1 Abstract

2 A new metric is introduced for representing the molecular signature of 3 atmospherically relevant organic compounds, the collision cross section (Ω), a quantity 4 that is related to the structure and geometry of molecules and is derived from ion mobility 5 measurements. By combination with the mass-to-charge ratio (m/z), a two-dimensional 6 $\Omega - m/z$ space is developed to facilitate the comprehensive investigation of the complex 7 organic mixtures. A unique distribution pattern of chemical classes, characterized by 8 functional groups including amine, alcohol, carbonyl, carboxylic acid, ester, and organic 9 sulfate, is developed on the 2-D Ω – m/z space. Species of the same chemical class, 10 despite variations in the molecular structures, tend to situate as a narrow band on the 11 space and follow a trend line. Reactions involving changes in functionalization and 12 fragmentation can be represented by the directionalities along or across these trend lines, 13 thus allowing for the interpretation of atmospheric transformation mechanisms of organic species. The characteristics of trend lines for a variety of functionalities that are 14 15 commonly present in the atmosphere can be predicted by the core model simulations, 16 which provide a useful tool to identify the chemical class to which an unknown species 17 belongs on the $\Omega - m/z$ space. Within the band produced by each chemical class on the 18 space, molecular structural assignment can be achieved by utilizing collision induced 19 dissociation as well as by comparing the measured collision cross sections in the context 20 of those obtained via molecular dynamics simulations.

28 **1. Introduction**

29 Organic species in the atmosphere — their chemical transformation, mass transport, 30 and phase transitions — are essential for the interaction and coevolution of life and 31 climate (Pöschl and Shiraiwa, 2015). Organic species are released into the atmosphere 32 through biogenic processes and anthropogenic activities. Once in the atmosphere, 33 organic species actively evolve via multiphase chemistry and gas-particle phase 34 conversion. The complexity and dynamic behaviors of organic species have prevented 35 our capability to accurately predict their levels, temporal and spatial variability, and 36 oxidation dynamics associated with the formation and evolution of organic aerosols in the 37 atmosphere.

38 Several two-dimensional frameworks have been developed in an effort to deconvolve 39 the complexity of organic mixtures and visualize their atmospheric transformations. The 40 Van Krevelen diagram, which cross plots the hydrogen-to-carbon atomic ratio (H:C) and 41 the oxygen-to-carbon atomic ratio (O:C), has been widely used to represent the bulk 42 elemental composition and the degree of oxygenation of organic aerosol (Heald et al., 2010). The average carbon oxidation state (\overline{OS}_{C}), a quantity that necessarily increases 43 44 upon oxidation, can be estimated from the elemental ratios (Kroll et al., 2011). When 45 coupled with carbon number (n_c) , it provides constraints on the chemical composition of 46 organic mixture and defines key classes of atmospheric processes based on the unique trajectory of the evolving organic chemical composition on the $\overline{OS}_{C} - n_{C}$ space. The 47 48 degree of oxidation has also been combined with the volatility (expressed as the effective saturation concentration, C^*), forming a 2-D volatility basis set to describe the coupled 49 50 aging and phase partitioning of organic aerosol (Donahue et al., 2012). These three 51 spaces are designed to represent fundamental properties of the organic mixtures and 52 provide insight into their chemical evolution in the atmosphere. Organic species span 53 large varieties in the physicochemical properties. Species of similar volatility or 54 elemental composition can differ vastly in structures and functionalities. One weakness of 55 these frameworks is that they do not provide information on the organic components at 56 molecular level.

57 In this article we introduce a new framework that is based on the collision cross 58 section (Ω), a quantity that is related to the structure and geometry of a molecule. The 59 collision cross section of a charged molecule determines its mobility as it travels through 60 a neutral buffer gas such as N₂ under the influence of a weak and uniform electric field. 61 Species with open conformation undergo more collisions with buffer gas molecules and 62 hence travel more slowly than the compact ones (Shvartsburg et al., 2000; Eiceman et al., 63 2013). Mobility measurements are usually performed with an Ion Mobility Spectrometer 64 (IMS), where ions are separated mainly on the basis of their size, geometry, and 65 subsequent interactions with the buffer gas. The combination of IMS with a Mass 66 Spectrometer (MS) allows for further selection of ions based on their mass-to-charge 67 ratios. The resulting IMS-MS plot provides separation of molecules according to two 68 different properties: geometry (as reflected by the collision cross section) and mass (as 69 reflected by the mass-to-charge ratio) (Kanu et al., 2008). The Ion Mobility Spectrometry 70 - Mass Spectrometry (IMS-MS) analytical technique has been widely employed in the 71 fields of biochemistry (McLean et al., 2005; Liu et al., 2007; Dwivedi et al., 2008; 72 Roscioli et al., 2013; Groessl et al., 2015) and homeland security (Eiceman and Stone, 73 2004; Ewing et al., 2001; Fernandez-Maestre et al., 2010). To our knowledge, the 74 application of IMS-MS to study organic species in the atmosphere, however, has only 75 been explored very recently (Krechmer et al., 2016).

76 We propose a two-dimensional collision cross section vs. mass-to-charge ratio 77 $(\Omega - m/z)$ space to facilitate the comprehensive investigation of complex organic 78 mixtures in the atmosphere. Despite the typical complexity of the detailed molecular 79 mechanism involved in the atmospheric oxidation of organics molecules, they can be 80 characterized by the distinctive functional groups attached to the carbon backbone 81 (Zhang and Seinfeld, 2013). We show that the investigated organic classes (m/z < 600), 82 characterized by functional groups including amine, alcohol, carbonyl, carboxylic acid, 83 ester, and organic sulfate, exhibit unique distribution patterns on the $\Omega - m/z$ space. Species of the same chemical class, despite variations in the molecular structures, tend to 84 85 develop a narrow band and follow a trend line on the space. Reactions involving changes 86 in functionalization and fragmentation can be represented by directionalities along or 87 across these trend lines. The locations and slopes of the measured trend lines are shown to be predicted by the core model (Mason et al., 1972), which characterizes the ionneutral interactions as elastic sphere collisions. Within the narrow band produced by each chemical class on the $\Omega - m/z$ space, molecular structural assignment is achieved with the assistance of collision induced dissociation analysis. Measured collision cross sections are also shown to be consistent with theoretically predicted values from the trajectory method (Mesleh et al., 1996; Shvartsburg and Jarrold, 1996) and are used to identify isomers that are separated from an isomeric mixture.

95

96 2. Collision Cross Section Measurements

97 2.1 Materials

A collection of chemical standards (ACS grade, \geq 96%, purchased from Sigma Aldrich, St. Louis, MO, USA), classified as amines, alcohols, carbonyls, carboxylic acids, esters, phenols, and organic sulfates, were used to characterize the performance of IMS-MS. These chemicals were dissolved in an HPLC-grade solvent consisting of a 70% methanol / 29% water with 1% formic acid, at a concentration of approximately 10 μ M.

103 2.2 Instrumentation

Ion mobility measurements were performed using an Electrospray Ionization (ESI)
Drift-Tube Ion Mobility Spectrometer (DT-IMS) interfaced to a Time-of-Flight Mass
Spectrometer (TOFMS). The instrument was designed and manufactured by TOFWERK
(Switzerland), with detailed descriptions and schematics provided by several recent
studies (Kaplan et al., 2010; Zhang et al., 2014; Groessl et al., 2015; Krechmer et al.,
2016). In the next few paragraphs, we will present the operating conditions of the ESIIMS-TOFMS instrument.

Solutions of chemical standards were delivered to the ESI source via a 250 μ L gastight syringe (Hamilton, Reno, NV, USA) held on a syringe pump (Harvard Apparatus, Holliston, MA, USA) at a flow rate of 1 μ L min⁻¹. A deactivated fused silica capillary (360 μ m OD, 50 μ m ID, 50 cm length, New Objective, Woburn, MA, USA) was used as the sample transfer line. The ESI source was equipped with an uncoated SilicaTip Emitter (360 μ m OD, 50 μ m ID, 30 μ m tip ID, New Objective, Woburn, MA, USA) and 117 connected to the capillary through a conductive micro union (IDEX Health & Science, 118 Oak Harbor, WA, USA). The charged droplets generated at the emitter tip migrate 119 through a desolvation region in nitrogen atmosphere at room temperature, where ions 120 evaporate from the droplets and are introduced into the drift tube through a Bradbury-Nielsen ion gate located at the entrance. The ion gate was operated in the Hadamard 121 122 Transform mode, with a closure voltage of \pm 50 V and an average gate pulse frequency of 123 1.2×10^3 Hz. The drift tube was held at a constant temperature (340±3 K) and atmospheric pressure (~ 1019 mbar). A counter flow of N₂ drift gas was introduced at the end of the 124 drift region at a flow rate of 1.2 L min⁻¹. Ion mobility separation was carried out at a 125 typical filed strength of 300 - 400 V cm⁻¹, resulting in a reduced electric field of 126 127 approximately 1.4 - 1.8 Td. After exiting from the drift tube, ions were focused into 128 TOFMS through a pressure-vacuum interface that includes two segmented quadrupoles that were operated at ~ 2 mbar and ~ 5×10^{-3} mbar, respectively. Collision Induced 129 130 Dissociation (CID) of parent ions is achieved by adjusting the voltages on the ion optical 131 elements between the two quadruple stages (Kaplan et al., 2010).

132 The ESI-IMS-TOFMS instrument was operated in the m/z range of 40 to 1500 with a 133 total recording time of 90 s for each dataset. The Mass Spectrometer was calibrated using 134 a mixture of quaternary ammonium salts, reserpine, and a mixture of fluorinated 135 phosphazines (Ultramark 1621) in the positive mode and ammonium phosphate, sodium 136 dodecyl sulfate, sodium taurocholate hydrate, and Ultramark 1621 in the negative mode. 137 The ion mobility measurements were calibrated using tetraethyl ammonium chloride as 138 the instrument standard and 2,4-lutidine as the mobility standard, as defined shortly 139 (Fernández-Maestre et al., 2010). Mass spectra and ion mobility spectra were recorded 140 using the acquisition package "Acquility" (v2.1.0, http://www.tofwerk.com/acquility). 141 Post-processing was performed using the data analysis package "Tofware" (version 2.5.3, 142 www.tofwerk.com/tofware) running in the Igor Pro (Wavemetrics, OR, USA) 143 environment.

144 2.3 Calculations

The average velocity of an ion in the drift tube (v_d) is proportional to its characteristic mobility constant $(K / \text{cm}^2 \text{ V}^{-1} \text{ s}^{-1})$ and the electric field intensity (E_d) , provided that the

147 field is weak (McDaniel and Mason, 1973):

$$v_{\rm d} = K E_{\rm d} \tag{1}$$

Experimentally, ion mobility constants can be approximated from the time of ion clouds spent in the drift tube (t_d / s), given by the rearranged form of Equation (1):

$$t_{\rm d} = \frac{1}{K} \frac{L_{\rm d}^2}{V_{\rm d}} \tag{2}$$

where L_d (cm) is the length of the drift tube and V_d (V) is the drift voltage. In the present study, drift time measurements were carried out at six different drift voltages ranging from 5 kV to 8 kV in ~ 1019 *mbar* of nitrogen gas at 340 K (Figure S1 in the supplement). The ion mobility constant (*K*) is derived by linear regression of the recorded arrival time (t_a) of the ion clouds at the detector versus the reciprocal drift voltage:

$$t_{\rm a} = \frac{L_{\rm d}^2}{K} \frac{1}{V_{\rm d}} + t_0 \tag{3}$$

Note that the arrival time was determined from the centroid of the best-fit Gaussian distribution, see Figure S2 in the Supplement. The *y*-intercept of the best-fit line represents the transport time of the ion from the exit of the drift tube to the MS detector (t_0) , which exhibits strong m/z dependency that is attributable to a time-of-flight separation in the ion optics, see Figure S3 in the Supplement.

160 It is practical to discuss an ion's mobility in terms of the reduced mobility constant 161 (K_0) , defined as:

$$K_0 = K \frac{273.15}{T} \frac{P}{1013.25} \tag{4}$$

where P(mbar) is the pressure in the drift region and T(K) is the buffer gas temperature. In theory, the parameter K_0 is constant for a given ion in a given buffer gas and can be used to characterize the intrinsic interactions of that particular ion-molecule pair. In practice, however, K_0 values from different measurements might not be in good agreement, primarily due to uncertainties in instrumental parameters such as inhomogeneities in drift temperature and voltage (Fernández-Maestre et al., 2010). In view of these uncertainties, the instrument standard is needed to provide an accurate constraint on the instrumental parameters, such as voltage, drift length, pressure, and temperature.

$$K_0 \times t_d = \frac{L_d^2}{V_d} \frac{P}{1013.25} \frac{273.15}{T} = C_i$$
 (5)

Tetraethyl ammonium chloride (TEA) is used here as the instrument standard, as its reduced mobility is not affected by contaminants in the buffer gas (Fernández-Maestre et al., 2010). Given the well-known K_0 and measured t_d of the protonated TEA ion (m/z =130), Equation (5) yields an instrument constant C_i to calibrate the IMS performance.

Unlike TEA, the reduced mobility of species that are more likely to cluster with contaminants can be significantly affected by impurities of the buffer gas. This category of species can be used as a 'mobility standard' to qualitatively indicate the potential contamination in the buffer gas. 2,4-Lutidine, with a well-characterized K_0 value of 1.95 cm² V⁻¹ s⁻¹, is used as such a mobility standard. As shown Figure S4 in the Supplement, the measured mobility of 2,4-Lutidine is 1.5% lower than its theoretical value, indicative of the absence of contaminations in the buffer gas.

In the low field limit, the collision cross section of an ion (Ω) with a buffer gas is related to its reduced mobility (K_0) through the modified zero field (so called Mason-Schamp) equation (McDaniel and Mason, 1973; Siems et al., 2012):

$$\Omega = \frac{3ze}{16N_0} \left(\frac{2\pi}{k_{\rm B}\mu T_0}\right)^{1/2} \frac{1}{K_0} \left[1 + \left(\frac{\beta_{\rm MT}}{\alpha_{\rm MT}}\right)^2 \left(\frac{\nu_{\rm d}}{\nu_{\rm T}}\right)^2\right]^{-1/2}$$
(6a)

where z is the net number of integer charges on the ion, e is the elementary charge, N_0 is the number density of buffer gas at 273 K and 1013 *mbar*, k_B is the Boltzmann constant, µ is the reduced mass for the molecule-ion pair, T_0 is the standard temperature, v_d is the drift velocity given by Equation (1), v_T is the thermal velocity, and α_{MT} and β_{MT} are correction coefficients for collision frequency and momentum transfer, respectively, given by:

$$\alpha_{\rm MT} = \frac{2}{3} [1 + \widehat{m} f_{\rm c} + \widehat{M} f_{\rm h}] \qquad \beta_{\rm MT} = [\frac{2}{\widehat{m}(1 + \widehat{m})}]^{1/2}$$
(7)

191 where \widehat{m} and \widehat{M} are molecular mass fractions of the ion and buffer gas molecule, 192 respectively, and f_c and f_h are the fractions of collisions in the cooling and heating classes, 193 respectively. Note that the reduced electric field used in this study is maximized at ~ 2 194 Td, at which the drift velocity of any given ion is \sim two orders magnitude lower than its 195 thermal velocity, thus the values for f_c and f_h are assigned to be 0.5 and 0.5, respectively. 196 As all measurements in this study were carried out with nitrogen as the buffer gas, the 197 reported collision cross sections will be referred to Ω_{N_2} . Matlab codes for calculating Ω_{N_2} are given in the Supplement. Experimental Ω_{N_2} values for a selection of ionic species are 198 199 consistent with those reported in literatures (see Table S1 in the Supplement).

200

201 **3. Collision Cross Section Modeling**

202 Kinetic theory indicates that the quantity Ω is an orientationally averaged collision integral ($\Omega_{avg}^{(l,l)}$), which depends on the nature of ion-neutral interaction potential 203 204 (McDaniel and Mason, 1973). Given the potential, the collision integral can be calculated 205 through successive integrations over collision trajectories, impact parameters and energy. 206 Here we adopt two computational methods, i.e., trajectory method and core model, to 207 simulate the average collision integral. The trajectory method is a rigorous calculation of $\Omega_{avg}^{(l,l)}$ by propagating classical trajectories of neutral molecules in a realistic neutral/ion 208 209 potential consisting of a sum of pairwise Lennard-Jones interactions and ion induced 210 dipole interactions (Mesleh et al., 1996; Shvartsburg and Jarrold, 1996). The core model 211 treats the polyatomic ion as a rigid sphere where the center of charge is displaced from 212 the geometry center. The ion-neutral interaction is approximately represented by the cross 213 section of two rigid spheres during elastic collisions. The potential during interaction 214 includes a long-range attraction term and a short-range repulsion term (Mason et al., 215 1972).

The two models employed here represent opposite directions in the $\Omega_{avg}^{(l,l)}$ computation methods. The trajectory method is a rigorous calculation of $\Omega_{avg}^{(l,l)}$ in a realistic intermolecular potential yet the computation is time consuming. The core model, on the other hand, substantially simplifies the calculation of $\Omega_{avg}^{(l,l)}$ as rigid sphere collisions at the expense of simulation accuracy. We will show shortly that the core model is used for locating individual chemical classes on the 2-D $\Omega_{N_2} - m/z$ space. Within the band developed by each chemical class, molecular structure information can be deduced by comparing the measured collision cross section with those calculated by the trajectory method.

225 3.1 Trajectory Method

Molecular structures for L-leucine and D-isoleucine were initially constructed by Avogadro v1.1.1 (Hanwell et al., 2012). For each molecule, both protonation and deprotonation sites are created by placing a positive charge on the N-terminal amino group and a negative charge on the C-terminal carboxyl group, respectively. The geometry of each ion is further optimized using the Hartree-Fock method with the 6-31G(d,p) basis set via GAMESS (Schmidt et al., 1993). Partial atomic charges were estimated using Mulliken population analysis.

A freely available software, MOBCAL, developed by Jarrold and coworkers (http://www.indiana.edu/~nano/software.html) was used for computing the collision integrals. The potential term employed in the trajectory method takes the form:

$$\Phi(\theta,\phi,\gamma,b,r) = 4\epsilon \sum_{i}^{n} \left[\left(\frac{\sigma}{r_{i}}\right)^{12} - \left(\frac{\sigma}{r_{i}}\right)^{6} \right] - \frac{\alpha_{p}}{2} \left(\frac{ze}{n}\right)^{2} \left[\left(\sum_{i}^{n} \frac{x_{i}}{r_{i}^{3}}\right)^{2} + \left(\sum_{i}^{n} \frac{y_{i}}{r_{i}^{3}}\right)^{2} + \left(\sum_{i}^{n} \frac{z_{i}}{r_{i}^{3}}\right)^{2} \right]$$
(8)

236 where θ , ϕ , and γ are three angles that define the geometry of ion-neutral collision, b is 237 the impact parameter, ϵ is the depth of the potential well, σ is the finite distance at which the interaction potential is zero, α_p is the polarizability of the neutral, which is 1.710×10^{-10} 238 ²⁴ cm³ for N₂ (Olney et al., 1997), *n* is the number of atoms in the ion, and r_i, x_i, y_i , and z_i 239 are coordinates that define the relative positions of individual atoms with respect to the 240 241 buffer gas. Values of the Lenard-Jones parameters, ϵ and σ , are taken from the universal 242 force field (Casewit et al., 1992). The ion-quadruple interaction and the orientation of N_2 243 molecule are not considered here (Kim et al., 2008; Campuzano et al., 2012).

244 3.2 Core Model

The core model, consisting of a (12-4) central potential displaced from the origin, is used to represent interactions of polyatomic ions with N₂ molecules (Mason et al., 1972). The (12-4) central potential includes a repulsive r^{-12} term, which describes the Pauli repulsion at short ranges due to overlapping electron orbitals, as well as an attractive r^{-4} term, which describes attractions at long ranges due to ion induced dipole:

$$\Phi(r) = \frac{\epsilon}{2} \left\{ \left(\frac{r_{\rm m} - a}{r - a}\right)^{12} - 3\left(\frac{r_{\rm m} - a}{r - a}\right)^4 \right\}$$
(9)

where *r* is the distance between the ion-neutral geometric centers, *a* is the location of the ionic center of charge measured from the geometrical center of the ion, and r_m is the value of *r* at the potential minimum. At temperature of 0 K, the *polarization potential* can be expressed as:

$$\Phi_{\rm pol}(r) = -\frac{e^2 \alpha_{\rm p}}{2r^4} \tag{10}$$

254

255 where α_p is the polarizability of the neutral. Thus ϵ is given by:

$$\epsilon = \frac{e^2 \alpha_{\rm p}}{3(r_{\rm m} - a)^4} \tag{11}$$

The collision cross section can be expressed in dimensionless form by extracting its dependence on $r_{\rm m}$:

$$\Omega = \Omega^{(l,l)*} \pi r_{\rm m}^2 \tag{12}$$

Tabulations of the dimensionless collision integral $(\Omega^{(l,l)^*})$ can be found in literatures (Mason et al., 1972) as a function of dimensionless temperature (T^*) and core diameter (a^*) , given by:

$$T^* = \frac{kT}{\epsilon} = \frac{3kT(r_{\rm m} - a)^4}{e^2 \alpha_{\rm p}} \qquad a^* = \frac{a}{r_{\rm m}}$$
(13)

261 Polynomial interpolation of the tabulated $\Omega^{(l,l)*}$ yielded an analytical expression of the 262 collision cross section, with r_m and a as adjustable parameters. This expression was then fit to the ion mobility datasets measured in N_2 buffer gas using a nonlinear least-square regression procedure (Matlab code is available upon request) (Johnson et al., 2004; Kim et al., 2005; Kim et al., 2008). Best-fit parameters, r_m and a, along with predicted vs. measured collision cross section are given in Table S2 in the Supplementary Information.

267

268 4. Collision Cross Section vs. Mass-to-Charge Ratio 2-D Space

269 4.1 Distribution of *multi*-Functional Organic Species

270 Figure 1 (A) shows the distribution of organic species, classified as (*di/poly/sugar*)-271 alcohol, tertiary-amine, quaternary-ammonium, (mono/di)-carbonyl, (mono/di/tri)-272 carboxylic acid, (di)-ester, organic sulfate, and multi-functional compounds, on the 273 collision cross section vs. mass-to-charge ratio $(\Omega_{N_2} - m/z)$ 2-D space. One feature of the 274 distribution pattern is that species with higher density as pure liquids and carbon oxidation state tend to occupy the lower region of the $\Omega_{N_2} - m/z$ space. This is not 275 276 surprising given that molecules of smaller collision cross sections tend to be much 277 denser, and potentially more functionalized, than those with extended and open 278 geometries. Furthermore, species of the same chemical class tend to occupy a narrow 279 region and follow a trend line on the $\Omega_{N_2} - m/z$ space. These observations form the basis of potentially utilizing locations and trends on the 2-D space to identify chemical classes 280 281 to which an unknown compound belongs.

282 Small molecules (m/z < 200) with similar size and geometry are situated closely 283 together, as visualized by the 'overlaps' on the space. Improved visual separation of the species within the overlapping region is obtained by transforming Ω_{N_2} to a quantity 284 $\Delta\Omega_{N_2},$ defined as the percentage difference between the measured collision cross section 285 286 for any given molecular ion and the calculated projection area for a rigid spherical ion-N₂ 287 pair with the same molecular mass. Since this idealized ion-N₂ pair does not account for 288 interaction potentials and molecular conformation, it is only used as a reference state to 289 improve visualization of the $\Omega_{N_2} - m/z$ 2-D space, as shown in Figure 1 (B).

290 4.2 $\Omega_{N_2} - m/z$ Trend Lines

The $\Omega_{N_2} - m/z$ trend line visualized on the 2-D space describes the intrinsic increase in collision cross sections resulting from the increase in molecular mass by extending the carbon backbone or adding functional groups. It has been used for conformation space separation of different classes of biomolecules including lipids, peptides, carbohydrates, and nucleotides (McLean et al., 2005). Here we demonstrate for the first time the presence of trend lines for small molecules of atmospheric interest, and the trend line pattern for each chemical class can be predicted by the core model simulations.

298 Figure 2 shows the measured Ω_{N_2} as a function of mass-to-charge ratio for (A) 299 tertiary-amine and quaternary-ammonium, (B) (di/poly/sugar)-alcohol, and (C) (mono/oxo/hydroxy)-carboxylic acid. Also shown are the predicted Ω_{N_2} by the core 300 model, with adjustable parameters optimized by the measured Ω_{N_2} for the subcategory 301 302 spanning the largest m/z range in each chemical class. Specifically, quaternary-303 ammonium, propylene glycol, and *alkanoic*-acid are used in constraining the core model performance to predict the $\Omega_{N_2} - m/z$ trend lines for amines, alcohols, and carboxylic 304 305 acids. Species in each chemical class, regardless of the variety in the carbon skeleton 306 structure, occupy a narrow range and appear along a $\Omega_{N_2} - m/z$ trend line. Such a relationship can be further demonstrated by the goodness of the core model predictions, 307 308 i.e., the difference between predicted and measured Ω_{N_2} for compounds that are not used to optimize the core model performance. For amine series, predicted Ω_{N_2} values for 309 lutidine and pyridine are 8.2% and 0.8% higher, respectively, than the measurements. For 310 311 alcohol series, the best-fit $\Omega_{N_2} - m/z$ trend line constrained by propylene glycol can be 312 used to predict the distribution of sugars and polyols within 3.5% difference on the space. 313 For carboxylic acid series, hydroxyl-hexadecanoic acid falls closely on the predicted 314 $\Omega_{N_2} - m/z$ trend line, despite the presence of an alcohol group on the C₁₆ carbon chain. Predicted Ω_{N_2} values for oxo-carboxylic acids are 4.4% - 6.1% lower than the 315 316 observations. Benzoic acid exhibits a relatively large measurement-prediction gap (6.7%) 317 potentially due to the presence of an aromatic ring.

The demonstrated $\Omega_{N_2} - m/z$ trend lines provide a useful tool for categorization of 318 319 structurally related compounds. Mapping out the locations and distribution patterns for 320 various functionalities on the 2-D space would therefore facilitate classification of 321 chemical classes for unknown compounds. It is likely that trend lines extracted from a 322 complex organic mixture overlap and, as a result, the distribution pattern of unknowns on 323 the space alone would not provide sufficient information on their molecular identities. In 324 this case, the fragmentation pattern of unknowns upon collision induced dissociation 325 (CID) needs to be explored for the functionality identification, as discussed in detail in 326 Section 4.4. As it is highly unlikely that two distinct molecules will produce identical 327 IMS, MS, as well as CID-based MS spectra, the 2-D framework therefore virtually 328 ensures reliable identification of species of atmospheric interest.

329 4.3 Trajectories for Atmospheric Transformation Processes

330 Functionalization (the addition of oxygen-containing functional groups) and fragmentation (the oxidative cleavage of C-C bonds) are key processes during 331 332 atmospheric transformation of organics. Reactions involving changes in functionalization and fragmentation can be represented by directionalities on the $\Omega_{N_2} - m/z$ space, as 333 illustrated by the distribution pattern of carboxylic acids in Figure 3. Addition of one 334 335 carbon atom always leads to an increase in mass and collision cross section, with a generic slope of approximately 5 $Å^2$ /Th. Although the addition of one oxygen atom in the 336 337 form of a carbonyl group results in a similar increase in the molecular mass, it leads to a 338 shallower slope compared with that from expanding the carbon chain. Addition of 339 carboxylic or hydroxyl groups does not necessarily lead to an increase in the collision cross section, as the formation of the intramolecular hydrogen bonding $(O - H \cdots O^{-})$ 340 341 could result in a more compact conformation of the molecule. In general, fragmentation 342 moves materials to the bottom left and functionalization to the right on the space.

343 4.4 Molecular Structure Elucidation of *multi*-Functional Species

The demonstrated $\Omega_{N_2} - m/z$ relationship provides a useful tool to identify the chemical class to which an unknown species belongs. To further identify its molecular structure, knowledge on the electrospray ionization mechanism for the generation of quasi-molecular ions, as well as fragmentation patterns of the molecular ion upon
 collision induced dissociation (CID), is required.

349 For species investigated in this study, their integral molecular structures are 350 maintained during electrospray ionization. An exhibition of molecular formulas of ionic 351 species is given in Table 1. Depending on the proton susceptibility of functional groups, 352 amines, esters, and aromatic aldehydes are sensitive to the ESI(+) mode, whereas 353 carboxylic acids and organic sulfates yield high signal-to-noise ratios in the ESI(-) 354 spectra. Specifically, the positive mass spectra collected for amines and amino acids 355 show major ions at m/z values corresponding to the protonated cations ($[M+H]^+$). 356 Sodiated clusters $([M+Na]^+)$ of esters were observed as the dominant peak in the ESI(+) 357 spectra. Aromatic aldehydes combine with a methyl group $([M+CH_3]^+)$ via the gas-phase 358 aldol reaction between protonated aldehydes and methanol in the positive mode. Sugars 359 and polyols can be readily ionized in both positive and negative mode with the addition 360 of a proton or sodium ion or deprotonation. Extensive formation of oligomers is observed 361 from the positive mass spectra of propylene glycol, with the deprotonated propanol (-362 $OCH_2CH(CH_3)$) as the primary building block. Monoanions ([M-H]⁻) were exclusively 363 observed in the negative mass spectra of (mono/di/tri/multi)-carboxylic acids due to the 364 facile ionization afforded by the carboxylic group. It is worth noting that quantification of 365 these species requires prior chromatographic separation to avoid matrix suppression on 366 the analyte of interest (Zhang et al., 2016) or alternative ionization scheme that is 367 compatible with the high-voltage IMS inlet and does not induce matrix effects.

368 The instrument used in this study enables the collision induced dissociation of the 369 abovementioned precursor ions after ion mobility separation but prior to the mass 370 spectrometer (IMS-CID-MS). As a consequence, product ions exhibit the identical 371 mobility (drift time) with that of the precursor ion. IMS-CID-MS spectra for individual 372 compounds are then generated by the extraction of "mobility-selected" MS spectra that 373 contain both precursor and fragments. The major advantage of this approach is that it is 374 possible to obtain fragmentation spectra for all precursor ions simultaneously. This is in 375 contrast to MS/MS techniques which require the isolation of a small mass window prior 376 to fragmentation which can be a problem for very complex samples or time-resolved 377 analysis. Figure 4 shows the measured drift time for the precursor and product ions

378 generated from species representative of amines, aldehvdes, carboxylic acids, esters, and 379 nitro compounds. Collision induced dissociation patterns of these species are used to 380 elucidate the fragmentation mechanisms for corresponding functional groups. The 381 deprotonated carboxylic acid is known to undergo facile decarboxylation to produce a 382 carbanion. If additional carboxylic groups are present in the molecule, combined loss of 383 water and carbon dioxide is expected (Grossert et al., 2005). Alternatively, the presence 384 of an –OH group adjacent to the carboxylic group would usually result in a neutral loss of 385 formic acid (Greene et al., 2013), see the fragmentation pattern for 16-386 hydroxyhexadecanoic acid as an illustration. Scission of the C-O bond in the ester 387 structure or the C-O bond between the secondary/tertiary carbon and the alcoholic 388 oxygen is observed for the ester series examined, consistent with previous studies (Zhang 389 et al., 2015). A primary fragmentation resulting in loss of CO was evident in the spectrum 390 of methylate derivative of protonated carbonyls (RCHOCH $_3^+$) (Neta et al., 2014). The 391 IMS-CID-MS spectrum of deprotonated 4-nitrophenol is shown as a representative of 392 organic nitro compounds. Two dominant peaks at m/z 108 and m/z 92 are observed, 393 resulting from the neutral loss of NO and NO₂, respectively.

394 Signal intensities of the fragments from the CID pathway of the precursor ion depend 395 on the collision voltage, as shown in Figure 5. At low collision voltages, the precursor 396 ions predominate with transmission optimized at approximately 5 V potential gradient. 397 As the collision voltage increases, the intensity of the precursor ion decreases and that of 398 each product ion increases, eventually reaching a maximum level, and then decreases due 399 to subsequent fragmentation. The dependence of the product ion abundance on the 400 collision voltage provides information on the relative strength of the covalent bond at 401 which the parent molecule fragments. Consequently, the energy required to induce a 402 certain fragmentation pathway could potentially also serve as an additional parameter for 403 structure elucidation. For example, the predominance of the product ion at m/z 149 404 suggests that cleavage of the carbonyl-oxygen bond in the ester moiety is the dominant 405 fragmentation pathway upon CID of dioctyl phthalate ($C_{24}H_{38}O_4$).

406 4.5 Resolving Isomeric Mixtures

Here we demonstrate the separation of isomers on the $\Omega_{N_2} - m/z$ space using the 407 408 mixture of L-leucine and D-isoleucine as an illustration, as they can be directly ionized 409 by electrospray in both positive and negative modes due to the presence of amino and 410 carboxyl groups. We refer the reader to Krechmer et al. (2016) for the mobility separation 411 of atmospheric relevant isomeric species. Figure 6 (A and B) shows a single peak that corresponds to the protonated ($[M+H]^+$, m/z = 132) and deprotonated ($[M-H]^-$, m/z = 132) 412 130) forms of the leucine mixture, respectively, in the positive and negative MS spectra. 413 414 Upon further separation based on their distinct mobility in the N₂ buffer gas, the leucine 415 mixture is clearly resolved in the positive mode, while a broad peak is observed in the 416 negative ion mobility spectrum, see Figure 6 (C and D). Note that a typical IMS resolving 417 power (t/dt_{50}) of 100 leads to a baseline separation of leucine isomers that differ by 0.3 418 ms in the measured drift time. Figure 6 (E-H) shows the IMS spectra for individual 419 leucine isomeric configurations, which provide precise constraints for the peak 420 assignment in the leucine mixture. Also given here are the measured vs. predicted 421 collision cross sections for each isomer, with predictions lower by $3.3 \sim 6.9\%$ compared with the measurements. However, despite the underprediction, the model using trajectory 422 423 method correctly predicts the relative collision cross sections of the isomers and therefore 424 also the order in which they appear in the IMS spectrum. The underprediction of Ω_{N_2} may result from the simplification that linear N2 molecules are considered as elastic and 425 426 specular spheres in the current model configuration (Larriba-Andaluz and Hogan Jr, 2014). Further development of the model to more appropriately predict Ω_{N_2} values is 427 428 needed.

429

430 **5.** Conclusions

We propose a new metric, collision cross section (Ω), for characterizing organic species of atmospheric interest. Collision cross section represents an effective interaction area between a charged molecule and neutral buffer gas as it travels through under the action of a weak electric field, and thus relates to the chemical structure and 3-D conformation of this molecule. The collision cross section of individual molecular ions is 436 calculated from the ion mobility measurements using an Ion Mobility Spectrometer. In 437 this study, we provide the derived Ω_{N_2} values for a series of organic species including 438 amines, alcohols, carbonyls, carboxylic acids, esters, organic sulfates, and *multi*-439 functional compounds.

440 The collision cross section, when coupled with mass-to-charge ratio, provides a 2-D 441 framework for characterizing the molecular signature of atmospheric organic components. The $\Omega_{N_2} - m/z$ space is employed to guide our fundamental understanding 442 443 of chemical transformation of organic species in the atmosphere. We show that different chemical classes tend to develop unique narrow bands with trend lines on the $\Omega_{N_2} - m/z$ 444 445 space. Trajectories associated with atmospheric transformation mechanisms either cross or follow these trend lines through the space. The demonstrated $\Omega_{\rm N_2} - m/z$ trend lines 446 provide a useful tool for resolving various functionalities in the complex organic mixture. 447 448 These intrinsic trend lines can be predicted by the core model, which provides a guide for 449 locating unknown functionalities on the $\Omega_{N_2} - m/z$ space.

450 Within each band that that belongs to a particular chemical class on the space, species 451 can be further separated based on their distinct structures and geometries. We 452 demonstrate the utility of collision induced dissociation technique, upon which the 453 resulted product ions share the identical drift time as the precursor ion, to facilitate the elucidation of molecular structures of organic species. We employ the $\Omega_{
m N_2}-m/z$ 454 framework for separation of isomeric mixtures as well by comparing the measured 455 456 collision cross sections with those predicted using the trajectory method. Further 457 advances in algorithms to correctly predict collision cross sections ab initio from 458 molecular coordinates are therefore also expected to significantly improve identification 459 of unknowns.

468 Appendix:

- a (Å): the location of the ionic center of charge from the geometrical center of the ion.
- a^* : the dimensionless core diameter.
- α_{MT} : the correction coefficient for collision frequency.
- $\alpha_{\rm p}({\rm cm}^3)$: the polarizability of the neutral.
- β_{MT} : the correction coefficient for momentum transfer.
- C_i : the instrument constant that is used to calibrate the IMS performance.
- ϵ (eV): the depth of the potential well.
- E_d (V/cm): the electric field intensity in the drift tube.
- Φ (eV): the ion-neutral interaction potential.
- f_c : the fraction of collisions in the cooling classes.
- $f_{\rm h}$: the fraction of collisions in the heating classes.
- $k_{\rm B} \,({\rm m}^2\,{\rm kg}\,{\rm s}^{-2}\,{\rm K}^{-1})$: Boltzmann constant.
- $K (\text{cm}^2 \text{ V}^{-1} \text{ s}^{-1})$: the characteristic mobility constant of a given ion.
- $K_0 (\text{cm}^2 \text{ V}^{-1} \text{ s}^{-1})$: the reduced mobility constant of a given ion.
- L_d (V/cm): the length of the drift tube.
- 484 m: the mass fraction of the ion in the ion-molecule pair.
- \widehat{M} : the mass fraction of the buffer gas molecule (N₂) in the ion-molecule pair.
- m/z (Th): the mass-to-charge ratio of any given ion.
- N_0 (# cm⁻³): the number density of buffer gas at 273 K and 1013 *mbar*.
- $\Omega(\text{\AA}^2)$: the collision cross section.
- Ω_{N_2} (Å²): the collision cross section using N₂ as the buffer gas.
- $\Omega_{avg}^{(l,l)}$: the orientationally averaged collision integral.
- $\Omega^{(l,l)*}$: the dimensionless collision integral.
- P(mbar): the pressure in the drift region.
- r (Å): the distance between the ion-neutral geometric centers.
- $r_{\rm m}$ (Å): the value of *r* at the potential minimum.

- 495 σ (Å): the finite distance at which the interaction potential is zero.
- 496 T(K): the buffer gas temperature.
- 497 T_0 (K): the standard temperature.
- 498 T^* : the dimensionless temperature.
- 499 t_a (s): the recorded arrival time of the ion clouds at the detector.
- 500 t_d (s): the time of ion clouds spent in the drift tube.
- 501 t_0 (s): the transport time of ion clouds from the exit of the drift tube to the MS detector.
- 502 v_d (s): the average velocity of an ion in the drift tube.
- 503 $v_{\rm T}$ (m s⁻¹): the thermal velocity.
- 504 $V_{\rm d}$ (V): the voltage applied to the drift tube.
- 505 *z*: the net number of integer charges on the ion.
- 506

Figure 1. Distribution of organic species including alcohol (R-(OH)_n, n = 2-8), amine (NR₃), *quaternary*-ammonium (NR₄), carbonyl (R-(C=O)_n, n = 1-2), carboxylic acid (R-(COOH)_n, n = 1-3), ester (R₁-COO-R₂), organic sulfate (R-SO₄), and *multi*-functional compounds ((OH)-R-(COOH)₂) on the (A) $\Omega_{N_2} - m/z$ space and (B) $\Delta\Omega_{N_2} - m/z$ space. Note that species that are detected in different ion modes (+/–) are plotted separately.

Figure 2. Measured collision cross sections (Ω_{N_2}) for (A) *tertiary*-amine and *quaternary*ammonium, (B) (*di/poly/sugar*)-alcohol, and (C) (*mono/oxo/hydroxy*)-carboxylic acid as a function of the mass-to-charge ratio. Also shown are the predicted $\Omega_{N_2} - m/z$ trend lines for amine, alcohol, and carboxylic acid by the core model. Here, *quaternary*ammonium, propylene glycol, and C₈-C₁₈ *alkanoic*-acid are used to optimize the adjustable parameters in the core model (The markers are in the same color as the trend lines). The colored shade in each figure represents the maximum deviations (8.21%, 3.54%, and 6.69% for amine, alcohol, and carboxylic acid, respectively) of the predicted Ω_{N_2} from the measured Ω_{N_2} for species that are not used to constrain the core model. A single plot showing the separation of these three chemical classes is given in Figure S5 in the supplement.

Figure 3. Trajectories associated with reactions involving functionalization (changes in the type and number of functional groups) and fragmentation (changes in the carbon chain length) through the 2-D $\Omega_{N_2} - m/z$ space using carboxylic acid series as an illustration.

Figure 4. Collision induced dissociation patterns for molecular ions generated from cinnamaldehyde, dioctyl phthalate, 2,6-di-tert-butylpyridine, 4-nitrophenol, 16-hydroxyhexadecanoic acid, and sebacic acid on the 2-D framework with mass-to-charge ratio on the *x*-axis and drift time on the *y*-axis. The corresponding mobility selected MS spectra for each species is given in Figure S6 in the supplement.

Figure 5. Product ion peak intensities as a function of collision voltage in the 'mobility-selected' MS spectra of (A) deprotonated sebacic acid, (B) deprotonated 16-hydroxyhexadecanoic acid, (C) sodiated dioctyl phthalate, and (D) deprotonated 4-nitrophenol.

Figure 6. (A/B) ESI mass spectra collected for an equi-molar mixture (20 μ M each) of Lleucine and D-isoleucine in positive and negative mode. (C/D) Measured drift time distributions for the leucine mixture in positive and negative mode. (E/F) Measured vs. predicted Ω_{N_2} for D-isoleucine, together with its drift time distributions in positive and negative mode. (G/H) Measured vs. predicted Ω_{N_2} for L-leucine, together with its drift time distributions in positive and negative mode. Note that all measurements were performed at ~ 303 K and ~ 1019 *mbar* with an electric field strength of 414 and 403 V cm⁻¹ in the positive and negative mode, respectively.
