^\circ \times 0.18^\circ$ (along-track/latitudinal \times cross-track/longitudinal) and $0.365^\circ \times 0.42^\circ$ for OMI;
219 0.12° and 0.36° for IASI,. To avoid issues from under-sampling, we require at least 10 valid
220 MODIS granules for the 60×60 km daily average to be computed and at least 5 daily averages
221 to compute a monthly average for each grid cell. Model evaluation of gaseous species is
222 performed on a seasonal basis using standard scores (z-scores), which are computed as the
223 difference between the seasonal mean within a grid cell and the seasonal spatial mean, divided
224 by the seasonal spatial standard deviation. The use of standard scores allows comparison of the

225 spatial patterns of satellite observations and model output in terms of standard deviation units
226 from the mean.

227 The simulated meteorological properties are evaluated using Modern-Era Retrospective
228 analysis for Research and Applications (MERRA-2) reanalysis data as the target. MERRA-2
229 is a homogenized and continuous in time description of atmospheric properties on a 3-
230 dimensional global grid (horizontal resolution of $0.5^\circ \times 0.625^\circ$, L72), developed by NASA and
231 was released in Fall 2015 (Molod et al., 2015). MERRA-2 provides hourly values of T_{2m} and
232 $PBLH$, and vertical profile of 3-dimensional variables every 3 hours on a large number of
233 pressure levels. Here we compute the total specific humidity (Q_{PBL}) of the lowest 8 pressure
234 levels (i.e. in the boundary-layer approximated as the layer from 1000 to 825 hPa) in MERRA-
235 2, assuming an average air density in the PBL of 1.1 kg m^{-3} . For the evaluation of simulated
236 precipitation, we use accumulated monthly total values.

237 **2.4 Quantification of model performance and added-value**

238 Taylor diagrams summarize three aspects of model performance relative to a reference: the
239 spatial correlation coefficient (i.e. Pearson correlation of the fields, r), the ratio of spatial
240 standard deviations of the two spatial fields ($\sigma_{\text{wrf}}/\sigma_{\text{sat}}$) and the root mean squared difference
241 (Taylor, 2001). Here Taylor diagrams are presented for monthly mean AOD from WRF60,
242 WRF12 and WRF12-remap relative to MODIS at different wavelengths (Fig. 1 d-f). Because
243 AOD is not normally distributed, Spearman's rank correlation coefficients (ρ) of the mean
244 monthly AOD spatial fields are also computed to reduce the impact of a few outliers and the
245 small sample size during cold months (Table 2). To assess the significance of ρ while
246 accounting for multiple testing, we apply a Bonferroni correction (Simes, 1986) in which for
247 m hypothesis tests, the null hypothesis is rejected if $p \leq \frac{\alpha}{m}$, where p is the p-value and α is the
248 confidence level (0.05 is used here).

249 We further quantify the value added (or lack of thereof) of the high-resolution simulations
250 using the following metrics:

251 **(i) Brier Skill Score**

252 The primary metric used to quantify the added value of WRF12-remap versus WRF60 is the
253 Brier Skill Score (BSS) (Murphy and Epstein, 1989):

$$BSS = \frac{r_{F'P'}^2 - \left(r_{F'P'} - \frac{\sigma_{F'}}{\sigma_{P'}} \right)^2 - \left(\frac{\langle P' \rangle - \langle F' \rangle}{\sigma_{P'}} \right)^2 + \left(\frac{\langle P' \rangle}{\sigma_{P'}} \right)^2}{1 + \left(\frac{\langle P' \rangle}{\sigma_{P'}} \right)^2} \quad (5)$$

254 where F is the “forecast” (i.e. the 12 km simulations mapped to 60 km, WRF12-remap); P is
 255 the “target” (i.e. MODIS at 60 km) and output from WRF60 are used as the reference forecast;
 256 F' the difference between 12 km estimates regridded to 60 km and MODIS; P' the difference
 257 between the 60 km simulation and MODIS.
 258

259 BSS measure how much a test simulation (i.e. WRF12-remap) more closely (or poorly)
 260 reproduces observations (from MODIS, MERRA-2 or other satellite products) relative to a
 261 control (WRF60) run. A $BSS > 0$ indicates WRF12, even when regridded to 60 km, does add
 262 value. The first term in (5) ranges from 0 to 1, is described as the potential skill, and is the
 263 square of the spatial correlation coefficient between forecast and reference anomalies to
 264 MODIS. It is the skill score achievable if both the conditional bias (second term) and overall
 265 bias (third term) were zero, and for most of the variables considered herein (particularly AOD)
 266 it contributes to a positive BSS in most calendar months (and seasons). The second term (the
 267 conditional bias, > 0), is the square of the difference between the anomaly correlation
 268 coefficient and the ratio of standard deviation of the anomalies and is small if for all points F'
 269 is linear to P' . The third term is referred to as the forecast anomaly bias, and is the ratio of the
 270 difference between the mean anomalies of WRF12-remap and the observations relative to
 271 WRF60 and the standard deviation of WRF60 anomaly relative to observed values. The fourth
 272 term is the degree of agreement and appears in both the numerator and denominator. It is
 273 computed as the square of the ratio of the mean anomaly between WRF60 and observations
 274 and the standard deviation of the anomalies.

275 (ii) Pooled paired t-test

276 To identify which areas in space contribute most to the added value, we compare daily mean
 277 AOD fields from WRF-Chem at different resolutions and MODIS. We perform a pooled paired
 278 t-test to evaluate the null hypothesis that those differences come from normal distributions with
 279 equal means and equal but unknown variances (the test statistic has a Student's t distribution
 280 with $df = n + m - 2$, and the sample standard deviation is the pooled standard deviation, where
 281 n and m are the two sample sizes). The test is conducted by climatological season (e.g. winter
 282 = DJF) since there are fewer than 20 valid AOD observations in most 60 km grid cells for each

283 calendar month (Fig. 2). Given the large number of hypothesis tests performed (i.e. one for
284 each 60 km grid cell), we adjust the p-values using the False Discovery Rate (FDR) approach
285 (Benjamini and Hochberg, 1995). In this approach, p-values from the t-tests are ranked from
286 low to high (p_1, p_2, \dots, p_m), then the test with the highest rank, j , satisfying:

$$287 \quad p_j \leq \frac{j}{m} \alpha \quad (6)$$

288 is identified. Here all p-values satisfying Eq. 6 with $\alpha=0.1$ are considered significant.

289 (iii) Accuracy and Hit Rate in identification of extremes

290 For each month we identify grid cells in which the wavelength specific AOD exceeds the 75th
291 percentile value computed from all grid cells and define that as an extreme. Thus grid cells
292 with extreme AOD are independently determined for MODIS and WRF-Chem at different
293 resolutions. The spatial coherence in identification of extremes in the fields is quantified using
294 two metrics: the *Accuracy* and the *Hit Rate (HR)*. The *Accuracy* indicates the overall spatial
295 coherence and is computed as the number of grid cells co-identified as extreme and non-
296 extreme between WRF-Chem and MODIS relative to the total number of cells with valid data.
297 The *HR* weights only correct identification of extremes in MODIS by WRF-Chem.

298 3 Results

299 3.1 Quantifying the value added of increased spatial resolution

300 When WRF-Chem is applied at 60 km resolution the degree of association of the resulting
301 spatial fields of mean monthly AOD at the three wavelengths with MODIS varies seasonally.
302 Smallest RMSD and highest Spearman spatial correlations (ρ) with MODIS observations
303 generally occur during months with highest mean AOD (i.e. during summer, Fig. 1 d-f and Fig.
304 3), and reach a maximum in August ($\rho = 0.60$, Table 2). However, while the patterns of relative
305 AOD variability are well captured, the absolute magnitudes and spatial gradients of AOD
306 during the summer are underestimated by WRF60 (Fig. 1 d-f and Fig. 3, Table S1). High spatial
307 correlations ($\rho > 0.40$) are also observed in March, April and November (Table 2), when the
308 ratio of spatial standard deviations is closer to 1 (Fig. 1 d-f, Table S1). Only a weak wavelength
309 dependence is observed in the performance metrics as described on Taylor diagrams. The
310 spatial variability is generally more negatively biased for AOD at 660 nm (Table S1), indicating
311 that WRF60 simulations tend to produce larger diameter aerosols homogeneously distributed
312 over the domain, whereas MODIS observations indicate more spatial variability.

313 The performance of WRF60 simulations relative to MODIS contrasts with analyses of WRF12
314 and WRF12-remap. WRF12 and WRF12-remap indicate highest spatial correlations with
315 MODIS observations throughout the summer months ($\rho = 0.5-0.7$, Table 2), although the bias
316 towards simulation of more coarse aerosols than are observed is consistent across the two
317 simulations and with prior research (see details provided in (Crippa et al., 2016)). However,
318 simulations at 12 km (WRF12) show positive ρ with MODIS for all λ in all calendar months,
319 while mean monthly spatial fields of AOD from WRF60 show low and/or negative correlations
320 with MODIS during May, June, September, October and December, indicating substantial
321 differences in the degree of correspondence with MODIS AOD in the two simulations, and
322 higher fidelity of the enhanced resolution runs (Tables 2 and S1).

323 Monthly mean spatial fields of AOD(λ) as simulated by WRF12 or WRF12-remap exhibit
324 positive Spearman correlation coefficients (ρ) with MODIS observations for all calendar
325 months and range from ~ 0.25 for WRF12-remap (0.20 for WRF12) during winter to ~ 0.70
326 and 0.64, respectively during summer (Table 2). Spearman's ρ are uniformly higher in WRF12-
327 remap than WRF12 indicating a mismatch in space in the high-resolution simulation (i.e. that
328 grid cells with high AOD are slightly displaced in the 12 km simulations possibly due to the
329 presence of sub-grid scale aerosol plumes (Rissman et al., 2013)). Mean monthly fields of AOD
330 (all λ) from both WRF12 and WRF12-remap exhibit lower ρ with MODIS in February-April
331 and November than the 60 km runs (Table 2). These discrepancies appear to be driven by
332 conditions in the south of the domain. For example, differences between WRF60/WRF12-
333 remap vs. MODIS during all seasons are significant according to the paired t-test over Florida
334 and along most of the southern coastlines (Fig. 2). This region of significant differences extends
335 up to $\sim 40^\circ\text{N}$ during summer and fall, reflecting the stronger north-south gradient in AOD from
336 MODIS and WRF12-remap that is not captured by WRF60 (see example for $\lambda = 550$ nm, Fig.
337 3). These enhancements in the latitudinal gradients from WRF12-remap are also manifest in
338 the physical variables (particularly specific humidity as discussed further below).

339 The differences in the absolute values of mean monthly AOD deriving from differences in the
340 resolution at which WRF-Chem was applied are of sufficient magnitude (a difference of up to
341 0.2 in regions with a mean AOD value of 0.4), particularly in the summer months (Fig. 4), to
342 raise concerns. However, detailed investigation of the simulations settings and repetition of the
343 60 km simulation resulted in virtually identical results indicating no fault can be found in the
344 analysis. Further, we note that the eastern-half of North America was also identified as a region

345 of high discrepancy in global ESM (Myhre et al., 2013a).

346 To further investigate differences in the simulation output due to spatial discretization we
347 computed Brier Skill Scores (BSS). In this analysis AOD for each λ from WRF12-remap are
348 used as the ‘forecast’, output from WRF60 are used as the reference forecast and MODIS
349 observations at 60 km are used as the target. BSS exceed 0 during all months except for
350 September and October, and largest BSS (> 0.5) for AOD (all λ) is found during most months
351 between December and July (Fig. 5). This indicates that running WRF-Chem at 12 km
352 resolution adds value relative to WRF60, even when the WRF12 output is remapped to 60 km.
353 BSS do not strongly depend on λ , indicating the added value from enhanced resolution
354 similarly affects particles of different sizes. Inspecting the terms defining the BSS provides
355 information about the origin of the added value (Fig. 5). The positive BSS derives principally
356 from the potential skill (first term in Eq. 5), which demonstrates a reduction in bias and/or more
357 accurate representation of the spatial gradients in WRF12-remap. This term exhibits weak
358 seasonality with values below 0.5 only during August and fall months. The second and third
359 terms are close to zero during most months, although bigger biases are found during August-
360 October. The substantial conditional bias during late summer and early fall is the result of the
361 large ratio of standard deviations (> 1 , i.e. the spatial variability of the anomaly relative to
362 MODIS is larger for WRF12-remap than WRF60, Table S1). It thus contributes to the negative
363 BSS found in September and October, which are also identified as outlier months in WRF12-
364 remap from the Taylor diagram analysis (Fig. 1). Output for these months show modest spatial
365 correlations with MODIS and higher ratio of standard deviations than in WRF60-MODIS
366 comparisons (Fig. 1, Table S1). Previous work showed that the lower model skill (in WRF12)
367 during September and October may be partially attributable to a dry bias in precipitation from
368 WRF-Chem relative to observations. As a result, simulated AOD and near-surface aerosol
369 nitrate and sulfate concentrations are positively biased over large parts of the domain (Crippa
370 et al., 2016).

371 Model resolution also affects the *Accuracy* and *Hit Rate (HR)* for identification of areas of
372 extreme AOD (AOD $>75^{\text{th}}$ percentile). Highest coherence in the identification of extreme AOD
373 in space identified in WRF12-remap (and WRF12) relative to MODIS is found during May-
374 August ($HR = 53\text{-}77\%$) vs. WRF60 ($HR = 17\text{-}54\%$, Table 3). Conversely highest *HR* are found
375 for WRF60 and MODIS during winter and early spring, and indeed exceed those for WRF12
376 and WRF12-remap (Table 3, e.g. Feb: $HR = 0.78$ for WRF60, and 0.67 and 0.68 for WRF12
377 and WRF12-remap, respectively). These differences are consistent with the observation that

378 WRF12-remap overestimates the scales of AOD coherence and AOD magnitude during the
379 cold season along coastlines and over much of the domain in April (Fig. 3).

380 The synthesis of these analyses is thus that the higher resolution simulation increases the
381 overall spatial correlation, decreases overall bias in AOD close to the peak of the solar spectrum
382 relative to MODIS observations and therefore the higher-resolution simulations better
383 represent aerosol direct climate forcing. However, WRF12-remap exhibits little improvement
384 over WRF60 in terms of reproducing the spatial variability of AOD in the visible wavelengths
385 and further that WRF12-remap tends to be more strongly positively biased in terms of mean
386 monthly AOD outside of the summer months (Fig. 2 and Fig. 3). Also the improvement in
387 detection of areas of extreme AOD in the higher resolution simulations (WRF12-remap) is
388 manifest only during the warm season.

389 **3.2 Investigating the origin of the added value and sources of error in simulated AOD**

390 As documented above, WRF-Chem applied at either 60 or 12 km resolution over eastern North
391 America exhibits some skill in reproducing observed spatial fields of AOD and the occurrence
392 of extreme AOD values. However, marked discrepancies both in space and time are found, and
393 at least some of them show a significant dependence on model resolution. Thus, we
394 investigated a range of physical conditions and gas phase concentrations known to be strongly
395 determinant of aerosol dynamics in terms of the BSS as a function of model resolution and also
396 in terms of the mean monthly spatial patterns.

397 WRF12 even when remapped to 60 km provides more accurate description of key
398 meteorological variables such as specific humidity (Q) within the boundary layer, $PBLH$,
399 surface temperature and precipitation (Fig. 6, S1, S2 and S3) when compared to MERRA-2, as
400 indicated by the positive BSS during almost all months (Fig. 7a). Good qualitative agreement
401 is observed for the spatial patterns and absolute magnitude of T_{2m} in both WRF60 and WRF12-
402 remap relative to MERRA-2 for all seasons (Fig. S1) leading to only modest magnitude of BSS
403 (i.e. value added by the higher resolution simulations (Fig. 7a)). The aerosol size distribution
404 and therefore wavelength specific AOD exhibits a strong sensitivity to Q (Santarpia et al.,
405 2005) due to the presence of hygroscopic components in atmospheric aerosols and thus the role
406 of water uptake in determining aerosol diameter, refractivity and extinction coefficient (Zieger
407 et al., 2013). For example, the hygroscopic growth factor, which indicates the change of aerosol
408 diameter due to water uptake, is ~ 1.4 for pure ammonium sulfate with dry diameter of 532 nm
409 at relative humidity of 80%, thus biases in representation atmospheric humidity may lead to

410 big errors in simulated aerosol size and AOD (Flores et al., 2012). Our previous analyses of
411 the 12 km resolution simulations indicated overestimation of sulfate aerosols (a highly
412 hygroscopic aerosol component, and one which in many chemical forms exhibits strong
413 hysteresis (Martin et al., 2004)) relative to observed near-surface $PM_{2.5}$ concentrations during
414 all seasons except for winter (Crippa et al., 2016), leading to the hypothesis that simulated
415 AOD and discrepancies therein may exhibit a strong dependence on Q . Consistent with that
416 postulate, Q_{PBL} from WRF12-remap exhibits a moist bias in cloud-free grid cells mostly during
417 warm months, whereas WRF60 is characterized by a dry bias during all seasons (Fig. 6).
418 Despite the positive bias, WRF12-remap better captures the seasonal spatial patterns of Q_{PBL}
419 in MERRA-2, leading to positive BSS in all calendar months. Thus, there is added value by
420 higher-resolution simulations in representation of one of the key parameters dictating particle
421 growth and optical properties. Spatial patterns of differences in Q_{PBL} from WRF60 and
422 WRF12-remap relative to MERRA-2 (Fig. 6) exhibit similarities to differences in AOD (Fig.
423 4). WRF60 is dry-biased relative to WRF12 particularly during the summer (and fall) and
424 underestimates Q_{PBL} relative to MERRA-2 during all seasons over the southern states and over
425 most of continental US during summer and fall. Conversely, WRF12-remap overestimates
426 Q_{PBL} over most of continental US during summer and fall relative to MERRA-2.

427 $PBLH$ is a key variable for dictating near-surface aerosol concentrations but is highly sensitive
428 to the physical schemes applied, and biases appear to be domain and resolution dependent.
429 However, this parameter is comparatively difficult to assess because differences in $PBLH$ from
430 WRF-Chem and MERRA-2 may also originate from the way they are computed (i.e. from heat
431 diffusivity in MERRA-2 (Jordan et al., 2010) and from turbulent kinetic energy in WRF-Chem
432 (Janjić, 2002; von Engeln and Teixeira, 2013)). Nevertheless, the Mellor-Yamada-Janjich PBL
433 scheme combined with the Noah Land Surface Model applied in this work was found to
434 produce lower PBL heights (Zhang et al., 2009) than other parameterizations. Thus, the positive
435 bias in simulated AOD and surface $PM_{2.5}$ concentrations (reported previously in (Crippa et al.,
436 2016)) may be linked to the systematic underestimation of $PBLH$ simulated by WRF12-remap
437 over continental US relative to MERRA-2 during all seasons (except winter) with greatest bias
438 over regions of complex topography (Fig. S2). A positive bias (of several hundred meters) in
439 terms of $PBLH$ for WRF simulations using the MYJ parameterization was previously reported
440 for high-resolution simulations over complex terrain (Rissman et al., 2013), and a positive bias
441 in $PBLH$ is also observed in the 60 km simulations presented herein (Fig. S2). This may provide
442 a partial explanation for the strong negative bias in AOD in WRF60 during summer (Fig. 3).

443 In general, the BSS indicate improvement in the simulation of *PBLH* in WRF12-remap than in
444 WRF60 (Fig. 7a).

445 Consistent with the dry bias in Q_{PBL} in WRF60, total accumulated precipitation is also
446 underestimated in WRF60, while WRF12-remap captures the absolute magnitudes and the
447 spatial patterns therein (Fig. S3). Analysis of hourly precipitation rates also showed higher skill
448 of WRF12-remap than WRF60 in correctly simulating precipitation occurrence (*HR*) relative
449 to MERRA-2 (Table S2). More specifically WRF12-remap correctly predicts between 40%
450 and 70 % of precipitation events in MERRA-2 with highest skill during winter months, whereas
451 WRF60 output exhibits lower HR (~6% during summer and 30% during winter). This result
452 thus confirms our expectation of a strong sensitivity of model performance to resolution due to
453 the inherent scale dependence in the cumulus scheme.

454 Gas phase concentrations (transformed into *z*-scores) from WRF12-remap show higher
455 agreement with satellite observations during almost all months, as indicated by the positive
456 BSS (Fig. 7b). However given the limited availability of valid satellite observations (especially
457 during months with low radiation intensity), the BSS are likely only robust for the summer
458 months for all species. Nevertheless, with the exception of NH_3 during June, BSS for all months
459 are above or close to zero indicating that on average, the enhanced resolution simulations do
460 improve the quality of the simulation of the gas phase species even when remapped to 60 km
461 resolution. Further, the seasonal average spatial patterns of the total columnar concentrations,
462 expressed in terms of *z*-scores, also exhibit qualitative agreement with the satellite observations
463 (Fig. S4-S7).

464 **4 Concluding remarks**

465 This analysis is one of the first to quantify the impact of model spatial resolution on the spatio-
466 temporal variability and magnitude of AOD, and does so using simulations for a full calendar
467 year. Application of WRF-Chem at two different resolutions (60 km and 12 km) over eastern
468 North America for a representative year (2008) leads to the following conclusions:

- 469 - Higher resolution simulations add value (i.e. enhance the fidelity of AOD at and near
470 to the peak in the solar spectrum) relative to a coarser run, although the improvement
471 in model performance is not uniform in space and time. Brier Skill Scores for the
472 remapped simulations (i.e. output from simulations conducted at 12 km (WRF12) then
473 averaged to 60 km, WRF12-remap) are positive for ten of twelve calendar months, and
474 for $\text{AOD}(\lambda=550 \text{ nm})$ exceed 0.5 for seven of twelve months.

- 475 - Spatial correlations of output from WRF12 and WRF12-remap with observations from
476 MODIS are higher than output from a simulation conducted at 60 km during most
477 months. For example, in contrast to WRF-Chem simulations at 60 km (WRF60),
478 simulations conducted at 12 km (WRF12) show positive spatial correlations with
479 MODIS for all λ in all calendar months, and particularly during summer ($\rho = 0.5-0.7$).
- 480 - Output from WRF12 and WRF12-remap exhibit highest accord with MODIS
481 observations in capturing the frequency, magnitude and location of extreme AOD
482 values during summer when AOD is typically highest. During May-August WRF12-
483 remap has *Hit Rates* for identification of extreme AOD of 53-78%.
- 484 - At least some of the improvement in the accuracy with which AOD is reproduced in
485 the higher resolution simulations may be due to improved fidelity of specific humidity
486 and thus more accurate representation of hygroscopic growth of some aerosol
487 components.
- 488 - Higher-resolution simulations also add value in the representation of other key
489 meteorological variables such as temperature, boundary layer height and precipitation.
490 Both spatial patterns and precipitation occurrence are better captured by WRF12-
491 remap.
- 492 - More accurate representation of spatial patterns and magnitude of gaseous species that
493 play a key role in particle formation and growth is also achieved by running WRF-
494 Chem at high resolution.

495 It is worthy of note that even the 12 km resolution WRF-Chem simulations exhibit substantial
496 differences in AOD relative to MODIS over eastern North America, and the agreement varies
497 only slightly with wavelength. This may be partially attributable to use of the modal approach
498 to represent the aerosol size distribution in order to enhance computational tractability. In this
499 application each mode has a fixed geometric standard deviation (σ_g), which can lead to biases
500 in simulated AOD in the visible wavelengths by up to 25% (Brock et al., 2016) (with the model
501 overestimating observations if the prescribed σ_g is larger than the observed one). Setting $\sigma_g =$
502 2 for the accumulation mode (the default in WRF-Chem) may lead to an overestimation of the
503 number of particles at the end of the accumulation mode tail, and there is evidence that a value
504 of $\sigma_{g,acc}=1.40$ leads to higher agreement with observations (Mann et al., 2012). Further possible
505 sources of the AOD biases reported herein derive from selection of the physical schemes (e.g.
506 planetary boundary layer (*PBL*) schemes and land-surface model (Misenis and Zhang,
507 2010;Zhang et al., 2009)). Further, it is worth mentioning that NEI emissions are specified

508 based on an average summertime weekday, so enhanced model performance might be achieved
509 if seasonally varying emissions were available. Future work will include a systematic
510 sensitivity analysis of these effects.

752

753

757 **Figure 1. Probability density function of once daily AOD at a wavelength (λ) of 550 nm**
 758 **for (a) MODIS, (b) WRF60 and (c) WRF12 and WRF12-remap during the year 2008. (d-**
 759 **f) Taylor diagrams of mean monthly AOD at wavelengths (λ) of (d) 470, (e) 550 and (f)**
 760 **660 nm as simulated by WRF-Chem at different resolutions (black diamonds=WRF60**
 761 **and red dots=WRF12-remap) relative to MODIS observations. The numbers by each**
 762 **symbol denote the calendar month (e.g. 1=January).**

764

765 **Figure 2. First line: Number of paired AOD observations at a wavelength (λ) of 550 nm**
 766 **(i.e. simultaneous values as output from WRF-Chem and observed by MODIS) used to**
 767 **perform a t-test designed to evaluate whether the difference computed for each grid cell**
 768 **as WRF60-MODIS differs from that computed as WRF12-remap-MODIS on a seasonal**
 769 **basis (columns show Winter (DJF), Spring (MAM), Summer (JJA) and Fall (SON)).**
 770 **Second line: Results of the t-test. Pixels that have p-values that are significantly different**
 771 **at $\alpha=0.10$ are indicated in red and have been corrected for multiple testing using a False**
 772 **Discovery Rate approach. The number of observations of cloud-free conditions summed**
 773 **across all days in each season and all grid cells is also reported (black=MODIS,**
 774 **blue=WRF60, red=WRF12-remap).**

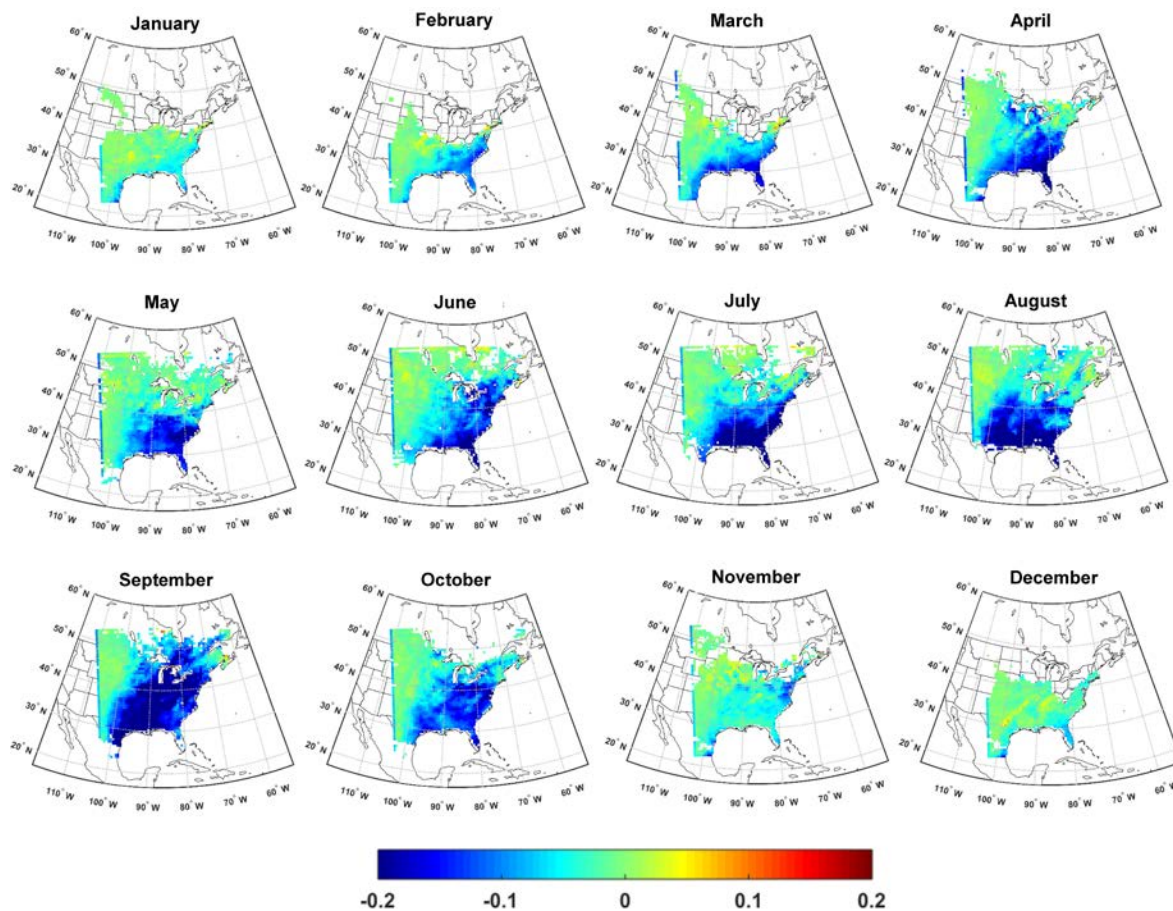

775

776

777 **Figure 3. Monthly mean AOD at a wavelength (λ) of 550 nm from MODIS (first line) and**
 778 **WRF-Chem at different resolutions (WRF60 and WRF12-remap, second and third line)**
 779 **during a representative month in each climatological season (columns). Note that a**
 780 **different color scale is applied for different months. For a monthly mean value for a grid**
 781 **cell to be shown, there must be at least 5-simultaneous daily values (for the time of the**
 782 **satellite overpass) available.**

783

784

785 **Figure 4. Difference in monthly mean AOD at a wavelength (λ) of 550 nm between WRF-**
 786 **Chem simulations conducted at 60 km resolution (WRF60) and output from WRF-Chem**
 787 **simulations conducted with a resolution of 12 km but remapped to 60 km (WRF12-**
 788 **remap). Differences are computed as WRF60 minus WRF12-remap. Similar spatial**
 789 **patterns and magnitudes of differences are found for λ of 470 and 660 nm. The calendar**
 790 **months of 2008 are shown in the titles of each panel.**

791

792

793 **Figure 5. Brier Skill Scores (BSS, black dots) for monthly mean AOD by calendar month**
 794 **(1=January) for AOD at 470, 550 and 660 nm. In this analysis of model skill WRF12**
 795 **output is mapped to the WRF60 grid (WRF12-remap) and BSS are computed using**
 796 **MODIS as the target, WRF60 as the reference forecast and WRF12-remap as the**
 797 **forecast. Also shown by the color lines are the contributions of different terms to BSS.**

798

799

800 **Figure 6. Seasonal mean specific humidity [kg m^{-2}] integrated from the surface to 825 hPa**
 801 **(Q_{PBL}) from MERRA-2 (first row) assuming an average air density in the *PBL* of 1.1 kg**
 802 **m^{-3} , WRF60 (second row), and WRF12-remap (third row). The data are 3-hourly and**
 803 **show only cloud-free hours in all three data sets.**

804

805

806 **Figure 7. Brier Skill Scores (BSS) for key (a) meteorological and (b) chemical variables.**

807 **BSS are computed using hourly data of T at 2m (T_{2m}) and PBLH, 3-hourly estimates of**

808 **specific humidity in the boundary layer (Q_{PBL}), and z-scores of monthly total precipitation**

809 **(PPT), and of monthly mean columnar gas phase concentrations.**

810

811

812 **Tables**

813 **Table 1. Physical and chemical schemes adopted in the WRF-Chem simulations presented**
814 **herein.**

Simulation settings	Values
Domain size	300 × 300 (60 × 60) grid points
Horizontal resolution	12 km (60 km)
Vertical resolution	32 levels up to 50 hPa
Timestep for physics	72 s (300 s)
Timestep for chemistry	5 s
Physics option	Adopted scheme
Microphysics	WRF Single-Moment 5-class (Hong et al., 2004)
Longwave Radiation	Rapid Radiative Transfer Model (RRTM) (Mlawer et al., 1997)
Shortwave Radiation	Goddard (Fast et al., 2006)
Surface layer	Monin Obhukov similarity (Janjić, 2002; Janjić, 1994)
Land Surface	Noah Land Surface Model (Chen and Dudhia, 2001)
Planetary boundary layer	Mellor-Yamada-Janjich (Janjić, 1994)
Cumulus parameterizations	Grell 3 (Grell and Dévényi, 2002)
Chemistry option	Adopted scheme
Photolysis	Fast J (Wild et al., 2000)
Gas-phase chemistry	RADM2 (Stockwell et al., 1990)
Aerosols	MADE/SORGAM (Ackermann et al., 1998; Schell et al., 2001)
Anthropogenic emissions	NEI (2005) (US-EPA, 2009)
Biogenic emissions	Guenther, from USGS land use classification (Guenther et al., 1994; Guenther et al., 1993; Simpson et al., 1995)

815

816

817 **Table 2. Spearman correlation coefficients (ρ) between AOD at wavelengths (λ) of 470,**
818 **550 and 660 nm from MODIS observations averaged over 12 or 60 km and WRF-Chem**
819 **simulations conducted at 60 km (WRF60, shown in the table as -60), at 12 km (WRF12,**
820 **shown in the table as -12), and from WRF-Chem simulations at 12 km but remapped to**
821 **60 km (WRF12-remap, shown in the table as -remap). Given WRF12-remap is obtained**
822 **by averaging WRF12 when at least half of the 5×5 12 km resolution cells contain valid**
823 **data, ρ from WRF60 and WRF12-remap may be computed on slightly different**
824 **observations and sample size. The bold text denotes correlation coefficients that are**
825 **significant at $\alpha=0.05$ after a Bonferroni correction is applied (i.e. $p \leq \frac{0.05}{9 \times 12} = 4.63 \times 10^{-4}$**
826 **is significant). The yellow shading is a visual guide that shows for each month and λ the**
827 **model output that has highest ρ with MODIS.**

830 **Table 3. Spatial coherence in the identification of extreme AOD values (i.e. areas with**
831 **AOD>75th percentile over space for each month) between WRF-Chem at different**
832 **resolutions relative to MODIS. No significant wavelength dependence is found for model**
833 **skill in identifying extreme AOD so results are only shown for $\lambda = 550$ nm. The different**
834 **model output is denoted by -60 for simulations at 60 km, -12 for simulations at 12 km**
835 **resolution, and as -remap for simulations at 12 km but with the output remapped to 60**
836 **km. The Accuracy (Acc) indicates the fraction of grid cells co-identified as extremes and**
837 **non-extremes between WRF-Chem and MODIS relative to the total number of cells with**
838 **valid data. The Hit Rate (HR) is the probability of correct forecast and is the proportion**
839 **of cells correctly identified as extremes by both WRF-Chem and MODIS. The yellow**
840 **shading indicates the model resolution with highest skill in each month for AOD at 550**
841 **nm.**
