Abstract. Megacities have strong interactions with the surrounding regions through transport of air pollutants. It has been frequently addressed that the air quality of Beijing is influenced by the influx of air pollutants from the North China Plain (NCP). Estimations of air pollutant cross-boundary transport between Beijing and the NCP are important for air quality management. However, evaluation of cross-boundary transport using long-term observations is very limited. Using the observational results of the gaseous pollutants SO₂, NO, NO₂, O₃, and CO from August 2006 to October 2008 at the Yufa site, a cross-boundary site between the megacity Beijing and the NCP, together with meteorological parameters, we explored a method for evaluating the transport flux intensities at Yufa, as part of the “Campaign of Air Quality Research in Beijing and Surrounding Region 2006–2008” (CAREBeijing 2006–2008). The hourly mean $\pm$ SD (median) concentration value of SO₂, NO, NO₂, NO_x, O₃, O_x, and CO was 15 ± 16 (9) ppb, 12 ± 25 (3) ppb, 24 ± 19 (20) ppb, 36 ± 39 (23) ppb, 28 ± 27 (21) ppb, 52 ± 24 (45) ppb, and 1.6 ± 1.4 (1.2) ppm during the observation period, respectively. The bivariate polar plots showed the dependence of pollutant concentrations on both wind speed and wind direction, and thus inferred their dominant transport directions. Surface flux intensity calculations further demonstrated the regional transport influence of Beijing and the NCP on Yufa. The net surface transport flux intensity (mean $\pm$ SD) of SO₂, NO, NO₂, NO_x, O₃, O_x, and CO was 6.2 ± 89.5 , -4.3 ± 29.5 , -0.6 ± 72.3 , -4.9 ± 93.0 , 14.7 ± 187.8 , 14.8 ± 234.9 , and $70 \pm 2830 \mu\text{g s}^{-1} \text{m}^{-2}$ during the observation period, respectively. For SO₂, CO, O₃, and O_x the surface flux intensities from the NCP to Yufa surpassed those from Beijing to Yufa in all seasons except winter, with the strongest net fluxes largely in summer, which

was about 4–8 times of other seasons. The surface transport flux intensity of NO_x from Beijing to Yufa was stronger than that from the NCP to Yufa except in summer, with the strongest net flux in winter, which was about 1.3–8 times of other seasons. The flux intensities were then assigned to the corresponding trajectories in the potential source contribution function analysis (PSCF), which confirmed the results of flux intensity calculations. Our study also suggested that various factors, such as the wind field, emission inventory, and photochemical reactions, could influence transport of air pollutants. The decrease of surface flux intensity during the Olympic Games period implied the role of both local emission reduction and regional cooperation in successful air quality management. Three dimensional observations are needed for further comprehensive discussion of the regional transport between Beijing and the NCP.

Keywords: Megacity Beijing, North China Plain, Yufa site, Regional transport, Long-term and multiple-species observation

1. Introduction

Megacities are large sources of air pollutants and greatly influence the surrounding areas (Parrish and Zhu, 2009). With a population over 20 million, the city of Beijing is an example of such a megacity. Beijing has faced severe air pollution problems over the past two decades and has intensive interactions with other emission hot spots within the North China Plain (NCP) (Chen et al., 2015; Shao et al., 2006; Zhang et al., 2012). Beijing and the NCP are surrounded by the Yanshan Mountains to the north and the Taihang Mountains to the west. The semi-basin geographical features

63 together with the continental monsoon climate make regional transport of air
64 pollutants between the megacity Beijing and the NCP an important factor affecting
65 air quality in Beijing and the NCP (An et al., 2007; Guo et al., 2010; Lin et al., 2008,
66 2009; Streets et al., 2007; Wang et al., 2006; Wang et al., 2011; Wang et al. 2015; Wu
67 et al., 2011; Xu et al., 2005; Xu et al., 2011). An improved understanding of the
68 regional transport of air pollutants between Beijing and the NCP is therefore
69 essential for air quality management of the megacity Beijing and establishment of
70 regional-scale emissions control measures.

71 Previous studies have shed light on the regional transport sources of the
72 megacity Beijing, and various techniques have been employed, including rural/urban
73 station observations (Guo et al., 2010; Lin et al., 2008, 2009; Wang et al., 2006; Xu et
74 al., 2011), mobile laboratory measurements (Wang et al., 2009, 2011; Zhu et al.,
75 2016), and modelling studies (An et al., 2007; Matsui et al., 2009; Wu et al., 2011). A
76 ground-based observation study from July 2006 to September 2007 at the Gucheng
77 site (Lin et al., 2009), a rural site south-west of Beijing, found that high
78 concentrations of gaseous pollutants, including nitric oxide (NO), nitrogen dioxide
79 (NO₂), nitrogen oxides (NO_x=NO+NO₂), sulphur dioxide (SO₂), carbon monoxide (CO),
80 ozone (O₃), and oxidant (O_x=NO₂+O₃), were accompanied by air masses moving
81 northward from Gucheng to Beijing, according to back-trajectory analysis. Similar to
82 Lin et al. (2009), regional transport of air pollutants between Beijing and the NCP was
83 observed consistently in these previous studies (Lin et al., 2008; Yuan et al., 2009;
84 Zhu et al., 2011), even though they were merely short-term observations.

Many studies have also attempted to quantify transport fluxes of the main gaseous pollutants. A mobile laboratory study in Beijing city demonstrated regional transport of SO₂ from the NCP in both emission-control and non-control scenarios during the Beijing 2008 Olympics (Wang et al., 2011). Extrapolated from five 1-day case studies, the annual transport fluxes of SO₂ through the south-east part of the 6th Ring Road into Beijing were estimated at 49.2 Gg yr⁻¹ and 146.3 Gg yr⁻¹, accounting for 70 % and 73 % of the annual SO₂ emissions in Beijing under emission-control and non-control scenarios, respectively. The Community Multi-scale Air Quality (CMAQ) model simulation by An et al. (2007) found that the regional transport from the surrounding areas of Beijing can contributed 39 % of PM_{2.5}, 30 % of PM₁₀, and 18 % of SO₂ to the city on average in a heavy pollution episode in the spring of 2005. Similarly, the CMAQ model simulation over the Beijing region for July 2001, reported by Streets et al. (2007), illustrated the regional transport of PM_{2.5} and O₃ between Beijing and the NCP. The study suggested that the average contributions of regional transport to PM_{2.5} concentrations in the megacity Beijing from Hebei Province, Shandong Province, and Shanxi Province were about 32 %, 11 %, and 3.5 %, with maximum contributions of 70 %, 63 %, and 21 %, respectively. The regional transport contributions to the concentrations of O₃ in Beijing were less significant, with maximum contributions of 28 % from Hebei Province, 24 % from Shandong Province, and 10 % from Shanxi Province, respectively.

In summary, long-term observation of transport flux is necessary to constrain regional models and to directly evaluate the influence of regional transport on air quality. Estimations of air pollutant cross-boundary transport between Beijing and

the NCP are important for air quality management. However, evaluation of cross-boundary transport using long-term observations is very limited. In this study, we developed a method of calculating the surface transport flux intensity across a cross-boundary site based on long-term ground-based measurement and evaluated the regional transport influence of Beijing and the NCP on the cross-boundary site. The results showed different transport directions and seasonal variations in the surface transport flux intensities of the main pollutants, including SO_2 , NO , NO_2 , NO_x , O_3 , and CO at the Yufa site. The key factors controlling regional transport are also discussed, which is important for the establishment of air quality control policy in future.

2. Measurements and Methods

2.1. Measurements

The Yufa site is located at the cross-boundary area between Beijing and the NCP and could be influenced by emissions from the megacity Beijing and long-range transport from the NCP. The measurements at the Yufa site ($39^{\circ}30'49''\text{N}$, $116^{\circ}18'15''\text{E}$) were conducted from the top of a building (about 20 m above ground level) on the campus of Huangpu College. There is no tall building around the Yufa site which affects the wind and gas measurements. This is a rural site about 50 km south of the center of Beijing and near the border of Beijing Municipality and Hebei Province. As shown in Fig. 1, the Yufa site locates in the temperate monsoon climate zone and the topography of its surrounding area is flat (Fig.1). The prevailing wind of the Yufa site is the same as the surrounding region (Lin et al., 2009), thus the wind field of the Yufa site is representative of the researched area in this study. The northern and

western sides of the site are mountain areas where dry and clean air masses come from, whereas the southern and south-eastern sides are surrounded by heavily industrialised and urbanised areas, such as Hebei Province and Tianjin City (Fig.1).

Figure 1. here

The gaseous pollutant species measured included SO₂, NO, NO₂, NO_x, O₃, and CO. SO₂ was measured using a sulphur dioxide analyser (9850B; Ecotech, Knoxfield, Australia) which combines microprocessor control with pulsed UV fluorescence detection with the precision of 0.5 ppb and uncertainty within 10 %. The detection limit for the analyser is 0.5 ppb and the time resolution is 1 min. Reactive nitrogen species (NO, NO₂, and NO_x) were measured using nitrogen analyser (9841B; Ecotech) which utilises microprocessor control and chemiluminescence detection with the precision of 0.5 ppb and uncertainty within 10 %. The detection limit for the instrument is 0.5 ppb and the time resolution is 1 min. CO was measured using a CO analyser (9830A; Ecotech) which utilises NDIR Gas Filter Correlation photometry and microprocessor control with the precision of 0.1 ppm and uncertainty within 1 %. The detection limit for the instrument is 50 ppb and the time resolution is 1 min. O₃ was measured using an ozone analyser (9810B; Ecotech) which combines microprocessor control with UV photometry with the precision of 1 ppb and uncertainty within 5 %. The detection limit for the instrument is 0.4 ppb and the time resolution is 1 min. Measurements of meteorological parameters, including wind direction (WD), wind speed (WS), temperature (T), barometric pressure (BP), and relative humidity (RH), were conducted with a LASTEM auto meteorology station (LASTEM, Milan, Italy). All trace gas instruments were maintained and calibrated

153 routinely following the manufacturer's protocols. The main reasons for missing data
154 were power and instrument failure. The detail information of the instruments was
155 listed in Table 1.

156 Table 1. here

157 **2.2. Methods**

158 **2.2.1. Transport direction analysis**

159 The transport of gaseous pollutants is markedly influenced by meteorological
160 parameters, especially wind speed and wind direction. For local emission sources,
161 wind can facilitate the dilution and diffusion of air pollutants. Strong wind usually has
162 marked diffusion capability, whereas weak wind usually leads to accumulation of air
163 pollutants. For regional sources, strong wind can transport pollutants over long
164 distances and may result in high concentrations of pollutants in downwind areas.
165 Therefore, the relationship between pollutant concentration and wind field is an
166 indicator of regional transport.

167 The bivariate polar plot graphical technique was used to investigate the
168 relationships between the concentrations of gaseous pollutants and wind field, and
169 to identify potential emissions sources and transport directions of air pollutants
170 according to the technique developed by Carslaw et al. (2006) and Westmoreland et
171 al. (2007). The variables (such as pollutant concentrations, wind speed, and wind
172 direction) were plotted in polar coordinates. The procedure was as follows. First, the
173 concentration data were partitioned into wind speed-wind direction bins, and the

mean concentrations were calculated within each bin. Then, the wind components u and v were calculated using Eq. (1):

$$u = WS \cdot \sin(\pi\theta/180), v = WS \cdot \cos(\pi\theta/180) \quad (1),$$

where WS is the hourly mean wind speed, and θ is the wind direction in degrees, with 90° being from the east. Then, a generalised additive model (GAM; Jayamurugan et al., 2013) was used for surface fitting to describe the concentration as a function of the wind components u and v . The concentrations calculated by the GAM can be expressed with Eq. (2):

$$\sqrt{C_i} = \beta_0 + s(u, v) + e_i \quad (2),$$

where C_i is the calculated pollutant concentration, β_0 is the overall mean of the response, $s(u, v)$ is the smooth function, and e_i is the residual.

Compared to the nonparametric regression used by Henry et al. (2002), the bivariate polar plot involves the dependence of pollutant concentration on both wind speed and wind direction. The non-linear relationships among the variables (such as concentrations of gaseous pollutants, wind speed, and wind direction) as well as the interactions among these variables can be considered using the GAM method for data smoothing. In addition, the use of polar coordinates makes the graphics more intuitive.

2.2.2. Transport flux assessment

The surface transport fluxes at the Yufa site were calculated with the following formula (White et al., 1976; Wang et al., 2011):

$$f = -\frac{1}{n} \sum_{j=1}^n C_j \times WS_j \times \cos\theta_j \quad (3),$$

$$\sigma = H_0 \times L_0 \quad (4),$$

$$FLUX = f \times \sigma \quad (5),$$

where f is surface flux intensity of the pollutants, i.e. the per unit area flux ($\mu\text{g s}^{-1} \text{m}^{-2}$); C_j is the mean concentration of the pollutants ($\mu\text{g m}^{-3}$) during the j th observation hour; ϑ_j is the angle between wind direction and the north-south direction during the j th observation hour; and WS_j is wind speed (m s^{-1}) during the j th observation hour; n is the total number of observation hour; σ is the surface cross-sectional area (m^2) with the width of L_0 (m) and height of H_0 (m); the average surface flux of the pollutants (i.e. $FLUX$) ($\mu\text{g s}^{-1}$) can be obtained by multiplying flux intensity f and the cross-section area σ .

Figure S1 shows a schematic diagram of the surface flux calculation. The flux intensity here is the product of wind sector and air pollutant concentration measured at the same location. Ideally, we need to use the wind speed and air pollutant concentration with infinite small time resolution to conduct the surface flux calculations. In this study, the hourly data of the pollutants and wind were used, mainly because the pollutants concentration data was converted from the minutes' data to hourly mean to remove the accidental fluctuation and reduce the noise. Therefore, we assumed the wind speed and wind direction were constant within one hour, and hourly wind data were used to match with the hourly air pollutant concentration data to calculate the flux intensity.

It also need to make it clear that the surface flux intensity calculated in this study is the per unit area flux across the Yufa site, which is different from the flux across a large area reported in other studies (e.g. Wang et al. 2011). Our results could only be

extrapolated if the concentrations of all the pollutants, wind speed and direction were homogenously distributed, vertically and horizontally. Otherwise, vertical profiles of air pollutants concentration and wind are needed to calculate the cross-section transport flux of two adjacent regions for the whole boundary layer with the integrating formula below:

$$FLUX = \iint C_{(x,z)} WS_{(x,z)} \sin\theta_{(x,z)} dx dz = \iint f_{(x,z)} dx dz \quad (6),$$

where x is horizontal distance to the observed point, z is the vertical distance from ground to the observed point. In this study, we focus on the method developing of the surface flux intensity calculation and evaluation of the regional transport influence of Beijing and the NCP on the cross-boundary site based on the ground-based observation data.

2.2.3 The backward trajectory model and PSCF analysis

The 12 h air mass back trajectories arriving at the Yufa site at 500 m above the ground level were calculated using the National Oceanic and Atmospheric Administration (NOAA) Hybrid Single-Particle Lagrangian Integrated Trajectory Version 4 model (HYSPLIT-4 model) (<http://ready.arl.noaa.gov/HYSPLIT.php>) during the study period (from 15 August 2006 to 31 October 2008) with a $1^\circ \times 1^\circ$ latitude-longitude horizontal resolution and the final meteorological database. The final archived meteorological data was obtained from the National Center for Environmental Prediction's (NCEP's) Global Data Assimilation System (GDAS) (<ftp://arlftp.arlhq.noaa.gov/pub/archives/gdas1>). The back trajectories were

generated with 6-h time resolution (four times per day) at starting times of 0:00, 6:00, 12:00 and 18:00 UTC (8:00, 14:00, 20:00, 4:00 LT-local time, respectively).

The potential source contribution function (PSCF) analysis is performed with the Gis-based software TrajStat (<http://www.meteothinker.com/products/trajstat.html>) (Wang and Zhang et al., 2009). The PSCF analysis has been widely used for identifying the possible source areas of the observed high concentrations of pollutants at the receptor site (Ashbaugh et al., 1985; Zhang et al., 2013). In this study the long-term calculated surface flux intensity data was assigned to the backward trajectories in the PSCF analysis to confirm the bi-directional transport of pollutants between Beijing and the NCP. The PSCF analysis was conducted as follows.

The study domain was divided into $i \times j$ equal size grid cells and the PSCF value for ij th cell is defined as:

$$PSCF_{ij} = m_{ij} / n_{ij} \quad (7),$$

where n_{ij} denoted the number of endpoints that fall in the ij th cell, and m_{ij} represented the number of endpoints for the same cell having arrival times at the observed site corresponding to measured data higher than an arbitrarily set criterion.

To reduce the effect of small values of n_{ij} , the PSCF values were multiplied by an arbitrary weigh function W_{ij} . In this study, W_{ij} is defined as below.

$$W_{ij} = \begin{cases} 1.00, & 80 < n_{ij} \\ 0.70, & 20 < n_{ij} \leq 80 \\ 0.42, & 10 < n_{ij} \leq 20 \\ 0.05, & n_{ij} \leq 10 \end{cases} \quad (8),$$

In this study, the study domain was 30–50 ° N, 100–125 ° E and the horizontal resolution was 0.25 ° × 0.25 °.

3. Results and discussion

3.1. Observations

Figure 2. here

The time series of hourly average and 24-hour smoothing concentrations of SO₂, NO, NO₂, NO_x, O₃, O_x, and CO observed at the Yufa site from 15 August 2006 to 31 October 2008 are shown in Fig. 2. The hourly mean $\pm$ SD (median) concentration value of SO₂, NO, NO₂, NO_x, O₃, O_x, and CO was 15 ± 16 (9) ppb, 12 ± 25 (3) ppb, 24 ± 19 (20) ppb, 36 ± 39 (23) ppb, 28 ± 27 (21) ppb, 52 ± 24 (45) ppb, and 1.6 ± 1.4 (1.2) ppm during the observation period from 01 September 2006 to 31 August 2008, respectively, with hourly mean values -3, 1, 6, 7, -1, 5 and 0 ppb higher for SO₂, NO, NO₂, NO_x, O₃, O_x, and CO than the Gucheng site, a polluted rural site to the southwest of Beijing, from July 2006 to September 2007 (Lin et al., 2009). The hourly mean values were 12, 11, 17, 28, -5, 22 and 972 ppb higher than those observed at the clean background at the Shangdianzi site, which is one of the regional Global Atmosphere Watch (GAW) stations in China over the period 2004–2006 (Lin et al., 2008). The compared results indicated that the Yufa site has become a relatively polluted rural site. Typical seasonal variations were observed for all gaseous pollutants. Concentrations of primary pollutants, including SO₂, NO, NO₂, NO_x, and CO, were high in winter and low in summer. In contrast, those of secondary pollutants, such as O₃, were high in summer and low in winter.

Figure 3. here

Meteorological parameters such as WS, WD, RH, T, and BP were also measured at the Yufa site; the monthly statistics are shown in Fig. 3. North (usually in winter) or south wind (usually in summer) prevailed at the Yufa site, with monthly average wind speed mostly below 2 m s^{-1} . Exceptional conditions occurred occasionally in spring and winter for the north wind, with monthly average wind speeds around $2\text{--}3 \text{ m s}^{-1}$. In addition, for the north wind, the mean speed was higher than the median speed, suggesting the prevalence of high wind speeds in both spring and winter. Prevailing north wind with high wind speed during winter and spring has been reported consistently in the Beijing area (Lin et al., 2008; Wehner et al., 2008). Another exceptional condition occurred in spring for the south wind, with a monthly average wind speed around 2 m s^{-1} . Figure 4 summarises the prevalence of wind direction in the four seasons. Generally, the prevailing surface wind directions were north-northeast and south-southwest in all seasons. In winter and spring, winds from the north-northeast sector made a contribution of about 40–50 % to wind frequency. Whereas under the influence of summer monsoon, winds from south increased significantly in summer, with the contribution to wind frequency above 40 %. RH was higher in summer and lower in spring and winter with the driest month in April of 2007 and February of 2008. The seasonal variation of RH may partially be related to the variations of WS (Lin et al., 2011). T was higher in summer and lower in winter. Surface pressure measurements showed high values in winter and low values in summer due to surface heating and lifting air masses in summer, which partly accounted for the wind field in the NCP (Takegawa et al., 2009).

Figure 4. here

The seasonal variations in gaseous pollutants and meteorological parameters could be linked in certain ways. For example, the high temperature and low pressure in summer suggested a high boundary layer and diluted gaseous pollutants to some extent. The high temperature, light intensity, and relative humidity also favoured the chemical transformation of these primary pollutants and the formation of secondary pollutants. The high wind speeds in spring and winter also affected regional transport, and therefore the concentrations of gaseous pollutants, as discussed below.

3.2. Transport direction

3.2.1. The bivariate polar plots for the whole observed period

As shown in Fig. 1, the Yufa site located at the boundary area of Beijing city and the NCP. Prevalent south/south-west or north/north-east wind would bring in polluted or clean air masses to the site. Air masses from both directions would pass over the Yufa site. Regional transport from the megacity Beijing and the NCP could therefore be observed at the Yufa site. The transport directions for gaseous pollutants, including SO_2 , NO , NO_2 , NO_x , O_3 , O_x , and CO , will be discussed in this section.

Figure 5. here

Figure 5a-g show the bivariate polar plots for SO_2 , NO , NO_2 , NO_x , O_3 , O_x , and CO at the Yufa site, respectively. In the low wind speed scenario, high or medium concentrations of NO , NO_2 , NO_x , SO_2 , and CO were generally observed, along with low O_3 and O_x concentrations. In the high wind speed scenario, the dependence of species concentration on wind speed and wind direction was more varied.

Specifically, the bivariate polar plot in Fig. 5b clearly shows dependence of high NO concentration (higher than 30 ppb) on low wind speed, with low NO concentration (lower than 5 ppb) at wind speeds $> 3 \text{ m s}^{-1}$. The bivariate polar plot in Fig. 5c shows similar dependence of high NO₂ concentration on low wind speed, but NO₂ concentrations up to 20 ppb were still observed with medium wind speeds of around 5 m s^{-1} from the south, east, and north-east. Accordingly, the dependence pattern of the NO_x concentration (Fig. 5d) on wind speed and wind direction reflected the features of both NO and NO₂. The dependence pattern of high CO concentration on low wind speed in Fig. 5g was similar to that for NO_x, but a considerable CO concentration, substantially higher than background level, was still observed at wind speeds exceeding 5 m s^{-1} from the south and the east. Figure 5a shows similar dependence of medium-high concentration of SO₂ (around 20 ppb) on low wind speed, with one unique feature being that high SO₂ concentration was observed under conditions of high wind speed ($> 5 \text{ m s}^{-1}$) in various wind directions (especially the south wind). Finally, the bivariate polar plot in Fig. 5e shows the dependence of O₃ concentration on wind speed and wind direction, which was somewhat opposite to the patterns for other species. The low O₃ concentration ($< 20 \text{ ppb}$) was related to low wind speed or calm wind conditions. With the north wind and medium or high wind speed, a typical background O₃ concentration (around 50 ppb) was observed. With south wind and medium or high wind speed, high O₃ concentration was observed. The dependence of the high O_x concentration on high wind speed from the south and south-east was similar to that of O₃, but no low concentration of O_x was

observed under low wind speed conditions (Fig. 5f), probably due to the compensation of high NO_x concentration at low wind speeds (Fig. 5d).

Figure 6. here

The high concentrations of NO, NO₂, NO_x, and CO and the medium-high concentration of SO₂ observed under low wind speed conditions were consistent with their high emission intensities in the Beijing area (Fig. 6). Due to the marked increase in the number of vehicles and heavy energy consumption, Beijing has been a well-known emission hot spot for NO and NO₂ (Tang, 2004). Meanwhile, the extremely high levels of CO emissions in the Beijing area are clearly shown in the emissions map (Fig. 6) and have been reported consistently (Wang et al., 2009) and directly observed, with peak CO concentrations up to 9.3 ppm. Only medium-high SO₂ concentration (~15 ppb) observed even at low wind speed suggested the successful reduction of SO₂ emission, which could be ascribed to the continuous effort of the Chinese government since the 1990s and during the Olympic Games (Qin et al., 2009; Tang, 2004; Wang et al., 2009, 2011). Accordingly, the O₃ concentration under low wind speed conditions was lower than the typical background level, which could be attributed to the rapid titration of O₃ by of accumulation NO.

3.2.2 Seasonal variations of the bivariate polar plots

Figure 7. here

The different patterns of the bivariate polar plots reflected the differences in local emission and regional transport for different species. The emissions, the

meteorological conditions, the chemical reaction rate and the species lifetime, which have essential influence on the regional transport, varied greatly by seasons. Thus the seasonal variations of the bivariate polar plots and the corresponding causes were discussed in this section.

Figure 7b-d show seasonal variations of the bivariate polar plots for NO, NO₂, and NO_x at the Yufa site, respectively. Generally, the mean concentrations of NO₂, NO_x and especially NO in the low wind speed scenario were higher than those in the higher wind speed scenario in all seasons. The mean concentration of NO was less than 10 ppb when the wind speed higher than 5 m s⁻¹ in all seasons (Fig. 7b). Figure 7c clearly shows the relatively higher concentration of NO₂ (~20 ppb) with winds at wind speed (> 5 m s⁻¹) from the south sector in spring, from the northeast and south sectors in summer and winter, and from the northeast sector in autumn. Figure 7d shows the dependence pattern of NO_x was similar to both NO and NO₂. Although emission hot spots of NO, NO₂, and NO_x are widespread in the NCP, the long-range transport of these species to Yufa is limited by the lifetime of these species. As the average O₃ concentration for spring, summer, autumn and winter was 20, 11, 32, and 42 ppb respectively at Yufa, the typical lifetime of NO was 66, 51, 106, and 181 s in spring, summer, autumn, and winter, respectively, just by assuming that all the NO is removed mainly by chemical reaction with O₃ (Sander et al., 2011). The transport distance of NO was therefore less than 5 km even with a high wind speed of 15 m s⁻¹. Even when considering the the conversion of NO from NO₂ with conversion efficiency ~30 % in summer and autumn (Takegawa et al. 2009), the transport distance of NO was still limited, for the lifetime of NO₂ is also relative short (Beirle et al., 2011; Gu et

al., 2013). That is, NO concentration is determined by local emissions rather than regional transport. NO₂ and NO_x have longer lifetimes in the atmosphere than NO has, typically on the order of 4–5 h and with longer photochemical lifetime in cold seasons (Beirle et al., 2011; Gu et al., 2013). Hence, the typical transport distance of these species is around 100 km at the wind speed of 5 m s⁻¹ (Beirle et al., 2011). Within such transport distance, the Yufa site is surrounded by various NO_x emission hot spots (Fig. 6), such as the megacity Beijing to the north, the Baoding-Cangzhou area to the south, and the Tianjin-Tangshan area to the east. Meanwhile the emission intensity was larger in winter and autumn than that in spring and summer (Fig. 6). It is therefore reasonable to observe the influence of short-range transport, in addition to local emissions, on the local NO₂ and NO_x concentrations, especially in cold seasons (Fig. 7c and 7d). Although our results suggested that short-range transport from these surrounding areas, especially the urban area of Beijing, was a non-negligible factor affecting the NO_x concentration at the Yufa site, the regional transport of NO_x is of less significance compared to SO₂ and CO due to its limited transport distance (see below).

Figure 7e is the seasonal bivariate polar plots of CO, which clearly shows the relatively higher mean concentration of CO (> 1 ppm) with winds at low wind speed (< 2 m s⁻¹), similar to nitrogen oxide species. The mean concentration of CO was relatively higher with wind at higher wind speed (> 5 m s⁻¹) from south sector in spring and summer, from northeast and south sector in autumn, and from north and south in winter. The oxidation lifetime of CO is typically ~20 days, under the assumption of OH radical concentration of 2 × 10⁶ cm⁻³ (Xu et al., 2011). This is

substantially longer than the lifetime of NO_x , making regional transport of CO an important process affecting local air quality in the downwind area. The different lifetimes of CO and NO_x appeared to explain the unique high concentration of CO, but not NO_x , at wind speeds exceeding 5 m s^{-1} from the south and the east. Our results suggest that regional transport from the south and central NCP and the Tianjin area could greatly affect local concentrations of CO at the Yufa site.

Figure 7a clearly shows the relatively higher mean concentration of SO_2 (~20 ppb) with winds at higher wind speed ($> 5 \text{ m s}^{-1}$) from the south sector in spring and summer. The mean concentration of SO_2 was high ($> 30 \text{ ppb}$) with winds at higher wind speed ($> 5 \text{ m s}^{-1}$) from the north-east, east, and south sectors in autumn and winter. Similar to CO, SO_2 has a relatively long lifetime in the atmosphere compared to NO_x , i.e. a couple of hours to 1–2 days with longer lifetime in winter and shorter lifetime in summer (Beirle et al., 2014; He et al., 2012; Lee et.al., 2014), and regional transport of SO_2 was expected to occur. Accordingly, regional transport from emission hot spots located south of the Yufa site (Fig. 6), was found to influence the concentrations of SO_2 (Fig. 7a) at Yufa in all seasons. Specifically, the highlighted emission hot spots in the central NCP and the south NCP, which accounted for about 70 % of China's coal consumption in 10 % of China's domestic area (China Statistical Yearbook, 2008), is a major source of SO_2 in the Beijing area by regional transport (Liu et al., 2016). Furthermore, regional transport from the north-east sector of the Yufa site, where the center of the megacity Beijing located, also was observed in autumn and winter, which indicated the increased emission of SO_2 in heating seasons.

Finally, the bivariate polar plot in Fig. 7f and 7g show the dependence of O_3 and O_x concentration on wind speed and wind direction by season. The low O_3 concentration (< 20 ppb) was observed at low wind speed ($< 2 \text{ m s}^{-1}$). With the north wind at higher wind speed ($> 5 \text{ m s}^{-1}$), a typical background O_3 concentration (around 50 ppb) was observed in spring and summer. With south wind at higher wind speed ($> 5 \text{ m s}^{-1}$), high O_3 concentration (above 60 ppb) was observed, especially in summer. The main difference of seasonal bivariate polar plots between O_3 and O_x was that no low concentration of O_x was observed under low wind speed conditions in all seasons. The low concentration of O_3 at low wind speed may be due to the titration of O_3 by NO , which is more obvious in autumn and winter. Background O_3 levels in the north-west wind under medium and high wind speed conditions clearly reflect the transport of background air mass to the Yufa site from locations where the emission intensities of pollutants were relatively low (Fig. 6), and this was more obvious in spring when the air masses from the north-west increased (Fig. 4). Whereas O_3 concentrations higher than background level in the south wind under medium and high speed conditions, especially in summer, suggest accumulation of O_3 during its transport from the central NCP area or even the south NCP area to the Yufa site. Emission intensities of O_3 precursors, such as NO_x and VOCs is high in the NCP, and the solar radiation is strong in summer, which facilitate the formation and transport of O_3 from the NCP to Beijing (Zhang et al., 2014).

In conclusion, the emissions in the Beijing area are closely related to the observed concentrations of NO , NO_2 , NO_x and CO at Yufa. Regional transport had a clear influence on the concentrations of all gaseous pollutants examined here, with

the exception of NO. The emission hot spots located east, north-east, and especially south of the Yufa site determined the regional transport directions. The influence of regional transport differed among species. Regional transport of SO₂, CO, and O₃ from the central and south NCP to the Yufa site was more important, whereas regional transport of NO_x from the NCP was less evident. Factors affecting regional transport included, but were not limited to, the atmospheric lifetime of pollutants, wind field, and local and regional emissions. As the Yufa site is a cross-boundary rural site between the megacity Beijing and the NCP, observation of transport flux there is appropriate in evaluating the regional transport influence by both the megacity Beijing and the NCP on the Yufa site.

3.3. Transport flux

To evaluate the surface transport of the main air pollutants from Beijing and the NCP to the Yufa site, the surface flux intensities were calculated with Eqs. (3) based on observations at the Yufa site. The mean surface flux intensities in each season were also calculated for the 2-year observation period (Table 2). The overall net surface flux intensities (mean $\pm$ SD) of SO₂, NO, NO₂, NO_x, O₃, O_x, and CO were 6.2 ± 89.5 , -4.3 ± 29.5 , -0.6 ± 72.3 , -4.9 ± 93.0 , 14.7 ± 187.8 , 14.8 ± 234.9 , and 70 ± 2830 $\mu\text{g s}^{-1} \text{m}^{-2}$ during the observation period from 01 September 2007 to 31 August 2008, respectively. The large standard deviation of the surface flux intensity indicated the large variations of the transport flux intensities. Table 3 shows the mean influx intensities (positive; from the NCP to Yufa) were highest in winter and lowest in summer, with the flux intensity values in winter 2–6 times of those in summer. The outflux intensities (negative; from Beijing to Yufa) show the same

pattern, with the absolute flux intensity values in winter 2–8 times of those in summer. Yet the overall net transport surface flux intensities show quite different seasonal variations (Table 2) comparing to the results in Table 3. For SO₂, CO, O₃, and O_x the surface transport flux intensities from the NCP to Yufa surpassed those from Beijing to Yufa in all seasons except in winter, with the strongest net fluxes largely appeared in summer, which was about 4–8 times of other seasons. The net surface transport flux intensity of NO_x from Beijing to Yufa was stronger than that from the NCP to Yufa except in summer, with the strongest net flux in winter, which was about 1.3–8 times of other seasons.

Table 2. here

Table 3. here

To understand the transport fluxes reported here, it is necessary to discuss the affecting factors. First, the prevalent wind is a dominant factor affecting the surface fluxes. Figure 8 shows the time series of daily average surface flux intensity, i.e. the per unit cell flux ($\mu\text{g s}^{-1} \text{m}^{-2}$) of SO₂, NO, NO₂, NO_x, O₃, O_x, and CO, and corresponding wind vectors (m s^{-1}) during the observation period. In general, the variations in the pollutant flux intensities showed a saw-teethed pattern, with influx (positive; from the NCP to Yufa) and outflux (negative; from Beijing to Yufa) prevailing according to the shift in wind direction. Meanwhile, mainly due to the seasonal variations in wind speed and wind direction (Fig. 3 and 4), the magnitude of surface fluxes showed similar seasonal variation (Table 2). High net positive influxes were observed in summer, and high net negative outfluxes in winter. As the

north wind prevailed significantly over the south wind in winter, and the south wind over the north wind in summer (Fig. 4), the values of net surface flux intensities in these two seasons were the highest. During the other two seasons, frequent changes in positive and negative fluxes tended to cancel each other out, making the net transport fluxes less significant. This dominant role of wind field could also be illustrated by conditions during the winter of 2006/07 and 2007/08. Exceptionally, the south wind prevailed in the winter of 2006/07 (Fig. 4), leading to the surface flux intensity of pollutants more positive in the winter of 2006/07 than 2007/08 (Table 2). For example, the increase of influx intensity for SO₂, NO, NO₂, NO_x and CO between winter of 2006/07 and 2007/08 was on the order of a factor of 1.5 (Table 3).

Figure 8. here

Second, the transport flux is determined not only by the wind field but also by the emissions of pollutants in the upwind area. Various pollutants showed different patterns of seasonal variations in flux as a result of relative emission strengths in the upwind area compared to local emissions. For example, the seasonal surface flux intensities of SO₂ were mainly positive influx, except in winter of 2007/08. The significant regional transport of SO₂ from the NCP to Yufa in all seasons except winter could be partly attributed to the high emission intensity of SO₂ in the NCP (Fig.6) and the reduction of SO₂ emission in Beijing (Qin et al., 2009; Wang et al., 2009, 2011), whereas the SO₂ outflux from Beijing to Yufa was determined by the prevalent north wind, as explained above. In contrast to the net positive influx of SO₂, the net seasonal surface flux intensities of CO were negative in both winter

and autumn. The small outflux of CO in autumn reflected increased CO emission in Beijing, which was sufficiently strong to account for the strong CO emissions in the NCP.

The influence of emissions on transport flux could also be inferred from an emissions-reduction scenario. For example, the 29th Olympic Games was held in Beijing during the period from 8 August 2008 to 20 September 2008. The Beijing government implemented aggressive long- and short-term air quality control measures in Beijing and its surrounding areas before and during the Olympic period to maintain good air quality during the Olympic Games (Wang et al., 2010; Wang et al., 2011). The control measures included moving the heavy polluted factories out the Beijing city, reducing the traffic emission through an odd/even plate number rule, and freezing construction activities (Wang et al., 2009). The concentrations of pollutants and the surface flux intensities during the 2008 Olympic Games were substantially reduced compared to the corresponding period of 2007 (Table 4). Besides the favored meteorological conditions (Fig. S2), the significant emission reduction both in the Beijing area and the NCP during the 2008 Beijing Olympic Games played a key role in the decrease of the transport flux intensities (Zhou et al., 2010).

Table 4. here

Finally, the chemical properties of these species could also affect the flux. Take O₃ for example, although both Beijing and the NCP are regarded as emissions hot spots for O₃ precursors, the short distance between Beijing and the Yufa site may hinder the secondary formation of O₃ to some extent. Thus the surface transport of

O₃ from to the NCP to Yufa was stronger than that from Beijing to Yufa, especially in summer time with a net average surface flux intensity value of about 60 $\mu\text{g s}^{-1} \text{m}^{-2}$, which is 4-9 times of that in autumn and spring (Table 2). The lifetime of the pollutants also determined the different net transport flux intensities for different species (Table 2 and 3), with the net transport of NO, NO₂ and NO_x from Beijing to Yufa and the net transport of SO₂, CO, O₃ and O_x from the NCP to Yufa. These results are consistent with bivariate polar plots analysis mentioned above (Fig. 7).

Overall, the flux intensities are influenced by at least the wind field, emissions inventory in both the megacity Beijing and the NCP, and the chemical fates of these pollutants in the atmosphere. These observations provide insight for the analysis of projected transport flux under various emissions-reduction scenarios in the future. On the other hand, the dependence of the fluxes on these factors, which can vary, suggests that the fluxes reported here should not be compared with other reports under different conditions.

3.4 The back trajectory and PSCF analysis

The discussion above suggested the regional transport from both Beijing and the NCP have important influence on the air quality of the Yufa site. However, both the bivariate polar plots and surface flux intensity calculation are based on the observation data at a ground measurement site. Considering the limitation of spatial representation of the Yufa site, the PSCF analysis based on the HYSPLIT-4 model was used to demonstrate the regional transport influence of the megacity Beijing and the NCP on Yufa in this section.

Figure 9. here

Figure 10. here

PSCF analysis was used in this study by combining backward trajectories and the corresponding surface transport flux intensities of pollutants. PSCF results of SO_2 , NO, NO_2 , NO_x , CO, O_3 and O_x in 6-h resolution are shown in Fig. 9 for positive influx intensities (i.e. from south to north) and Fig. 10 for negative outflux intensities (i.e. from north to south). It can be seen from Fig. 9, that the higher PSCF values for most pollutants were located at the area south-west to the Yufa site, which indicates the positive surface flux intensities of the Yufa site is consistent with the air masses moving from south to Yufa. Figure 10 shows the higher PSCF values for most pollutants were located at the area north to the Yufa site, which indicates the negative surface flux intensities of the Yufa site is consistent with the air masses moving from north to Yufa. The PSCF analysis results validate the calculated flux intensities based on observation data can be used to evaluate the regional transport influence of Beijing and the NCP on the Yufa site. However, it should be noticed that the PSCF results of NO, NO_2 , and NO_x was inconsistent with the flux calculation results sometimes (Fig. 9 and 10), which may partially ascribe to the lifetime of these species is much shorter than 12 h. As a cross-boundary site between the megacity Beijing and the NCP, the surface flux intensities at the Yufa site may also indicate the transport between the megacity Beijing and the NCP.

3.5 Uncertainty and limitation

Uncertainty in calculation of the surface flux intensities in this study mainly comes from the measurement of the pollutants and the wind. Based on the instruments used, the uncertainty of the measurement of the concentrations of SO₂, NO_x, CO, and O₃ was within 10 %, 10 %, 1 %, and 5 %, respectively. The uncertainty of wind speed measurement was less than 5 % and the uncertainty of wind direction was about 1 %. Thus, the uncertainty of the overall surface flux intensity for SO₂, NO_x, CO, and O₃ was less than 12 %, 12 %, 6 %, and 8 %, respectively.

In this study, we did not intent to extrapolate from Yufa site to the entire region. We focus on the method developing and evaluation of the regional transport influence of Beijing and the NCP on the cross-boundary site based on the ground-based observation data. Bivariate Polar plots analysis and surface flux intensity calculation were conducted, and we obtained clear evidences of surface pollutants transport from Beijing to the Yufa site and from the NCP to the Yufa site. Considering the variations of the vertical and horizontal distributions of the air pollutants and meteorological parameters, and the influence of the boundary layer on the regional transport, three dimensional observations with high precision and resolution are needed for further comprehensive discussion of the regional transport between Beijing and the NCP.

4. Conclusions

We used 2-year continuous observation data at a cross-boundary rural site between the megacity Beijing and the NCP to investigate regional transport influence on the Yufa site, as part of the “Campaign of Air Quality Research in Beijing and Surrounding Region 2006–2008” (CAREBeijing 2006–2008). The gaseous pollutants SO₂, NO, NO₂,

NO_x, CO, O₃, and O_x, together with meteorological data, were determined at Yufa from August 2006 to October 2008. During the observation period, the average concentrations of the pollutants at the Yufa site were relatively high, suggesting a profound influence of the emissions from the megacity Beijing and regional transport from the NCP.

Through bivariate polar plots, we found that the south wind, at relatively high wind speed, was essential for the inflow of SO₂, CO, and O₃ from the NCP to Yufa. For NO, NO₂, NO_x, and even CO, the emission from Beijing played a dominant role. The seasonal variations of emission intensity, meteorological conditions, pollutant lifetimes lead to the seasonal variations of the regional transport of pollutants, hence the different bivariate polar plot patterns.

The the surface flux intensities showed strong net surface transport from the NCP to Yufa in summer and net surface transport from Beijing to Yufa in winter, mainly varied with the prevailing wind. The positive net influxes of SO₂, CO, and O₃ in this study indicate a northward regional transport of these species from the NCP. Whereas the fluxes of NO_x indicate the influence of NO_x emission in Beijing city could only influence downwind area adjacent to Beijing, due to the limited transport distance of NO_x.

PSCF analysis demonstrated the regional transport from Beijing and the NCP to Yufa can be evaluated by the surface flux intensity calculation based on the ground-based measurement data. As a cross-boundary site between the megacity Beijing and the NCP, the surface transport flux intensities at the Yufa site may also indicate the transport between the megacity Beijing and the NCP.

Our results again suggested that Beijing and the NCP have tight interactions through regional transport of air pollutants. Factors affecting the transport flux such as meteorological parameters, especially wind speed and wind direction, emissions inventory, and photochemical reactions are essential for the regional transport fluxes and thus the air quality of the megacity Beijing and its surrounding areas. Therefore, both local emissions reduction and regional cooperative control should be taken considered in air quality management of Beijing.

Author contribution. T. Zhu designed the experiments and L. Zeng and the staff of the Yufa site carried out the experiment. Y. Li conducted the data analysis with contributions from all co-authors. J. Liu provided the emission maps. J. Wang managed the observation data of the program. Y. Li prepared the manuscript with the help of T. Zhu, C. Ye, J. Liu and Y. Zhu.

Data availability. The observation data of the Yufa site used in this paper is available on requests.

Acknowledgements. The authors express their sincere thanks to the staff of the Yufa site for carrying out the measurements. This work as part of CAREBeijing (Campaign of Atmospheric Researches in Beijing and surrounding area) was supported by Beijing Council of Science and Technology. This study was also supported by the National Natural Science Foundation Committee of China (21190051, 41121004, 41421064), the European 7th Framework Programme Project PURGE (265325), the Collaborative Innovation Center for Regional Environmental Quality.

844

Figure 1. The location information of the Yufa site.

Figure 2. Time series of hourly mean (black line) and 24-hour smoothing (red line) concentrations of SO₂, NO, NO₂, NO_x, O₃, O_x, and CO at the Yufa site from 15 August 2006 to 31 October 2008.

Figure 3. Monthly statistics of wind speed (WS) for north wind (a) top and south wind (a) bottom, relative Humidity (RH) (b), temperature (T) (c) and barometric pressure (BP) (d) at the Yufa site. The red point represents the mean value. The black cross bar stands for the median value. The black box and whisker denote the 5th, 25th, 75th and 95th percentiles, respectively. The plus and minus symbols represent the maximum and minimum, respectively. It should be clarified that the North and South wind here is different from the wind direction definition in meteorology. The South wind here is the wind with direction from 90° to 270°, while the North wind is from 0° to 90° and from 270° to 360°.

870

871 **Figure 5.** Bivariate polar plots for SO₂ (a), NO (b), NO₂ (c), NO_x (d), O₃ (e), O_x (f) and CO
 872 (g) concentrations based on hourly average data at the Yufa site from 1 September
 873 2006 to 31 August 2008. The colour scale shows the concentrations of pollutants in
 874 ppb (or ppm specially for CO) and the radial scale shows the wind speed (m s^{-1}),
 875 which increases from the centre of the plot radially outwards.

876

Figure 6. Spatial distribution of seasonal NO_x , CO, and SO_2 emissions in Northern China in 2008 based on the Multi-resolution Emission Inventory of China (MEIC; www.meicmodel.org) (unit: $\text{Mg km}^{-2} \text{ day}^{-1}$, horizontal resolution: $25 \text{ km} \times 25 \text{ km}$).

Figure 7. Seasonal bivariate polar plots for SO_2 (a), NO (b), NO_2 (c), NO_x (d), CO (e), O_3 (f), O_3x (g) and concentrations based on hourly mean data at the Yufa site from 1 September 2006 to 31 August 2008. The colour scale shows the concentrations of pollutants in ppb (or ppm specially for CO) and the radial scale shows the wind speed (m s^{-1}), which increases from the centre of the plot radially outwards.

887

888 **Figure 8.** Time series of surface flux intensity (i.e. flux per unit cell, $\mu\text{g s}^{-1} \text{m}^{-2}$ or mg
889 $\text{s}^{-1} \text{m}^{-2}$) for SO_2 , NO , NO_2 , NO_x , O_3 , O_x , CO and wind vector, i.e. $-\frac{1}{n} \sum_{j=1}^n WS_j \cdot \cos\theta_j$
890 (WSVECTOR , m s^{-1}) based on daily average data at the Yufa site from 15 August 2006
891 to 31 October 2008. The red shaded line indicates the positive transport direction of
892 gaseous pollutants from south to north (i.e. from the NCP to Yufa) and the black
893 shaded line represents the negative transport direction of gaseous pollutants from
894 north to south (i.e. from Beijing to Yufa).

895

897 **Figure 9.** The PSCF maps for the SO₂ (a), NO (b), NO₂ (c), NO_x (d), O₃ (e), O_x (f) and CO
898 (g) surface influx intensity (positive; from the NCP to Yufa). The criterion value of the
899 surface flux intensity is set to greater than the median values, i.e. 20, 3, 30, 34, 40, 94,
900 and 1200 µg s⁻¹ m⁻² for SO₂, NO, NO₂, NO_x, O₃, O_x, and CO, respectively.

902 Figure 10. The PSCF maps for the SO₂ (a), NO (b), NO₂ (c), NO_x (d), O₃ (e), O_x (f) and CO
903 (g) surface outflux intensity (negative; from Beijing to Yufa). The criterion value of the
904 surface flux intensity is set to lower than the median values, i.e. -18, -5, -35, -43, -16,
905 -67, and -1200 µg s⁻¹ m⁻² for SO₂, NO, NO₂, NO_x, O₃, O_x, and CO, respectively.
