

Revision of the paper “Continental pollution in the Western Mediterranean Basin: large variability of the aerosol single scattering albedo and influence on the direct shortwave radiative effect” by C. Di Biagio et al.

At first, we would like to thank the reviewers for having read the paper and provided valuable comments which helped to improve the quality of the manuscript. We have taken into consideration all the questions raised by the reviewers, and changed the paper accordingly. The details of our changes are highlighted in the text. The point by point answers to Reviewer #1 and #2 are provided in the following.

Some other minor changes, mostly regarding typos or grammar issues, were performed throughout the text. I also decided to refer to the “SkyGRIMM” only as “GRIMM” to be consistent with the spelling used in Di Biagio et al. (2015):

Di Biagio, C., et al.: Continental pollution in the western Mediterranean basin: vertical profiles of aerosol and trace gases measured over the sea during TRAQA 2012 and SAFMED 2013, Atmos. Chem. Phys., 15, 9611-9630, doi:10.5194/acp-15-9611-2015, 2015.

Reviewer #1

Line 78: Change “. . . aerosol optical properties represents one the main source. . .” to “. . . aerosol optical properties represents the main source. . .”

Done

Line 80: Change “In this sense, intensive studies providing with the characterization. . .” to “In this sense, intensive studies providing the characterization. . .”

Done

Line 86: Rephrase “. . . which makes that anthropogenic..”, it doesn’t make sense as is.

The sentence has been rewritten as: “On its northern bound, it is limited by Europe, with a consequent frequent export of anthropogenic pollution from the continent towards the basin (Lelieveld et al., 2002; Pace et al., 2006)”

Lines 461-520 (Section 4.4): Since you use the refractive index to derive the size distribution, it would be better to take this into account in your “optical closure” process: change the size distribution based on the retrieved refractive index and see if you achieve the optical closure for the new size distribution. If not, retrieve a new refractive index using the new size distribution and the measured optical properties, change the size distribution based on the new refractive index and continue the process until you achieve the closure. I think that especially the large range of the imaginary part of the refractive index should have a distinctive effect on the derived size distribution and, consequently, on your optical closure procedure. If not, please provide relevant evidence.

I agree with the reviewer that this iterative approach is more appropriate and I applied it in this study to estimate the size distribution and refractive index of pollution aerosols. The details of the procedure are reported in Sect. 3.2 and illustrated in the new Figure 2. The results are discussed in the new Sect. 4.4: “Complex refractive index of pollution aerosols”.

By applying the new retrieval procedure I obtain larger values (<20-50% increase) of both n and k at all wavelengths for five of the eight SLRr analysed, while no changes in the spectral refractive index are obtained in the other three cases. Conversely, no major changes are observed in the size distribution as a result of the iterative optical-to-geometrical refractive index correction (Fig. 4).

Due to the new retrieval, the results in Table 3 and Figures 4, 8, and 9 have also slightly changed.

Lines 485-490: How do the retrieved values of n and k compare with the ones used to derive the size distribution from PCASP and GRIMM measurements? Provide a comparison in a plot.

The optical-to-geometrical diameter conversion is now performed iteratively as explained in Sect. 3.2 and in the previous answer. In any case, the old values used to correct the PCASP and SkyGrimm data ($n=1.50\div 1.72$ and $k=0.01$ at 632.8 and 655 nm, i.e. the operating wavelengths of the PCASP and the SkyGrimm) were in the range of variability of the obtained n and k by optical closure. In particular, k was at the mean of the estimated imaginary parts of the refractive index for the different cases at 660 nm. We can thus argue that the former approach used to perform the optical-to-geometrical diameter correction could be valuable to represent the “average” aerosol, as observed in this study.

Reviewer #2

The manuscript by Di Biagio et al. presents particle number size distributions, aerosol scattering and absorption coefficients and the derived quantities, which were performed in the course of the seventeen flights during the TRAQA campaign. The objective of the paper solves a well-defined questions: what is the heterogeneity on the optical properties in the Mediterranean Basin? and, how the observed variability is influencing in the evaluation of the radiative efficiency? To response these two questions, an analysis of the single scattering albedo is used.

The topic of the paper is suitable for ACP, the paper is well written and structured, the experimental approach is sound, and the data interpretation is reasonable. Then, the reviewer recommends the manuscript for publication with minor revisions: for which I give some suggestions below.

Specific comments:

Line 268: Please, modify the sentence: ‘The total particle number concentration in the Aitken (4nm-0.1 μm ; dNAitken). . .’ to ‘The total particle number concentration in the ultrafine (4nm-0.1 μm ; dNUFP). . .’. It is because nucleation mode is (4-30) nm and Aitken mode is (30-100)nm. Nucleation+Aitken modes is called the ultrafine mode (UFP= UltraFine Particles). Modify the term dNAitken to dNUFP throughout the manuscript.

We replaced Aitken with UFP throughout the manuscript.

Line 387: please, check the reference section. Some references are missed (e.g. Toledano et al., 2007).

I checked the reference list and added missing references.

Lines 421-422 and Table 3: include the correlation coefficient between observed and fitted size distribution with the aim to analyze the goodness of fit function value.

The correlation coefficient is larger than 0.97 for all analysed cases. We have added this information in the main text: “The correlation coefficient for the fit functions is larger than 0.97 for all cases.” (Sect. 4.2).

Section 4.2 and Figure 3: Number and volume size distributions in terms on the different air mass origin will be welcome.

Figure 3 has been redrawn by separating the data based on the origin of the sampled air masses. Also, the following text has been added in Section 4.2, as a comment to the new figure: “The minimum of the size distribution over the whole diameter range was measured in the Western sector (V32_R3), whilst the largest number concentrations in the super-micron range were observed in correspondence of V19_R1 and V32_R1. For all the other SLRs, the size distributions were very similar, especially at diameters below $\sim 5 \mu\text{m}$.”.

Lines 430-433: The single scattering albedo increasing with wavelength may also suggest

a desert dust contribution. For dust particles, the scattering is fairly constant with wavelength so the SSA matches the decrease in absorption with wavelength (e.g. see Bergstrom et al., 2007 in ACP).

We have modified the text as:

“For these cases also very high values of ω were observed (0.92-0.97 for V19_R1 and 0.98-1.0 for V30_R2), which may suggest the possible mixing of pollution with sea spray or desert dust particles, both showing low absorption in the shortwave range (Bergstrom et al., 2007).”

The Abstract has been modified accordingly.

Figure 5: What is the meaning of the horizontal bars? Please, indicate in the Figure legend.

Horizontal bars represent the uncertainty on the measured/retrieved quantities shown in the plot. This has been specified in the figure caption.

Figure 6: please, check the comment for Figure 5.

See the previous answer.

During the revision we detected an error with the error-bars (which were inverted between the x and the y axes). We corrected this and also, for the sake of clarity, we decided only to show horizontal bars (measurements uncertainties) in the plot.

34 **Abstract**

35 Pollution aerosols strongly influence the composition of the Western Mediterranean basin,
36 but at present little is known on their optical properties. We report in this study in situ
37 observations of the single scattering albedo (ω) of pollution aerosol plumes measured over
38 the Western Mediterranean basin during the TRAQA (TRAnsport and Air QuAlity) airborne
39 campaign in summer 2012. Cases of pollution export from different source regions around
40 the basin and at different altitudes between ~ 160 and 3500 m above sea level ~~have been~~
41 sampled during the flights. Data from this study show a large variability of ω , with values
42 between 0.84-0.98 at 370 nm and 0.70-0.99 at 950 nm. The single scattering albedo generally
43 decreases with the wavelength, with some exception associated to the mixing of pollution
44 with sea spray or dust particles over the sea surface. ~~The~~ Lowest values of ω (0.84-0.70
45 between 370 and 950 nm) are measured in correspondence of a fresh plume possibly linked
46 to ship emissions over the basin. The range of variability of ω observed in this study seems to
47 be independent of the source region around the basin, as well as of the altitude and ageing
48 time of the plumes. The observed variability of ω reflects in a large variability for the
49 complex refractive index of pollution aerosols, which is estimated to span in the large range
50 1.41-1.75 and 0.002-0.068 for the real and the imaginary parts, respectively, between 370 and
51 950 nm.

52 Radiative calculations in clear-sky conditions ~~have been~~ performed with the GAME
53 radiative transfer model to test the sensitivity of the aerosol shortwave Direct Radiative
54 Effect (DRE) to the variability of ω as observed in this study. Results from the calculations
55 suggest up to a 50% and 30% change of the forcing efficiency (FE), i.e. the DRE per unit of
56 optical depth, at the surface ($-160 \div -235 \text{ Wm}^{-2}\tau^{-1}$ at 60° solar zenith angle) and at the Top-Of-
57 Atmosphere ($-137 \div -92 \text{ Wm}^{-2}\tau^{-1}$) for ω varying between its maximum and minimum value.
58 This induces a change of up to an order of magnitude ($+23 \div +143 \text{ Wm}^{-2}\tau^{-1}$) for the radiative
59 effect within the atmosphere.

1. Introduction

69 Atmospheric aerosols play a crucial role on climate by affecting the radiative transfer of
70 atmospheric radiation and by modifying cloud properties and lifetime (Boucher et al., 2013).
71 The capability of atmospheric aerosols to interact through processes of scattering and
72 absorption with the atmospheric radiation, so to exert a direct radiative effect (DRE), depends
73 on their spectral optical properties (extinction efficiency, k_{ext} , single scattering albedo, ω , and
74 asymmetry factor, g). In particular the single scattering albedo has been demonstrated to be a
75 key parameter in modulating the surface, Top-of-Atmosphere (TOA), and atmospheric
76 aerosol DRE (e.g., Ramana and Ramanathan, 2006; Di Biagio et al., 2010; Loeb and Su,
77 2010). Aerosol optical properties can largely vary depending on the particles composition,
78 size distribution, and shape, which are function of the aerosol source, type, and processing
79 occurring during atmospheric lifetime. At present, the capability of climate models in
80 reproducing all the possible heterogeneity in aerosol optical properties represents ~~one~~-the
81 main source of uncertainty in evaluating their DRE on climate (McComiskey et al., 2008;
82 Stier et al., 2013). In this sense, intensive studies providing ~~with~~-the characterization of the
83 aerosol optical properties and their local and regional variability are of great importance in
84 order to reduce these uncertainties.

85 This is particularly the case of the Western Mediterranean basin. Indeed, the Mediterranean is
86 a very complex region, characterized by the presence of air masses carrying aerosols of
87 different origins and types (Gkikas et al., 2012). On its northern bound, it is limited by
88 Europe, with a consequent frequent export of which ~~makes that~~ anthropogenic pollution ~~is~~
89 ~~usually exported~~ from the continent towards the basin (Lelieveld et al., 2002; Pace et al.,
90 2006). In particular, the Western part of the Mediterranean basin, surrounded by large coastal
91 megacities, commercial harbours, and under the direct influence of some of the most
92 industrialized areas of the continent (such as the Po Valley in Northern Italy or the Fos/Berre
93 area in Southern France), is strongly affected by continental pollution outflows (Pérez et al.,
94 2008; Pey et al., 2010; Di Biagio et al., 2015). The build-up of high pollution levels over the
95 Western basin is particularly favoured during summer when the strong insolation enhances
96 photochemical reactions and the stable meteorological conditions promote the stagnation of
97 pollutants (Millan et al., 2000; Mallet et al., 2005).

98 In spite of this, the characterization of the optical properties of anthropogenic aerosols in this
99 part of the basin remains only limited to coastal and inland regions (Mallet et al., 2003, 2011,
100 2013; Lyamani et al., 2006; Estelles et al., 2007; Saha et al., 2008; Esteve et al., 2012;
101 Piazzola et al., 2012; Pandolfi et al., 2011 and 2014), or remote islands actually far from the
102 strong influence of continental outflows (Lyamani et al., 2015). Moreover, the majority of
103 these studies uses remote sensing measurements and analyse aerosol properties integrated
104 over the entire atmospheric column, without information on their vertical variability. Thus, at
105 present, we miss a detailed characterization of the optical properties of the pollution aerosol
106 over the entire region, in particular over the remote sea, and its vertical distribution.

107 To fill this gap, the international ChArMEx (Chemistry-Aerosol Mediterranean Experiment;
108 <http://charmex.lsce.ipsl.fr>) research program has supported in recent years two airborne
109 campaigns over the Western Mediterranean basin: TRAQA (Transport and Air QuAlity) in
110 2012 and SAFMED (Secondary Aerosol Formation in the MEDiterranean) in 2013.

111 In a recent paper, Di Biagio et al. (2015) have presented in situ measurements of the aerosol
112 vertical profiles acquired over the remote sea during these campaigns. Observations from
113 TRAQA and SAFMED have shown that in the Western basin pollution plumes extend as far
114 as hundreds of km from the coastline and reach up to ~4000 m, presenting a complex
115 stratified structure, and pollution plumes show a large heterogeneity in terms of composition,
116 origin, and lifetime.

117 Following these observations, we may ask: does the heterogeneity in pollution plume
118 composition, origin, and lifetime as observed in Di Biagio et al. (2015) induce heterogeneity
119 on the optical properties (in particular the single scattering albedo) of pollution aerosols in
120 this part of the basin? And, if observed, does this heterogeneity on the optical properties
121 influence the aerosol DRE? Is it necessary to take it into account to better evaluate the aerosol
122 radiative impact in the Western Mediterranean?

123 With the aim of answering these questions, in this paper we analyse data of the optical
124 properties (spectral scattering and absorption coefficients, ~~and~~ single scattering albedo) and
125 size distributions of pollution aerosols measured over the Western Mediterranean basin
126 during TRAQA. SAFMED observations have been excluded here given that only limited data
127 on the aerosol optical properties ~~are~~ were available from this campaign. The objective of the
128 paper is twofold: to provide a new dataset of aerosol single scattering albedo values which
129 can be representative of the polluted aerosols over the Western basin, and investigate the
130 sensitivity of the aerosol direct DRE to the variability of this parameter.

2. Overview of flights during the TRAQA campaign

The TRAQA campaign took place in the period 20 June – 13 July 2012. Instruments were installed on board the SAFIRE (Service des Avions Français Instruments pour la Recherche en Environnement, <http://www.safire.fr/>) tropospheric aircraft ATR-42, based in Toulouse (43° 36' N, 1° 26' E, France). A total of seventeen flights, most often two flights per day, with intermediate stops in different airports in southern France and Corsica, were performed (flight numbers V16 to V32). The majority of flights were over the sea, with some exceptions investigating inland areas in southern France. The flight altitude for the ATR-42 ranged between a minimum of ~60 m to a maximum of ~5000 m above sea level (a.s.l.), and the maximum flight time was 4 h. The general flight strategy consisted of legs at constant altitude to sound the vertical structure by lidar observations, vertical ascents/descents to describe the vertical atmospheric column and identify the main aerosol plumes, followed by straight levelled runs (SLRs) within the detected aerosol layers. In the present study we will exclusively consider measurements acquired during SLRs, since only during these phases the whole set of aerosol optical properties (scattering and absorption coefficients) were measured. A total of 21 SLRs were performed over the sea surface or inland close to the coastline and will be considered in this study. Figure 1 and Table 1 summarise the geographical location, date, time, and altitude of these 21 SLRs. As indicated in Table 1 each SLR was about 15-20 min long. At the cruise speed of the ATR (93 ms⁻¹), this integration time corresponds to about 100 km.

3. Measurements and methods

3.1 Aircraft observations

Aerosol sampling on the ATR-42 was performed using the AVIRAD system. AVIRAD is an iso-axial and iso-kinetic inlet which samples air at a volumetric flow of ~350 L min⁻¹. The 50% passing efficiency of the inlet is 12 µm diameter. Various lines depart from AVIRAD to connect to different instruments for the measurement of the aerosol physico-chemical and optical properties. Additionally, several sensors for the measurements of the atmospheric composition were installed on the ATR-42 aircraft as basic equipment. A brief description of

163 the different in situ measurements considered in this study from the AVIRAD system and the
164 ATR-42 equipment and their data analysis is reported in the following.

165 - The aerosol scattering coefficient (σ_s) at 450, 550, and 700 nm ~~has been was~~ measured by a
166 3-wavelengths integrating nephelometer (TSI Inc., model 3563, 6s resolution). The
167 nephelometer was calibrated prior the campaign by using air and CO₂ as reference gases.
168 Nephelometer measurements ~~have been were~~ corrected for angular truncation and
169 Lambertian non-idealities by applying the formula by Anderson and Ogren (1998),
170 appropriated to submicron aerosols which we expected in the pollution plumes sampled
171 during the campaign. The measurement uncertainty on σ_s , calculated taking into account
172 for the photon counting, gas calibration, and angular corrections uncertainties, ~~is was~~
173 estimated to be lower than 10% at the three wavelengths. Averages of the scattering
174 coefficient ~~are were~~ calculated over the different SLRs. The uncertainty on the SLR
175 average values ~~is was~~ estimated as the combination of the measurement uncertainty and
176 the standard deviation along each individual run. For each SLR, the particle scattering
177 Ångström exponent (SAE) ~~has been was~~ calculated as the power law fit of the measured
178 scattering coefficients versus wavelength to extrapolate the scattering coefficient at other
179 wavelengths than those of operation.

180 The nephelometer measured the scattering coefficient in dry air conditions. This is due to
181 the heating of the airflow while entering the aircraft cabin and the temperature increase in
182 the sensing volume of the instrument due to illumination. The relative humidity measured
183 during the flights inside the nephelometer cavity was <25% in more than 90% of cases,
184 with values up to ~40% occasionally observed <200 m over the sea surface.

185 - The aerosol absorption coefficient (σ_{abs}) at 370, 470, 520, 590, 660, 880, and 950 nm ~~has~~
186 ~~was been~~ measured by a 7-wavelengths aethalometer (Magee Sci., model AE31, 2min
187 resolution). The principle of operation of the aethalometer consists in measuring the
188 attenuation of light through an aerosol-laden filter compared to that of another portion of
189 the filter which is unexposed to the air flow and is used as a reference (Weingartner et al.,
190 2003). To yield the aerosol absorption coefficient, the spectral attenuation $\sigma_{ATT}(\lambda)$
191 measured by the aethalometer ~~has was been~~ corrected following the procedure described by
192 Collaud Coen et al. (2010):

193
$$\sigma_{abs}(\lambda) = \frac{\sigma_{ATT}(\lambda) - \alpha(\lambda)\overline{\sigma_s(\lambda)}}{C_{ref}R(\lambda)} \quad (1).$$

194 The different terms in equation 1 are: (i) $\alpha(\lambda)\overline{\sigma_s(\lambda)}$ or “scattering correction”. In this work
 195 $\alpha(\lambda)$ ~~has-been~~was calculated with the formula by Arnott et al. (2005) and ~~varies~~varied
 196 between 0.02 and 0.07, while $\overline{\sigma_s(\lambda)}$ ~~is~~was the average of the scattering coefficient along
 197 the considered SLR extrapolated at the aethalometer wavelengths; (ii) C_{ref} or “multiple
 198 scattering correction”. C_{ref} ~~is~~was set to 2.14 ± 0.21 (wavelength-independent) following
 199 Weingartner et al. (2003); (iii) $R(\lambda)$ or “shadowing effect correction”. $R(\lambda)$ depends on
 200 the charge and absorptivity properties of the sampled aerosol and can be calculated as a
 201 function of the particle single scattering albedo (ω). In this study, because of the absence
 202 of an independent determination of ω , we used an estimated “first-guess” single scattering
 203 albedo (ω^*) to calculate R . This ~~has-been~~was determined as the ratio of the measured
 204 scattering (σ_s) to extinction ($\sigma_s + \sigma_{\text{abs}}^*$) coefficients, with σ_{abs}^* corrected for the scattering
 205 and the multiple scattering corrections, but not for the shadowing effect. The obtained
 206 $R(\lambda)$ ~~varies~~varied between 0.75 and 1 for ω^* between 0.75-0.99 at 370 nm and 0.70-0.99
 207 at 950 nm. The whole uncertainty on the absorption coefficient ~~has-been~~was estimated
 208 with the propagation error formula taking into account for the different factors in Eq. (1)
 209 and ~~varies~~varied between 11-36% at 370 nm and 12-70% at 950 nm.

210 It has to be noticed that an enhanced absorption at single wavelengths ~~has-been~~was
 211 observed in several cases for the aethalometer. This ~~is~~was possibly due to the absorption
 212 on the exposed filter of gases or volatile compounds absorbing at some of the instrument
 213 operating wavelengths (Weingartner et al., 2003). These anomalous points ~~have-been~~were
 214 accurately selected and screened from the dataset. As a result of this screening, data in
 215 correspondence of only 60% of the considered SLRs ~~are~~were available for aerosols
 216 analyses.

217 The measured aerosol scattering and absorption coefficients ~~have-been~~were used to
 218 calculate the particle spectral single scattering albedo (~~ω~~) between 370 and 950 nm as:

$$219 \quad \omega(\lambda) = \frac{\sigma_s(\lambda)}{\sigma_s(\lambda) + \sigma_{\text{abs}}(\lambda)} \quad (2).$$

220 The uncertainty on ω ~~has~~was~~been~~ calculated with the propagation error formula and
 221 ~~varies~~varied between 0.02 and 0.04 at all wavelengths.

222 Additionally, for each SLR for which aethalometer data ~~are~~were available, the particle
 223 absorption Ångström exponent (AAE) ~~has-been~~was calculated as the power law fit of the
 224 measured absorption coefficients versus wavelength.

225 | - The aerosol number size distribution ($dN/d\log D_g$) ~~has been was~~ measured by two different
 226 | optical particle spectrometers: the passive cavity aerosol spectrometer probe (PCASP,
 227 | model 100-X, 1-s resolution, 31 size classes between 0.1 and 3.0 μm diameter, operating
 228 | wavelength 632.8 nm), and the optical particle spectrometer ~~SkyGRIMM-GRIMM~~
 229 | (GRIMM Inc., model 1.129, 6-s resolution, 32 size classes between 0.3 and 32 μm
 230 | diameter, operating wavelength 655 nm). For both the PCASP and the
 231 | ~~SkyGRIMMGRIMM~~, the measured sphere-equivalent optical diameter ~~has been was~~
 232 | converted in a sphere-equivalent geometrical diameter (D_g) by taking into account the
 233 | complex refractive index of the sampled aerosol (Liu and Daum, 2000). Differently from
 234 | Di Biagio et al. (2015), where the complex refractive index used to correct the size was
 235 | fixed based on literature values ($n=1.52\div 1.70$, $k=0.01$ for pollution aerosols in the
 236 | Mediterranean), here the Calculation are performed by fixing the imaginary part of the
 237 | refractive index at 0.01, thus representing a medium absorbing aerosol, while varying the
 238 | real part between 1.50 and 1.72, following the range of variability found in the literature
 239 | for pollution aerosols in the Mediterranean (see Di Biagio et al., 2015 for further details).
 240 | complex refractive index to correct the size was iteratively adjusted based on optical
 241 | closure calculations. Full details of the procedure are provided in Sect. 3.2. D_g is then set
 242 | at the mean \pm one standard deviation of the values obtained for the different n . After
 243 | optical closure and refractive index correction the D_g ranges varied between 0.10-4.24 and
 244 | 0.10-4.84 μm for the PCASP and 0.26-58.75 and 0.30-73.60 μm for the
 245 | SkyGRIMMGRIMM as a function of the assumed aerosol refractive index become 0.10-
 246 | 4.47 and 0.28-65.80 μm . The uncertainty on D_g with an uncertainty is between 1 and
 247 | 25%. For comparison, the D_g values obtained in Di Biagio et al. (2015) were 0.10-4.47
 248 | and 0.28-65.80 μm for the PCASP and the GRIMM, respectively. The smallest and the
 249 | largest size bins of both instruments, for which the minimum and maximum edges
 250 | respectively are not defined, ~~have been were~~ excluded from the datasets, thus reducing the
 251 | PCASP and GRIMM D_g ranges to 0.10-3.94 and 0.11-4.53 μm for the PCASP and 0.28-
 252 | 50.01 and 0.34-63.03 μm for the GRIMM., thus reducing the PCASP and SkyGRIMM D_g
 253 | ranges to 0.11-4.17 μm and 0.31-56.21 μm , respectively.
 254 | Corrected data from the PCASP and the ~~SkyGRIMMGRIMM~~ are were then merged to
 255 | obtain the aerosol size distribution over a larger size range. The two instruments
 256 | superimpose in a large interval covering the diameter range $\sim 0.301\text{--}4.170$ μm . In this
 257 | interval the PCASP and the GRIMM showed a good agreement below 0.4 μm and above

258 1.0 μm (less than $\sim 10\%$ difference), while significant differences were observed in the
 259 0.4-1.0 μm range where the PCASP underestimates the SkyGRIMMGRIMM
 260 measurements by more than $\sim 50\%$. This difference is of great relevance in terms of optical
 261 properties because particles in the 0.4-1.0 μm size interval are very efficient for interaction
 262 with shortwave radiation. With the aim of understanding which of the two instruments
 263 measures correctly in the 0.4-1.0 μm range we ~~have~~ performed an optical test, which
 264 consisted in calculating with Mie theory the scattering coefficient at 450, 550, and 700 nm
 265 based on the PCASP and SkyGRIMMGRIMM size data, and then in comparing it with
 266 simultaneous nephelometer measurements. Optical calculations ~~have been~~ performed
 267 by fixing the complex refractive index at 1.6-0.01i, so at the mean of the range of values
 268 reported in the literature for pollution aerosols (Ebert et al., 2002 and 2004; Mallet et al.,
 269 2003 and 2011; Müller et al., 2002; Raut and Chazette, 2008). SLRs characterized by a
 270 low variability in terms of scattering coefficient and particle concentration ~~have been~~
 271 selected. The results of the optical test indicate that in the 0.4-1.0 μm range the size
 272 distribution of the SkyGRIMMGRIMM is more accurate since it permits to most closely
 273 reproduce nephelometer observations ($< 5\%$ mean difference between calculations and
 274 observations at the three wavelengths, compared to differences up to 15-21% if PCASP
 275 data are used in the 0.4-1.0 μm size range). Thus, a combined PCASP-
 276 SkyGRIMMGRIMM number size distribution $dN/d\log D_g$ in the ~ 0.14 to 50.01 -
 277 63.036 - 24 μm diameter range ~~has been~~ was calculated-estimated by considering PCASP
 278 data up to 0.31 - 30 μm and SkyGRIMMGRIMM data above. ~~Together with the number~~
 279 ~~size distribution, for each SLR also~~ The volume size distribution was also computed as
 280 $dV/d\log D_g = \pi/6 D_g^3 dN/d\log D_g$ ~~has been~~ calculated. Averages of the number and volume
 281 size distributions over each SLRs were calculated.

282 Nonetheless, due to a technical problem, SkyGRIMMGRIMM data were only available
 283 below ~ 350 m (~ 970 hPa).

284 - The total particle number concentrations in the Aitken-ultrafine mode (4 nm-0.1 μm ;
 285 dN_{Aitken} dN_{UFP} , i.e. formerly defined as Aitken mode in Di Biagio et al., 2015) and
 286 accumulation mode (0.1-1.0 μm ; dN_{Acc}) ~~modes have been~~ were calculated by combining
 287 condensation particle counter measurements of particle concentration in the 0.004 – 3 μm
 288 range (CPC, TSI Inc., model 3775, 5-s resolution) and size distribution data. Due to the
 289 fact that above 350 m the SkyGRIMMGRIMM ~~is~~ was not available, only PCASP data ~~are~~
 290 were used in the calculations of $dN_{\text{AitkenUFP}}$ and dN_{Acc} over the whole altitude range.

291 $dN_{\text{AitkenUFP}}$ ~~is-was~~ estimated as the difference between CPC concentration and the integral
292 of PCASP data between 0.1 and 3.0 μm , while dN_{Acc} ~~is-was~~ obtained by integrating the
293 PCASP number concentrations in the 0.1-1.0 μm interval. The underestimation of the
294 PCASP number concentration between 0.4 and 1.0 μm , as discussed above, ~~is-was~~
295 estimated to induce a $\sim 20\%$ underestimation of the dN_{Acc} calculated here, whilst it ~~has-had~~
296 almost a negligible impact on $dN_{\text{AitkenUFP}}$. The ~~dN_{UFP} and dN_{Acc} and dN_{Aitken}~~ obtained in
297 correspondence of each SLR ~~have-been-were~~ used to calculate the ~~Aitkenultrafine~~-to-
298 accumulation ratio $dN_{\text{AitkenUFP}}/dN_{\text{Acc}}$.

299 - The carbon monoxide (CO) and ozone (O_3) mixing ratios ~~have-been-were~~ measured by the
300 MOZART instrument (CO, 30-s resolution and $\pm 5\%$ nominal uncertainty, O_3 , 4-s
301 resolution and $\pm 2\%$ nominal uncertainty) (Nedelec et al., 2003). Starting from the
302 measured O_3 and CO, the ozone enhancement ratio ($\Delta\text{O}_3/\Delta\text{CO}$) ~~has-been~~ calculated, i.e.
303 the ratio of the ozone to carbon monoxide variations compared to their baseline values. A
304 background value of ~ 70 ppbv in the boundary layer and ~ 60 ppbv in the free troposphere
305 ~~has-been-was~~ used for CO, while the background ~~has-been-was~~ set at ~ 30 ppbv for O_3 at all
306 levels (Di Biagio et al., 2015). $\Delta\text{O}_3/\Delta\text{CO}$ data ~~have-been-were~~ used together with
307 $dN_{\text{AitkenUFP}}/dN_{\text{Acc}}$ to retrieve information on the age of the sampled air masses, as
308 discussed in Di Biagio et al. (-2015).

309 In order to compare SLRs measurements obtained at different altitudes, the data analysed
310 here ~~are-were~~ reported to standard temperature and pressure (STP) using $T=293.15$ K and
311 $P=1013.25$ hPa. In this case, the scattering and absorption coefficients ~~are-were~~ scaled to STP
312 conditions and the particle concentrations (in number or volume) ~~are-were~~ given as particles
313 per standard cm^{-3} (scm^{-3}). Where not explicitly indicated, data refer to STP conditions.

314 In Table 2 we summarize main information and uncertainties for the different aerosol
315 instruments considered in this study.

316

317 3.2 Optical closure and estimation of the aerosol complex refractive index

318 An optical closure study was realised to estimate the complex refractive index ($m=n-ik$) of
319 pollution aerosols based on optical and size data. The flowchart of the procedure is illustrated
320 in Fig. 2. Optical closure consisted in recalculating the spectral scattering σ_s and absorption
321 σ_{abs} coefficients measured for each SLR by using the measured size distribution as input and
322 by varying the real (n) and imaginary (k) parts of the complex refractive index in the
323 calculations. Then, n and k were fixed when the best agreement between measurements and

324 calculations was found. Given that the size distribution measured by the PCASP and the
325 GRIMM depends on the aerosol refractive index, the optical-to-geometrical diameter
326 conversion was recalculated at each iteration based on the assumed n and k. Optical
327 calculations were performed using Mie theory for spherical particles. The Mie_single.pro
328 IDL routine available at http://www.atm.ox.ac.uk/code/mie/mie_single.html was used. In the
329 calculations the real part of the refractive index was varied in the range 1.30-1.80 at steps of
330 0.01, while the imaginary part in the range 0.001-0.1 at steps of 0.001, for a total of 5100
331 inversions for each SLR dataset. The uncertainty on the real and imaginary parts of the
332 refractive index was estimated with a sensitivity study. To this purpose, the values of n and k
333 were also obtained by using as input the observed σ_{sa} , σ_{absa} and $\frac{dN}{d \log D_g}$ plus or minus one
334 standard deviation on their measurement. The deviations of the values of n and k retrieved in
335 the sensitivity study with respect to those obtained in the first inversions were assumed to
336 correspond to the one standard deviation uncertainty. The estimated uncertainty was <5% for
337 n and ~25-30% for k.

338
339
340

341 **3.2.3** Boundary layer height estimation

342 The planetary boundary layer (BL) top height ~~has been~~was estimated from meteorological
343 observations (temperature, T, potential temperature, θ , and relative humidity, RH) for each
344 vertical sounding performed during TRAQA flights (see Di Biagio et al., 2015). The
345 boundary layer top height ~~is~~was between 730 and 1500 m, with an average of ~1000 m. The
346 location of each SLR, so if it is within the boundary layer or in the free troposphere, ~~has~~
347 ~~been~~was determined based on the planetary boundary layer top height estimated from the
348 closest vertical sounding performed during each flight.

349

350 **3.3.4** Tracking the origin of the sampled air masses

351 As discussed in Di Biagio et al. (2015), aerosol observations during TRAQA were mostly
352 influenced by pollution/anthropogenic particles exported from different sources around the
353 basin (Northern Italy/Po Valley, Southern France, Barcelona area). The Lagrangian trajectory
354 model FLEXPART (FLEXible PARTicle dispersion model, Stohl et al., 1998), adapted for

355 | the WRF (Weather Research and Forecasting) meteorological input (Brioude et al., 2013)
356 | ~~has been was~~ used here to track the origin of air masses sampled during SLRs. Five-day three-
357 | dimensional back-trajectories ~~have been were~~ calculated using the WRF meteorological
358 | output at a 30 km horizontal resolution and 28 vertical model levels up to 50 hPa. The model
359 | specific humidity and potential vorticity ~~is were~~ also interpolated along the trajectory path.
360 | Based on FLEXPART simulations, data for the different SLRs ~~have been were~~ separated as a
361 | function of the origin of the sampled air masses. Three different sectors ~~have been were~~
362 | defined: the Western sector, which includes trajectories coming from the Atlantic Ocean and
363 | travelling over France or northern Spain before reaching the Western basin; the Eastern
364 | sector, including air mass trajectories from continental Europe that have travelled over
365 | northern Italy-Po Valley before entering the basin; and the Open sea sector, which consists of
366 | trajectories coming from the Western or Eastern sectors which have experienced at least 2
367 | days of subsidence over the sea in the Western basin and thus can be taken as representative
368 | of the regional background aerosol or local pollution sources, i.e. ship emissions. The three
369 | different selected ~~Sectors sectors~~ are shown in Fig. 1, while Table 1 also reports the identified
370 | ~~Sector sector~~ of origin for the air masses sampled during the different SLRs.
371 | -As discussed in Di Biagio et al. (2015), several flights were affected by dust particles
372 | exported over the basin from Northern Africa. SLRs data dominated by dust ~~have been were~~
373 | identified based on the combined analysis of back-trajectories, lidar profiles and optical data,
374 | and ~~have been were~~ excluded from the dataset. However, for some SLRs, the possible mixing
375 | of dust aerosols with pollution particles cannot be a priori excluded.

376

377 | **3.4.5 Radiative model calculations**

378 | Radiative transfer calculations ~~have been were~~ performed to estimate the instantaneous
379 | aerosol direct radiative effect in the shortwave spectral range for different cases and in clear-
380 | sky conditions. The objective of the calculations ~~is was~~ to test the sensitivity of the DRE to
381 | the variability of the aerosol optical properties, in particular the single scattering albedo, as
382 | observed in this study. The GAME radiative transfer model (Dubuisson et al., 1996 and
383 | 2006) ~~has been was~~ used in this study to compute the vertical profiles of downward and
384 | upward shortwave irradiances over the 0.28-3.0 μm spectral range. The model calculates
385 | radiances and irradiances at various atmospheric levels at 400 cm^{-1} spectral resolution
386 | between 0.28 and 0.5 μm , and 100 cm^{-1} resolution between 0.5 and 3 μm . Spectral absorption
387 | by principal atmospheric gases (H_2O , CO_2 , O_3 , CH_4 , N_2O , O_2) is taken into account in the

388 | model. The discrete ordinate method (Stamnes et al., 1988) with twelve streams ~~was~~ used in
 389 | the simulations to describe multiple scattering. Simulations ~~have been were~~ performed with
 390 | and without aerosols by fixing the solar zenith angle (θ) at 60° , i.e. at about the mean of the
 391 | diurnal value at the latitudes of north-Western Mediterranean, and for a mid-latitude
 392 | climatological summer meteorological profile. The aerosol optical properties that are used as
 393 | input in the GAME radiative code are the spectral variation of the optical depth (τ), the
 394 | asymmetry parameter (g) and the single scattering albedo (ω). The difference of the net
 395 | shortwave fluxes (downward minus upward irradiances) with and without aerosols at the
 396 | surface and at TOA ~~was~~ used to estimate the aerosol DRE at these two levels. The
 397 | atmospheric DRE ~~was~~ then calculated as the difference between the TOA and the surface
 398 | values. Finally, the ratio of the DRE to the aerosol optical depth at 500 nm, i.e. the aerosol
 399 | forcing efficiency (FE), ~~was~~ obtained. The shortwave heating rate at the altitude z ~~was~~ also
 400 | calculated as:

$$401 \quad \frac{\partial T}{\partial t} = -\frac{1}{\rho C_p} \frac{\partial F(z)}{\partial z} \quad (3)$$

402 | where T is the air temperature, ρ is the air density, C_p is the specific heat of the air, and $F(z)$
 403 | is the net flux at the altitude z .

404 |
 405 |

406 | **4. Results**

407 | **4.1 Overview over the different SLRs**

408 | Figure ~~2-3~~ shows the averages altitude, spectral scattering (σ_s) and absorption (σ_{abs})
 409 | coefficients, scattering and absorption Ångström exponent (SAE and AAE, respectively),
 410 | ozone enhancement factor ($\Delta O_3/\Delta CO$), and ~~Aitkenultrafine~~-to-accumulation particle ratio
 411 | ($dN_{AitkenUFP}/dN_{Acc}$) measured for the different SLRs during TRAQA.

412 | As shown in Fig. ~~2-3~~ and Table 1, the large majority of the SLRs were performed within the
 413 | boundary layer at an altitude <1000 m. Only four SLRs (V25_R2, V25_R3, V26_R1, and
 414 | V30_R1) measured aerosols in the free troposphere between 1800 and 3500 m. The sampled
 415 | aerosols originated in each of the three different source sectors identified based on
 416 | FLEXPART back-trajectories (Western, Eastern, and Open sSea), with a larger number of
 417 | cases from the Western sector compared to the Eastern and the Open Sea-sea areas.

418 | For all the different cases, the measured scattering coefficient ~~is-was~~ in the range 16-73 Mm⁻¹
419 | at 450 nm and 8-30 Mm⁻¹ at 700 nm. The absorption coefficient ~~is-was~~ generally below 10
420 | Mm⁻¹ at all wavelengths, with the exception of V27_R1 and V32_R1 for which values up to
421 | ~20 Mm⁻¹ at 370 nm ~~have-been-were~~ measured. For these two cases also the highest values of
422 | the particle concentration in the accumulation mode (~1700-2200 # cm⁻³, not shown) and
423 | among the highest values of the scattering coefficient ~~are-were~~ measured. For all cases, both
424 | σ_s and σ_{abs} decrease with the wavelength. The pronounced spectral variability of σ_s , in
425 | particular, indicates the dominance of pollution/anthropogenic fine particles in the sampled
426 | plumes.

427 | The SAE ~~varies-varied~~ between 0.96 and 1.94, while the AAE ~~varies-varied~~ between 0.92 and
428 | 1.65, with an average of ~1.20. The AAE ~~has-been-was~~ not calculated for few cases with very
429 | low values of the absorption coefficient (σ_{abs} at 370 nm < 1.5 Mm⁻¹). Both the SAE and the
430 | AAE obtained in this study fall in the range of variability indicated by several authors to
431 | identify pollution/anthropogenic aerosols or pollution mixed with other aerosol types in the
432 | Mediterranean basin (SAE>1-1.5, and AAE~1-1.5; Pace et al., 2006; Toledano et al., 2007;
433 | Mallet et al., 2013). Values of AAE larger than unity, in particular, might suggest the possible
434 | mixing of pollution with brown carbon or dust particles over the basin (Russell et al., 2010;
435 | Mallet et al., 2013).

436 | For all the measured SLRs the $\Delta O_3/\Delta CO$ and the $dN_{AitkenUFP}/dN_{Acc}$ ratios ~~variedy~~ in the range
437 | 0.37-1.02 and 1-50, respectively, for O₃ and CO varying between 24-78 and 69-136 ppbv and
438 | $dN_{AitkenUFP}$ and dN_{Acc} between 320-22500 and 100-2170 # cm⁻³. $\Delta O_3/\Delta CO$ and the
439 | $dN_{AitkenUFP}/dN_{Acc}$ are linked to the photochemical (rate of ozone formation) and physical (rate
440 | of ~~Aitkenultrafine~~ to accumulation particle conversion) processes responsible for the
441 | ~~ageingaging~~ of the aerosol plumes. The range of measured values here includes both cases
442 | with high $dN_{AitkenUFP}/dN_{Acc}$ and low $\Delta O_3/\Delta CO$, typical of fresh plumes, and cases with low
443 | $dN_{AitkenUFP}/dN_{Acc}$ and high $\Delta O_3/\Delta CO$, indicative of more aged air masses (Di Biagio et al.,
444 | 2015).

445 | The summary of ~~these~~ observations ~~from Fig. 3~~ suggests that the set of SLRs measurements
446 | considered in this study can be considered representative of a wide range of different
447 | atmospheric conditions occurring over the basin both in terms of sources, loadings, and
448 | lifetime for pollution aerosols.

449

450 | 4.2 Particle size distributions

451 | Figure 3-4 shows the mean and the range of variability of the number and volume size
 452 | distributions measured during horizontal SLRs within pollution layers during TRAQA. Data
 453 | were separated based on the origin of the sampled air masses and refers only to cases at <350
 454 | m altitude within the boundary layer. The absolute uncertainty on the measured
 455 | concentration, as also reported in Table 2, is ~15% for particle diameters below 0.31 µm and
 456 | ~10% at larger sizes. The grey shading indicates considerable variability in the number
 457 | concentration of the size distributions, of approximately one order of magnitude for much of
 458 | the size range measured. This reflects the relative wide range of aerosol loadings encountered
 459 | during the campaign. The minimum of the size distribution over the whole diameter range
 460 | was measured in the Western sector (V32_R3), whilst the largest number concentrations in
 461 | the super-micron range were observed in correspondence of V19_R1 and V32_R1. For all the
 462 | other SLRs, the size distributions were very similar, especially at diameters below ~5 µm.
 463 | The measured number size distribution from each SLR ~~has been~~was fitted with multi-mode
 464 | lognormal functions:

$$465 \quad \frac{dN}{d \log D_g} = \sum_i \frac{N_{\text{tot},i}}{\sqrt{2\pi} \log \sigma_{g,i}} \left(-\frac{(\log D_p - \log D_{g,i})^2}{2 \log^2 \sigma_{g,i}} \right) \quad (4).$$

466 | For each mode i , N_{tot} represents the total aerosol number concentration, D_g the median
 467 | diameter, and σ_g the geometric standard deviation. The logarithm refers to base 10. Size data
 468 | were fitted automatically using the MPCURVEFIT IDL routine available at
 469 | <http://www.physics.wisc.edu/~craigm/idl/fitting.html>. Since the aim of the fitting is to
 470 | describe as closely as possible the measured number size distributions for subsequent optical
 471 | calculations (Sect. 4.4), up to seven modes were used to fit the data. The correlation
 472 | coefficient for the fit functions was larger than 0.97 for all cases. The parameters of the
 473 | lognormal fits are reported in Table 3. The first mode of the size distribution is generally at
 474 | 0.13-0.14 µm, whilst the largest mode is between ~5 and 8 µm for the different cases.

475

476 | **4.3 Spectral single scattering albedo: variability as a function of air mass origin and** 477 | **height**

478 | Figure 4-5 shows the spectral ω for the different SLRs considered in this study. Data ~~have~~
 479 | ~~been~~were separated based on the origin of the sampled air masses. The single scattering
 480 | albedo varies in the range 0.84-0.98 at 370 nm and 0.70-0.99 at 950 nm and generally
 481 | decreases with the wavelength, as it is typical for pollution particles (Dubovik et al., 2002).

482 Only in two cases (V19_R1 and V30_R2) the single scattering albedo increases with
483 wavelength. For these cases also very high values of ω ~~are-were~~ observed (0.92-0.97 for
484 V19_R1 and 0.98-1.0 for ~~V32~~V30_R2), which may suggest the possible mixing of pollution
485 with sea spray or desert dust particles, both showing low absorption in the shortwave range
486 (Bergstrom et al., 2007). The lowest values of the single scattering albedo ~~are-were~~ measured
487 for V27_R1 (0.84-0.70 between 370 and 950 nm) sampled at ~160 m and originated in the
488 Open Sea sector. Data in Fig. 2-3 also indicate for V27_R1 very low values of $\Delta O_3/\Delta CO$
489 (~0.37) and a relatively high $dN_{\text{AitkenUFP}}/dN_{\text{Acc}}$ (~7), which suggests that V27_R1 ~~is-was~~ a
490 fresh plume possibly associated to local emissions, i.e. ship plumes, over the basin. If we
491 exclude V27_R1, the range of measured values appears comparable (within error bars) for the
492 three considered sectors (Western, Eastern, and Open sea; ω between 0.88 and 0.98 at 370
493 nm and 0.83 and 0.99 at 950 nm).

494 The vertical variability of ω , together with $dN_{\text{AitkenUFP}}/dN_{\text{Acc}}$, $\Delta O_3/\Delta CO$, SAE, and AAE, is
495 shown in Fig. 5-6 for the different considered cases. With the only exception of V27_R1, for
496 which the lowest values ~~are-were~~ observed below 200 m, the single scattering albedo does not
497 show a clear trend with height, with a similar range of values measured in the boundary layer,
498 below ~1000 m, and in the free troposphere up to ~3500 m. As for ω , the AAE does not
499 significantly vary with height. At the same time, $dN_{\text{AitkenUFP}}/dN_{\text{Acc}}$ and SAE decrease with
500 height, with a concurrent slight $\Delta O_3/\Delta CO$ increase, which may suggest an increase of plume
501 age with height. The ensemble of these observations seems to indicate that, for our observed
502 cases, the absorptivity properties of the sampled plumes do not depend on the altitude and
503 associated air mass age of the plume. It should be pointed out, however, that the majority of
504 cases considered here ~~have-been-were~~ sampled below 1000 m, so in the boundary layer, and
505 the statistics in the free troposphere is only limited to a few events.

506 Values of the single scattering albedo measured in this study are comparable with values
507 reported at several other sites in the Central and Western Mediterranean region for pollution
508 aerosols (Mallet et al., 2003 and 2013; Meloni et al., 2006; Saha et al., 2008; Di Biagio et al.,
509 2009; Pandolfi et al., 2011). The single scattering albedo from these studies ~~is-observed-to~~
510 variesy in the range 0.84-0.95 at 440 nm, 0.76-0.98 at 500-550 nm, and 0.80-0.87 at 870 nm.
511 Compared with the literature, larger and lower values are obtained in the present study for
512 few cases mostly influenced by sea spray, desert dust, and local fresh emissions, respectively.

513

4.4 ~~Optical closure and estimation of the aerosol complex refractive index~~ of pollution aerosols

As discussed in the previous section, the single scattering albedo of pollution aerosols shows a relatively large variability. Here we investigate the impact of this variability on the complex refractive index ($m=n-ik$) of the particles.

For eight selected SLRs for which both complete optical (scattering and absorption coefficients, and single scattering albedo) and size distribution measurements were available, the aerosol spectral complex refractive index ~~has been~~was estimated by optical closure study as described in Sect. 3.2. These cases correspond to V19_R1, V21_R1, V21_R3, V23_R2, V27_R1, V31_R1, V32_R1, V32_R3 sampled within the boundary layer at <350 m altitude.

The comparison of the measured and ~~calculated~~modelled σ_s and σ_{abs} are shown in Fig. 67, while the retrieved real and imaginary parts of the refractive index for the different SLRs are reported in Fig. 78. Data in Fig. 78 are also compared to the real and imaginary parts of the refractive index for the single components (insoluble, water soluble, soot, and sea salt) considered in the OPAC model (Optical Properties of Aerosols and Clouds, Hess et al., 1998) to represent continental, urban and maritime polluted aerosols.

As shown in Fig. 67, a very good agreement ~~is~~was found between the calculated and the measured scattering and absorption coefficients, with an average difference of less than 5% for both σ_s and σ_{abs} . For our analysed cases n and k vary in the range 1.67-1.75 and 0.~~003~~004-0.03850 at 370 nm and 1.41-1.~~75-77~~ and 0.002-0.0~~68~~97 at 950 nm, respectively. The imaginary part of the refractive index slightly increases with wavelength, while ~~a not a clear tendency is found for the decrease is observed for the~~ real part in most cases, which in some of the cases increases with wavelength and in others decreases. Highest values of k are obtained for V27_R1, which also shows the absolute lowest values of ω in our dataset (0.84-0.70), followed by V32_R1 and V32_~~R2~~R3, which also present relatively low values of ω (0.~~95~~92-0.83). The lowest k , as well as among the lowest n , is instead obtained for V19_R1 ($\omega=0.92$ -0.96). The comparison of our data with OPAC values for single components suggests that in most cases particles are composed of a mixing of insoluble and water soluble components, with possible contributions of soot (V27_R1) and sea salt (V19_R1).

The results of the complex refractive index obtained in this study are in agreement with previous estimates obtained for pollution aerosols in continental Europe ($n\sim 1.50$ -1.72 and $k\sim 0.001$ -0.1 for UV-visible wavelengths e.g. Ebert et al., 2002, 2004; Müller et al., 2002; Mallet et al., 2003, 2011; Raut and Chazette, 2008). Larger values of both n and k are instead

547 obtained here compared to AERONET retrievals at different sites in the Western
548 Mediterranean (1.38-1.46 for n and 0.003-0.01 for k at 440 and 670 nm; Mallet et al., 2013).

549 Figure 8-9 shows the results of the correlation analysis between the single scattering albedo
550 and the complex refractive index obtained for the analysed cases. For the real part, the range
551 of retrieved n values is larger (1.41-1.7074) for ω greater than ~ 0.95 , while as the single
552 scattering albedo decreases the real part converges to ~ 1.7065 -1.75 at all wavelengths. A
553 strong correlation is observed between ω and k at all wavelengths, that is the lower the single
554 scattering albedo, the higher the imaginary part. A linear regression fit was applied to the ω - k
555 datasets at the seven wavelengths (~~$R^2=0.83-0.95$ at all wavelengths for the different fits~~). The
556 slope of the fit varies between -2.2 and -6.9, and decreases with the wavelength (in particular
557 if the outlier points of k in correspondence of V27_R1 are eliminated), in agreement with the
558 decrease of ω with λ for pollution aerosols. ~~The~~ intercept for all cases is lower than 1
559 (0.934-0.97), with lowest values (~~0.94~~) obtained at 880 and 950 nm. This is possibly
560 associated to a slight underestimation of ω which, especially at these wavelengths, is difficult
561 to determine given the high uncertainty on the particle absorption coefficient. Another source
562 of uncertainty is the size distribution, which influences the results of Mie calculations, and
563 thus has a direct impact on the refractive index retrieval.

564

565 **4.5 Influence of the single scattering albedo variability on the aerosol direct shortwave** 566 **radiative effect (DRE)**

567 Radiative transfer model calculations with the GAME model ~~have been were~~ performed with
568 the aim of investigating the impact of the variable optical properties, and in particular the
569 single scattering albedo, on the shortwave direct radiative effect of pollution particles in the
570 Western Mediterranean basin.

571 Simulations ~~have been were~~ performed by considering three different vertical aerosol profiles,
572 based on observations reported by Di Biagio et al. (2015): i. aerosols only confined in the BL
573 (whose altitude is fixed at 1000 m, in the mean of observations during TRAQA); ii. 50% of
574 the aerosol optical depth in the BL and 50% in the FT (which is considered to extend between
575 1000 and 4000 m); iii. 20% of the aerosol optical depth in the BL and 80% in the FT. For the
576 different cases we fixed the total aerosol optical depth at 0.2 at 550 nm, which corresponds to
577 the mean of observations obtained over the Western basin during TRAQA (Di Biagio et al.,
578 2015). However, results will be given as FE_{λ} , so they are independent on the chosen optical
579 depth. We assumed d a uniform aerosol distribution and constant optical properties within the

580 | BL and the FT for the three different considered profiles. This assumption ~~comes~~ from the
581 | observations of the present study, which do not evidence any significant change of the
582 | aerosol properties with height. Aerosol spectral optical properties, both in the BL and in the
583 | FT up to 4000 m, ~~are-were~~ assumed from observations, as explained in the following.

584 | The GAME model requires as input the aerosol optical depth, single scattering albedo, and
585 | asymmetry factor at 7 wavelengths between 330 and 1500 nm. The spectral optical depth
586 | between 330 and 1500 nm ~~was~~ extrapolated from the fixed value of 0.2 at 550 nm by
587 | assuming a Ångström exponent of 1.5, in the mean of our observations for pollution aerosols
588 | (see Fig. 2). For the single scattering albedo, we considered 3 different sets of values which
589 | correspond to the minimum, maximum, and mean of the values observed in this study (the
590 | absolute minimum for V27_R1 ~~has-been-was~~ excluded for calculations since it represents an
591 | outlier in our data). The ω values at 370-950 nm as obtained from experimental data ~~are-were~~
592 | then extrapolated at the 7 GAME wavelengths (Table 4). The asymmetry factor ~~was~~
593 | calculated from Mie theory based on the refractive index values and size distribution data for
594 | the eight cases considered in the previous Section. The spectral variation of g used in the
595 | radiative transfer calculations ~~was~~ estimated as the mean of the values obtained for these
596 | eight cases extrapolated at the 7 GAME wavelengths. The obtained g ~~variesd~~ between 0.60 at
597 | 330 nm and 0.51 at 1500 nm. These values are consistent with previous estimates of g
598 | obtained for pollution aerosols over the Mediterranean basin (Meloni et al., 2006; Saha et al.,
599 | 2008; Mallet et al., 2011).

600 | Background stratospheric aerosols (above 12 km) ~~are-were~~ also taken into account for
601 | radiative calculations; optical properties from the OPAC stratospheric aerosol model (Hess et
602 | al., 1998) ~~awere~~ assumed.

603 | Finally, in addition to aerosol optical properties, the GAME model requires as input the
604 | albedo of the surface (A_S) at 5 wavelengths between 448 nm and 2130 nm. In this study,
605 | simulations ~~are-were~~ performed over the sea surface. The albedo of the sea surface ~~is-was~~
606 | obtained from Jin et al. (2004), which provide a parameterisation of A_S as a function of
607 | chlorophyll concentration (Chl), wind speed (w), aerosol optical depth at 500 nm (τ), and the
608 | solar zenith angle (θ). For this study A_S ~~is-was~~ estimated for Chl=0, $w=6-9$ m s⁻¹, $\tau=0.24$
609 | (extrapolated from the value of 0.2 at 550 nm), and $\theta=60^\circ$, and it ~~varies-varied~~ between 0.009
610 | and 0.005 in the considered 448-2130 nm spectral range.

611 | Results of the radiative transfer simulations are shown in Fig. 910, which reports the FE at
612 | the surface, TOA, and atmosphere (FE_S , FE_{TOA} and FE_{ATM}) for the maximum, mean, and

613 minimum of the single scattering albedo observed in this study. Results of the simulations are
614 mostly independent on the vertical distribution of the aerosols (less than $\sim 5\%$ changes for
615 FE_S , FE_{ATM} , and FE_{TOA} for the three different profiles used in the simulations), so the mean
616 of the results obtained for the three cases is reported in Fig. 910. The forcing efficiency varies
617 between -160 and -235 (FE_S), -137 and -92 (FE_{TOA}), and +23 and +143 (FE_{ATM}) $W m^{-2} \tau^{-1}$ for
618 ω varying between its maximum and minimum values. Estimates of the forcing efficiencies
619 in correspondence of the mean of ω are -198, -113, and +85 $W m^{-2} \tau^{-1}$ at the surface, TOA,
620 and atmosphere, respectively. The corresponding instantaneous shortwave heating rate at the
621 surface varies between 0.2 and 2.0 $K day^{-1}$ for ω between its maximum and minimum.

622 As expected, the lower the single scattering albedo, the larger in absolute value the FE_S and
623 FE_{ATM} and the lower the FE_{TOA} . This is due to the impact of absorption on the amount of
624 radiation trapped in the atmosphere and transmitted towards the surface, which thus enhance
625 the radiative effect in the atmosphere and at the surface for decreasing ω . Conversely, the
626 larger the particle absorption, the lower the effect on the radiation reflected back to space,
627 and thus the decrease of the intensity of the cooling effect at the TOA. Changes in the single
628 scattering albedo of the particles between its maximum and minimum ($\Delta\omega=0.1-0.2$ at the
629 different wavelengths) determine about a 50% strengthening of the direct shortwave radiative
630 effect at the surface, and a reduction of $\sim 30\%$ the effect at the TOA. Consequently, the
631 atmospheric FE may vary up to an order of magnitude. These results thus highlight the
632 sensitivity of the DRE on the absorptivity properties of the particles, as well as the
633 importance of accurately reproducing the single scattering albedo of aerosols to correctly
634 evaluate their direct radiative effect.

635 The results of the present study are in quite good agreement with previous estimates of the
636 aerosol forcing efficiency for pollution aerosols in the Mediterranean area. FE_S , FE_{ATM} , and
637 FE_{TOA} obtained here compare well with data obtained in the Central Mediterranean by Di
638 Biagio et al. (2009, 2010), who provide estimates based only on observational data, i.e.
639 without any assumption on the aerosol optical properties. In these studies they report a
640 forcing efficiency of ~ -200 and $-164 W m^{-2} \tau^{-1}$ at the surface and TOA at solar zenith angles
641 of $50^\circ-60^\circ$ for mixed aerosols (pollution plus sea salt particles). They estimate an increase in
642 absolute value of FE_S of about 20-40% due to a decrease of 0.1-0.2 of the single scattering
643 albedo (at 415 and 868 nm) of the aerosols, as well as a concurrent increase of FE_{TOA} of
644 about 10-40%. The observations obtained in this study fall in the range of variability reported
645 by Di Biagio et al. (2009, 2010). Our data also agree with estimates of Saha et al. (2008),
646 reporting for pollution aerosols measured in the French Mediterranean coast up to 40%

647 variability in the FE_S and FE_{TOA} , concurrently with 70% increase of FE_{ATM} , due to a ω
648 change of 0.15 at 525 nm. Conversely, our estimates at the surface and TOA are larger in
649 absolute value compared to data reported for continental Europe by Horvath et al. (2002),
650 who estimated a FE_S of $\sim -164 \text{ W m}^{-2} \tau^{-1}$ and a FE_{TOA} of $-50 \text{ W m}^{-2} \tau^{-1}$ for polluted aerosols
651 with $\omega=0.90$ at 520 nm, thus comparable with our mean values of single scattering albedo for
652 pollution aerosols.

653

654 **5. Conclusions**

655 In this study we have presented measurements of the spectral optical properties (scattering
656 and absorption coefficients and single scattering albedo) and particle size distributions for
657 pollution aerosols obtained over the remote sea in the Western Mediterranean basin during
658 the TRAQA campaign in summer 2012. The set of observations analysed in this study can be
659 assumed to be representatives of a wide range of different conditions that can be observed
660 over the basin, both in terms of pollution sources, aerosol loadings, and lifetimes of the
661 plumes. The detailed characterization of the spectral optical properties of pollution aerosols
662 in the Western basin was missing to date.

663 Observations from the present study show a large variability of the optical properties of
664 pollution aerosols over the basin, in particular of the spectral single scattering albedo. Values
665 of ω in the range 0.84-0.98 at 370 nm and 0.70-0.99 at 950 nm are observed in this study.
666 This variability of ω does not seem to be clearly linked neither to the particle origin, nor to
667 the altitude and associated **ageingaging** of the sampled plumes. The variability of ω reflects in
668 a large variability for the complex refractive index of pollution aerosols, which is estimated
669 to span in the range 1.41-1.75 for the real part and 0.002-0.068 for the imaginary part
670 between 370 and 950 nm. The analysis of the complex refractive index suggests that possible
671 differences in terms of particle compositions can explain in part the observed variability of ω .
672 A large range of compositions has been however reported for pollution aerosols in Europe
673 and the Mediterranean basin (Mallet et al., 2003; Ebert et al., 2004; Pey et al., 2010; Piazzola
674 et al., 2012) and a more detailed analysis of the **aerosol** composition for the cases
675 ~~obtainmeasured herein this study~~ should be addressed.

676 Based on the observations of the present study, the variability of optical properties for
677 pollution aerosols can arise from the combination of different factors, linked to the origin,
678 production mechanism, and **ageingaging** of the plumes along their lifetime, as well as the
679 possible mixing of different plumes with different characteristics. So, the inherent

680 heterogeneity of sources, coexistence of different air masses, and multiple physical and
681 chemical processes occurring in a complex environment such as the Western Mediterranean
682 may give rise to this inherent variability of the particle single scattering albedo.

683 This observed variability on ω has a large influence on the direct shortwave radiative effect
684 of pollution aerosols at the surface, TOA, and within the atmosphere. For instance, a change
685 of up to an order of magnitude (from +23 to +143 W m⁻² τ^{-1} at 60° solar zenith angle) in the
686 atmospheric radiative effect is estimated due to the variability of the single scattering albedo
687 within the range of values observed in this study. The change in the amount of atmospheric
688 absorbed solar radiation may have a strong impact on the temperature profile and the
689 atmospheric thermal structure, with important consequences on several processes, such as
690 cloud formation and precipitations. The strong sensitivity of the DRE also at the surface, up
691 to 50% for varying ω , on its turn, may largely impact the rate of evaporation over the basin,
692 which is also a crucial component of the hydrological cycle (Nabat et al., 2015). Given the
693 large sensitivity of the Mediterranean area and the high risk of desertification for this region
694 (Giorgi and Lionello, 2008; IPCC, 2013) any factor possibly impacting the hydrological cycle
695 should be taken carefully into account by regional climate models. In this view, results from
696 the present study can be used to provide a constraint of the absorption properties of pollution
697 particles in the Western Mediterranean basin to use in regional modeling studies.
698 Constraining these properties constitutes a crucial step in order to better assess the role of
699 aerosols on the radiative balance of this region and to ameliorate the capability of making
700 projection on future climate changes.

701

702 **Author contributions**

703 J.-L. Attié, F. Ravetta, G. Ancellet, and P. Formenti designed the TRAQA experiment and
704 coordinated the campaign. C. Gaimoz, N. Grand, and C. Di Biagio operated the instruments
705 on board the ATR-42 during the flights. C. Di Biagio performed the data analysis with
706 contributions from L. Doppler and P. Formenti. S. Bucci and F. Fierli performed the
707 FLEXPART simulations. M. Mallet and P. Dubuisson provided the GAME code for radiative
708 calculations. C. Di Biagio wrote the manuscript with contributions from ~~the~~all co-authors.

709

710

711

712 **Acknowledgements**

713 All measurement presented here are from the Chemistry-Aerosol Mediterranean Experiment
714 project (ChArMEx, <http://charmex.lsce.ipsl.fr>), which is the atmospheric component of the
715 French multidisiplinary program MISTRALS (Mediterranean Integrated Studies at Regional
716 And Local Scales). ChArMEx-France was principally funded by INSU, ADEME, ANR,
717 CNES, CTC (Corsica region), EU/FEDER, Météo-France, and CEA. TRAQA was funded by
718 ADEME/PRIMEQUAL and MISTRALS/ChArMEx programmes and Observatoire Midi-
719 Pyrénées. C. Di Biagio thanks the Centre National des Etudes Spatiales (CNES) for financial
720 support.

721 The authors wish to thank the technicians, pilots and ground crew of SAFIRE (Service des
722 Avions Français Instruments pour la Recherche en Environnement) for facilitating the
723 instrument integration and conducting flying operations. We thank S. Chevaillier, R. Loisil, J.
724 Pelon, and P. Zapf for their contribution during the campaign. We also wish to thank G. Siour
725 for his help to run the GAME radiative code. [Helpful comments and suggestions by two](#)

932 **Tables**

933

934 **Table 1.** Summary of information on the SLRs analysed in this study. The SLR location
 935 (within the boundary layer or in the free troposphere) ~~has been~~was determined based on the
 936 boundary layer top height estimated for the closest vertical sounding performed during each
 937 flight (see Di Biagio et al., 2015). The ~~Sector~~sector of origin for sampled air masses ~~has~~
 938 ~~been~~was determined based on FLEXPART back-trajectories.

939

Flight number	SLR_ID	Date	Time start-stop	Altitude (m)	Location	Sector of origin
V19	V19_R1	26/06/2012	11:23-11:38	322	Within the boundary layer	Eastern
V19	V19_R2	26/06/2012	11:44-11:59	897	Within the boundary layer	Eastern
V21	V21_R1	27/06/2012	10:54-11:12	312	Within the boundary layer	Eastern
V21	V21_R2	27/06/2012	11:48-12:04	629	Within the boundary layer	Eastern
V21	V21_R3	27/06/2012	12:05-12:19	311	Within the boundary layer	Western
V22	V22_R1	29/06/2012	7:42-8:01	478	Within the boundary layer	Eastern
V23	V23_R2	29/06/2012	12:05-12:20	319	Within the boundary layer	Open sea
V25	V25_R1	04/07/2012	9:08-9:24	639	Within the boundary layer	Western
V25	V25_R2	04/07/2012	9:32-9:48	2015	Free troposphere	Western
V25	V25_R3	04/07/2012	9:50-10:08	2538	Free troposphere	Western

942 **Table 2.** Summary of the aerosol in situ measurements on the ATR-42 during the TRAQA
 943 campaign. Details on the data treatment and uncertainty estimation for the different instruments are
 944 provided in Sect. 2.
 945

946

Property measured	Instrument	Location on aircraft	Flow rate ($l\ min^{-1}$)	Time resolution	Size range	Sensitivity or uncertainty	Comments
Aerosol number concentration	Condensation Particle Counter (CPC 3775)	in the cabin behind AVIRAD inlet	1.5	5 sec	0.004 – 3 μm	$\pm 10\%$ (concentration)	
Aerosol size distribution	Passive cavity aerosol spectrometer probe (PCASP 100x)	aircraft fuselage, left side before the wing	0.06	1 sec	Nominally 0.1 – 3.0 μm Corrected for refractive index 0.10 – 4.47 μm	$< \pm 25\%$ (diameter optical to geometric conversion) $\pm 15\%$ (concentration) (e.g., Highwood et al., 2012)	Aerosol concentration underestimated by 50% between 0.4 and 1.0 μm
	GRIMM 1.129	in the cabin behind AVIRAD inlet	1.3	6 sec	Nominally 0.3 – 32 μm Corrected for refractive index 0.28 – 65.80 μm (AVIRAD 50% cut-off efficiency at $\sim 12\ \mu m$ diameter)	$< \pm 25\%$ (diameter optical to geometric conversion) $\pm 10\%$ (concentration)	Data not available $> 350\ m$
Dry aerosol scattering coefficient σ_s (450, 550, 700 nm)	TSI 3563 integrating nephelometer	in the cabin behind AVIRAD inlet	30	6 sec	50% cut-off efficiency at $\sim 12\ \mu m$ diameter	$< \pm 10\%$ for σ_s at 450, 550, and 700 nm	
Aerosol absorption coefficient (σ_a) (370, 470, 520, 590, 660, 880, 950 nm)	Magee AE31 aethalometer	in the cabin behind AVIRAD inlet	13	2 min	50% cut-off efficiency at $\sim 12\ \mu m$ diameter	11-70% variable at the different wavelengths	Data available only for 60% of SLRs

947

948

949

950

951 **Table 3.** Lognormal mode parameters of the measured aerosol size distribution (total aerosol
 952 number concentration, N_{tot} , median diameter, D_g , and geometric standard deviation, σ_g). Data
 953 corresponds to SLRs below ~ 350 m altitude. Diameters are given in microns and number
 954 concentrations refer to ambient conditions.

966

967 **Figure 1.** Upper panel: geographical position of the different straight levelled runs (SLRs)
968 performed during the TRAQA campaign and analysed in this paper. The label for each point in the
969 figure identifies the flight number and the corresponding SLR: for example V22_R1 indicates the
970 coordinates of the first SLR of flight V22. Lower panel: definition of three different source areas for
971 the various SLRs (see Sect. 3.4.4 for more details). The Western sector includes trajectories coming
972 from the Atlantic Ocean and travelling over France or northern Spain before reaching the Western
973 basin; the Eastern sector includes air mass trajectories from continental Europe that have travelled
974 over northern Italy-Po Valley before entering the basin; and the Open sea sector consists of
975 trajectories which have experienced at least 2 days of subsidence over the sea in the Western basin.
976

1113 **Figure 78.** Spectral real (n , left panel) and imaginary (k , right panel) parts of the complex refractive
 1114 index obtained by optical closure for the 8 selected case studies. For sake of clarity, uncertainties on
 1115 n and k are not reported in the plot. The values of the single scattering albedo measured at 370 and
 1116 950 nm for the different cases are reported in the legend. The spectral real and imaginary parts of
 1117 the complex refractive index as obtained from the Optical Properties of Aerosols and Clouds
 1118 (OPAC, Hess et al., 1998) database for insoluble, water soluble, soot and sea salt components are
 1119 also reported in the plot. These components are used in OPAC to model continental polluted,
 1120 continental rural, urban, and maritime polluted aerosols.

1139 **Figure 89.** Spectral single scattering albedo plotted against the real (left panel) and the imaginary
 1140 (right panel) parts of the complex refractive index. The results of the linear fit between ω and k are
 1141 reported in the legend. The fits are performed for the whole ω - k dataset, and also eliminating the
 1142 data in correspondence of V27_R1, for which the largest values of k were observed.
