12 **Abstract:** Chemical ionization (CI) mass spectrometers are used to study atmospheric nucleation by detecting clusters
13 produced by reactions of sulfuric acid and various basic gases. These instruments typically use nitrate to deprotonate
14 and thus chemically ionize the clusters. In this study, we compare cluster concentrations measured using either nitrate
15 or acetate. Clusters were formed in a flow reactor from vapors of sulfuric acid and dimethylamine, ethylene diamine,
16 tetramethylethylene diamine, or butanediamine (also known as putrescine). These comparisons show that nitrate is
17 unable to chemically ionize clusters with high base content. In addition, we vary the ion-molecule reaction time to
18 probe ion processes which include proton-transfer, ion-molecule clustering, and decomposition of ions. Ion
19 decomposition upon deprotonation by acetate/nitrate was observed. More studies are needed to quantify to what extent
20 ion decomposition affects observed cluster content and concentrations, especially those chemically ionized with
21 acetate since it deprotonates more types of clusters than nitrate.

22 Model calculations of the neutral and ion cluster formation pathways are also presented to better identify the
23 cluster types that are not efficiently deprotonated by nitrate. Comparison of model and measured clusters indicate that
24 sulfuric acid dimer with two diamines and sulfuric acid trimer with two or more base molecules are not efficiently
25 chemical ionized by nitrate. We conclude that acetate CI provides better information on cluster abundancies and their
26 base content than nitrate CI.

27 **Introduction:**

28 Atmospheric nucleation is an important source of global atmospheric particles (IPCC, 2014). In the
29 atmospheric boundary layer, sulfuric acid often participates in nucleation (Weber et al., 1996;Kuang et al.,
30 2008;Kulmala et al., 2004;Riipinen et al., 2007) by reacting with other trace compounds to produce stable, electrically
31 neutral molecular clusters; these compounds include ammonia (Kirkby et al., 2011;Coffman and Hegg, 1995;Ball et
32 al., 1999), amines (Almeida et al., 2013;Zhao et al., 2011;Glasoe et al., 2015), water (Leopold, 2011), and oxidized
33 organics (Schobesberger et al., 2013). The primary instruments used for detecting freshly nucleated, sulfuric acid-
34 containing clusters are atmospheric pressure chemical ionization mass spectrometers (CIMS) such as the Cluster
35 CIMS (Zhao et al., 2010;Chen et al., 2012) and the CI atmospheric pressure interface-time of flight mass spectrometer
36 (CI-APi-ToF) (Jokinen et al., 2012). Both mass spectrometers use nitrate to chemically ionize neutral sulfuric acid
37 clusters. Depending upon conditions, NO_3^- core ions generally have one or more HNO_3 and possibly several H_2O
38 ligands The signal ratio of the ion cluster to the reagent ion translates to the neutral cluster concentration (Berresheim
39 et al., 2000;Hanson and Eisele, 2002;Eisele and Hanson, 2000).

40 The amounts and types of ions detected by the mass spectrometer are affected by four key processes: the
41 abundance of neutral clusters, their ability to be chemically ionized, product ion decomposition, and clustering
42 reactions of the product ions (ion-induced clustering, IIC). The first process, neutral cluster formation, follows a
43 sequence of acid-base reactions (Chen et al., 2012;Jen et al., 2014;Almeida et al., 2013;McGrath et al., 2012) whereby
44 sulfuric acid vapor and its subsequent clusters react with basic molecules to produce clusters that are more stable than

47 aqueous sulfuric acid clusters. The concentration of a specific cluster type depends on its stability (i.e. evaporation
48 rates of the neutral cluster) and the concentrations of precursor vapors (i.e. the formation rate).

49 Neutral clusters then need to be ionized to be detected with a mass spectrometer. In most prior work, this has
50 been accomplished by chemical ionization with the nitrate ion whereby the neutral clusters are exposed to nitrate for
51 a set amount of time known as the chemical ionization reaction time (or ion-molecule reaction time). Chemical
52 ionization (CI) can be conceptualized as another acid-base reaction where an acid (sulfuric acid) donates a proton to
53 the basic reagent ion (nitrate, the conjugate base of nitric acid). To illustrate, the CI reaction of an aminated sulfuric
54 acid dimer, $(H_2SO_4)_2 \bullet DMA \bullet (H_2O)_x$, is shown in Reaction 1.

55 This dimer of sulfuric acid contains a dimethylamine (DMA) molecule and x water molecules. At room temperature,
56 water molecules evaporate upon ionization or entering the vacuum region and are assumed to not significantly affect
57 chemical ionization rates. The forward rate constant, k_2 , is assumed to be the collisional rate coefficient of 1.9×10^{-9}
58 $\text{cm}^3 \text{s}^{-1}$ (Su and Bowers, 1973), while the reverse rate constant is zero.

59 Reaction 1 can be extended to CI reactions for larger neutral clusters of sulfuric acid, with the assumption
60 that every collision between nitrate and a sulfuric acid cluster results in an ionized cluster. However, Hanson and
61 Eisele (2002) presented evidence that some clusters of sulfuric acid and ammonia were not amenable to ionization by
62 $(HNO_3)_{1-2} \bullet NO_3^-$. Acetate CI has been used previously to detect organic acids less acidic than sulfuric acid in the
63 atmosphere, providing evidence that its higher proton affinity could chemically ionize more basic clusters (Veres et
64 al., 2008). Subsequently, Jen et al. (2015) showed that CI with $(HNO_3)_{1-2} \bullet NO_3^-$ leads to significantly lower neutral
65 concentrations of clusters with 3 or more sulfuric acid molecules and varying numbers of DMA molecules compared
66 to results using acetate reagent ions. Furthermore, neutral cluster concentrations detected using acetate CI are in overall
67 better agreement with values measured using a diethylene glycol mobility particle sizer (DEG MPS). As no other
68 experimental conditions changed except the CI reagent ion, we hypothesized that nitrate's lower proton affinity than
69 that of acetate renders it less able to chemically ionize clusters that contain nearly equal amounts of sulfuric acid and
70 base. Poor CI efficiency reduces the amount and types of ions detected by the mass spectrometer.

71 After neutral clusters are ionized, the resulting ion may decompose. Experimental studies have shown ion
72 decomposition in the ammonia-sulfuric acid system at 275 K (Hanson and Eisele, 2002), and computational chemistry
73 studies present evaporation rates of ion clusters of sulfuric acid with various bases on the order of the CI reaction time
74 used here (Kurtén et al., 2011; Lovejoy and Curtius, 2001; Ortega et al., 2014). For example, these studies predict an
75 evaporation rate, E_d (Reaction 2), of DMA from a sulfuric acid dimer ion with 1 DMA molecule of $\sim 100 \text{ s}^{-1}$ at 298 K
76 (Ortega et al., 2014).

77 Experimental observations at room temperatures have never seen the aminated sulfuric acid dimer ion, even at CI
78 reaction times as short as a few ms. Thus, the decomposition rate is likely even faster than the computed value of ~ 100
79 s^{-1} at 298 K (Ortega et al., 2014).

80 Ion clusters can also be produced by ion-induced clustering (IIC) whereby the bisulfate ion (HSO_4^-), formed
81 by CI of sulfuric acid monomer, further reacts with H_2SO_4 (with ligands) and larger clusters. Charged clusters can also
82 cluster with neutrals to form larger ion clusters. The signal due to these IIC products must be subtracted from the
83 observed signals to determine neutral cluster concentrations. Specifically, the sulfuric dimer ion can be formed via the
84 IIC pathway given in Reaction 3, with ligands not shown.

85 The forward rate constant, k_{21} , is the collisional rate constant of $2 \times 10^{-9} \text{ cm}^3 \text{s}^{-1}$ because this reaction involves switching
86 ligands between the two clusters. Both reactants also contain water, nitrate, and/or base ligands that detach during

87 measurement. IIC-produced dimer signal interferes with the CI detected neutral dimer but can be calculated from
88 measured sulfuric acid vapor concentrations and CI reaction times (Chen et al., 2012; Hanson and Eisele, 2002).

89 IIC can also produce larger clusters, but in general its contribution is less than for the dimer, even if all rates
90 are assumed to be collisional. Furthermore, bisulfate may not efficiently cluster with chemically neutralized sulfate
91 salt clusters formed by reactions of sulfuric acid and basic compounds. If so, assuming the collisional rate constant
92 for all IIC-type reactions would lead to an over-correction of the neutral cluster concentrations.

93 Measured CIMS signals reflect the combined influences of all these processes, with each occurring on time
94 scales that depend on the chemistry, experimental parameters, and techniques. Assuming a process is either dominant
95 or negligible can lead to large errors in reported neutral cluster compositions and concentrations. Here, neutral cluster
96 formation, chemical ionization, IIC, and ion decomposition are examined experimentally and theoretically to
97 determine the influence of each process on the abundance of ion clusters composed of sulfuric acid and various bases.
98 These bases include DMA, ethylene diamine (EDA), trimethylethylene diamine (TMEDA), and butanediamine (also
99 known as putrescine, Put). The diamines, recently implicated in atmospheric nucleation, react with sulfuric acid vapors
100 to very effectively produce particles compared to monoamines (Jen et al., 2016). We present observations that 1) show
101 a clear difference between acetate and nitrate CI for all clusters larger than the sulfuric acid dimer with any of the
102 bases, 2) provide evidence of ion decomposition, and (3) identify specific bases that influence the detectability of the
103 dimer neutral clusters. Also presented are modeling results that help elucidate specific processes that influence
104 measurement: neutral cluster formation pathways, cluster types that do not undergo nitrate CI, and clusters that are
105 formed by IIC.

106 **Method:**

107 Sulfuric acid clusters containing either DMA, EDA, TMEDA, or Put were produced in a flow reactor that
108 allows for highly repeatable observations (see Jen et al. (2014) and Glasoe et al. (2015)). Glasoe et al. (2015) showed
109 that the system has a high cleanliness level: 1 ppqv level or below for amines. Each amine was injected into the flow
110 reactor at a point to yield ~3 s reaction time between the amine and sulfuric acid (see Jen et al. (2014) for a schematic).
111 The initial sulfuric acid concentration ($[A_1]_0$) before reaction with basic gas was controlled at specified concentrations.
112 The base concentration, [B], was measured by the Cluster CIMS in positive ion mode (see SI of Jen et al. (2014) for
113 further details) and confirmed with calculated concentrations (Zollner et al., 2012; Freshour et al., 2014). The dilute
114 amines were produced by passing clean nitrogen gas over either a permeation tube (for DMA and EDA) or a liquid
115 reservoir (TMEDA and Put), and further diluted in a process described in Zollner et al. (2012). The temperature of the
116 flow reactor was held constant throughout an experiment but varied day-to-day from 296–303 K to match room
117 temperature. This was done to minimize thermal convection which induces swirling near the Cluster CIMS sampling
118 region. The relative humidity was maintained at ~30%, and measurements were done at ambient pressure (~0.97 atm).
119 Total reactor N₂ flow rate was 4.0 L/min at standard conditions of 273 K and 1 atm.

120 Two types of experiments were conducted: one set where specific base, base concentration ([B]), and $[A_1]_0$
121 were varied at constant CI reaction time (similar to those in Jen et al. (2014)), and the second set where CI reaction
122 time was varied for a subset of reactant conditions (see Hanson and Eisele (2002) and Zhao et al. (2010)). The resulting
123 concentrations were measured with the Cluster CIMS using either nitrate or acetate as the CI reagent ion. Nitrate and
124 acetate were produced either by passing nitric acid or acetic anhydride vapor over Po-210 sources. Separate Po-210
125 sources and gas lines were used for the acetate and nitrate to avoid cross-contamination. The measured reagent ions
126 for nitrate CI was $(HNO_3)_{1-2} \cdot NO_3^-$, and the reagent ions for acetate CI were $H_2O \cdot CH_3CO_2^-$, $CH_3CO_2H \cdot CH_3CO_2^-$, and
127 $CH_3CO_2^-$ (in order of abundance). The nitrate dimer and trimer are assumed to chemically ionize at equal rate
128 constants, and the three acetate ions are assumed to chemically ionize in identical manners. The inferred neutral cluster
129 concentrations were calculated from the CI reaction time, measured and extrapolated mass-dependent sensitivity (see
130 Supporting Information), and the assumed collisional rate constant between CI ion and sulfuric acid clusters (see Jen
131 et al. (2014) and (2015) for a discussion on the data inversion process). The CI reaction time, t_{CI} , was determined from
132 the inlet dimensions and electric field strength inside the sampling region; for this set of experiments, t_{CI} was fixed at
133 18 ms for nitrate and 15 ms for acetate.

134 Varying t_{CI} at fixed [B] and $[A_1]_0$ was achieved by changing the electric field used to draw ions across the
135 sample flow into the inlet. Similar experiments have been performed with other atmospheric pressure, CI mass
136 spectrometer inlets (Hanson and Eisele, 2002; Zhao et al., 2010; Chen et al., 2012) with the detailed mathematical
137 relationship between t_{CI} and ion signal ratios developed more in depth in the following sections and the SI.

138 **Acetate vs. Nitrate Comparison:**

139 Figure 1 (a and c) compare inferred cluster concentrations derived from measured signals (assuming the
140 collisional rate constant, k_c , and no ion breakup) using acetate (red squares) and nitrate (black triangles) reagent ions
141 at a constant $[A_1]_0 \sim 4 \times 10^9 \text{ cm}^{-3}$ for two different [DMA]. The grouped points represent clusters that contain equivalent
142 number of sulfuric acid molecules (N_1 is the monomer, N_2 is the dimer, etc.) but with different number of DMA
143 molecules (e.g., $A_4^- \bullet \text{DMA}_{0-3}$ where A is sulfuric acid). The number of base molecules in each cluster is given by the
144 grouping bracket. Since the tetramers and pentamers have similar mass ranges, N_4 clusters are given as half-filled
145 symbols and N_5 clusters as outlined symbols. Note, N_1 is detected at different masses between the two reagent ions,
146 with nitrate at 160 amu = $\text{HSO}_4^- \bullet \text{HNO}_3$ and acetate at 97 amu = HSO_4^- . The total cluster concentrations, $[N_m]$, compared
147 between the two CI ions are shown in Figure 1 (b and d). The notation used here differs slightly from Jen et al. (2014)
148 such that $[N_m]$ denotes the total concentration for clusters that contain m sulfuric acids molecules (i.e.,
149 $[N_m] = [A_m] + [A_m \bullet B_1] + [A_m \bullet B_2] \dots$) and $A_m \bullet B_j$ represents a specific cluster type with m sulfuric acid molecules and j
150 basic molecules (B). The measured $[N_1]$ and $[N_2]$ obtained using nitrate and acetate are in good agreement for DMA.
151 In the set of bases studied in Jen et al. (2014) (ammonia, methylamine, DMA, and trimethylamine), DMA is the
152 strongest clustering agent, and these results reaffirm the accuracy of previously reported values of $[N_1]$ and $[N_2]$ in
153 Jen (2014) at high $[A_1]_0$.

154 Figures 2, 3, and 4 show the acetate and nitrate comparison for EDA, TMEDA, and Put, respectively.
155 Although nitrate appears to consistently detect less $[N_1]$ than with acetate, the estimated systematic uncertainty on
156 acetate detected $[N_1]$ is higher than with nitrate due to higher background signals detected by acetate, sensitivity for
157 the low masses (see SI), and possible influence of diamines on the ion throughput in the mass spectrometer. Other
158 factors that may influence the detected $[N_1]$ are discussed in the SI. The true acetate $[N_1]$ could be up to a factor of 5
159 lower. Therefore, for monomer clusters formed from diamines, it is difficult to conclude that acetate and nitrate lead
160 to significant differences in measured $[N_1]$.

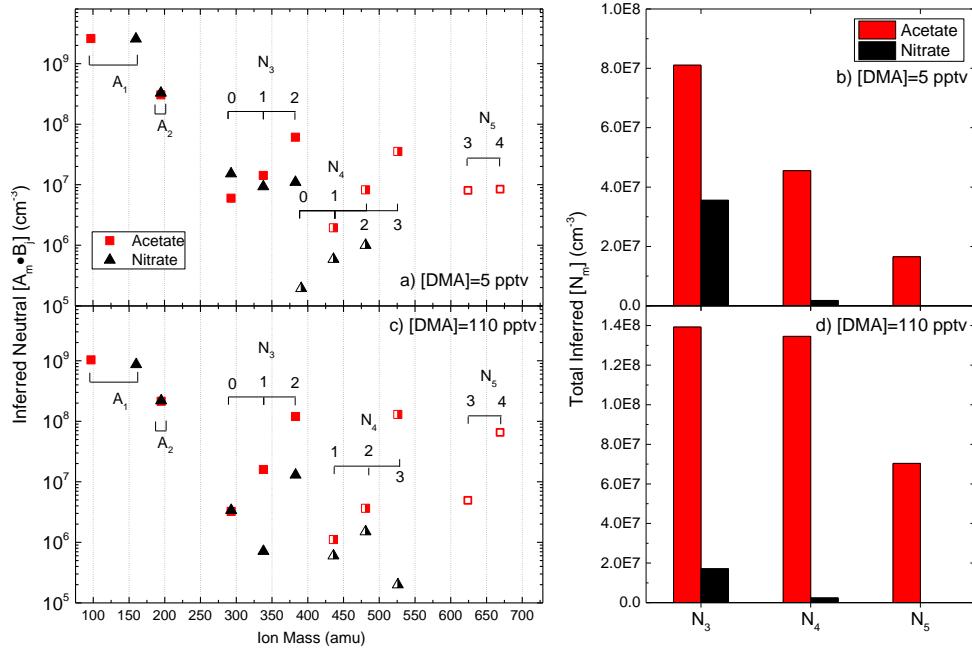

161 Unlike the other bases, Put was observed in the monomer using either nitrate or acetate CI (Figure 4). The
162 presence of $A_1 \bullet \text{Put}$ indicates its binding energy must be higher than monomers containing the other bases. However,
163 this ion still decomposes in roughly the $t_{CI} = 15 \text{ ms}$ as it is $\sim 0.1\%$ of $[N_1]$. Elm et al. (2016) has shown that the binding
164 energy of $A_1 \bullet \text{EDA}$ is -11.1 kcal/mol and $A_1 \bullet \text{Put}$ is -15.4 kcal/mol , with $A_1 \bullet \text{DMA}$ closely matching $A_1 \bullet \text{EDA}$ at -11.38
165 kcal/mol (Nadykto et al., 2014; Bork et al., 2014). The higher neutral binding energies of $A_1 \bullet \text{Put}$ may translate to
166 stronger ion binding energies than the other aminated monomers, though more studies are needed to confirm this.
167 Both acetate and nitrate primarily detect the bare dimer, with $[N_2]$ up to a factor of 5 higher with acetate CI than
168 nitrate. The systematic uncertainties of the acetate measurement are due to similar reasons as those for $[N_1]$ and could
169 lead to a factor of 2-3 times lower $[N_2]$ than reported here. These comparisons suggest that for clusters formed from
170 diamines, nitrate does not detect as many types of N_2 as does acetate; however, the large uncertainty in acetate $[N_2]$
171 prevents a definitive conclusion as to whether or not nitrate chemically ionizes all types of dimers. More information
172 is gained from experiments that vary t_{CI} as they are more sensitive to the various formation pathways. These results
173 are presented in the subsequent sections.

174 Figures 1 through 4 (b and d) clearly show that more of the larger clusters (N_3 and higher) were detected by
175 acetate CI than nitrate. For all bases, the measured $[N_3]$ by acetate is 2 to 100 times higher than concentrations
176 measured by nitrate CI. Nitrate detected small amounts of N_4 and no N_5 , likely due to the ionizable fraction of $[N_4]$
177 and $[N_5]$ falling below detection limits ($< 10^5 \text{ cm}^{-3}$). In addition as [B] increases, the differences between acetate and
178 nitrate cluster concentrations become more pronounced. This likely occurs because sulfuric acid clusters become more

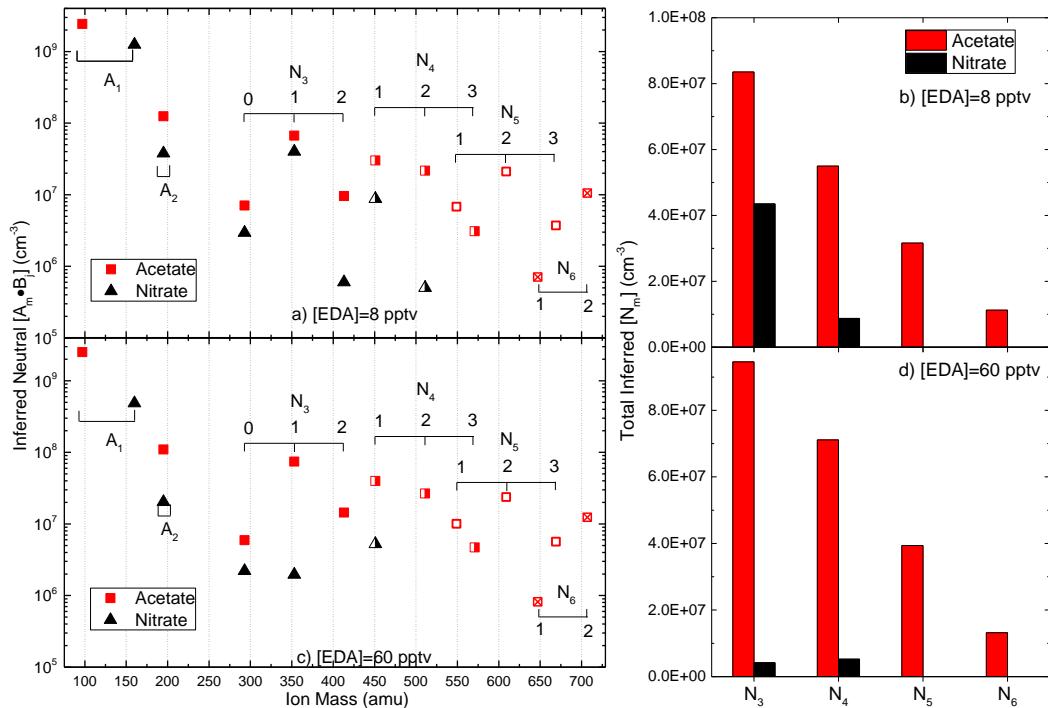

179 chemically neutral as [B] increases, thereby decreasing their tendencies to donate protons to nitrate ions. The
 180 differences between acetate and nitrate measured cluster concentrations cannot be explained only by the larger
 181 uncertainties in the acetate measurements. The systematic uncertainties in acetate detected larger clusters is at most a
 182 factor of 2 below reported concentrations. Thus, acetate is more efficient than nitrate at chemically ionizing the larger
 183 cluster population.

184 The large differences between nitrate and acetate measured $[N_3]$ and $[N_4]$ provide information to better
 185 understand recent atmospheric and chamber measurements. Chen et al. (2012) and Jiang et al. (2011) published $[N_3]$
 186 and $[N_4]$ measured in the atmosphere using a larger version of the Cluster CIMS (Zhao et al., 2010). For both studies,
 187 the measurements were conducted using nitrate CI and only at the clusters' bare masses (A_3 and A_4). Trimer and
 188 tetramer may have been under-detected, though this is uncertain because the atmosphere contains numerous
 189 compounds that may behave differently than DMA and diamines. If the actual concentrations of trimer and tetramer
 190 were higher than those reported by Jiang et al. (2011), then the fitted evaporation rate of $E_3=0.4\pm0.3\text{ s}^{-1}$ from Chen et
 191 al. (2012) is too high and the true value would be closer to 0 s^{-1} (collision-controlled or kinetic limit) that was reported
 192 by Kürten et al. (2014) at 278 K. In addition, Kürten et al. measured $[N_3]$ and $[N_4]$ about a factor of 10 lower than the
 193 collision-controlled limit. They attribute this discrepancy to decreased sensitivity for the larger ions, but it could also
 194 be due to inefficient CI by nitrate.

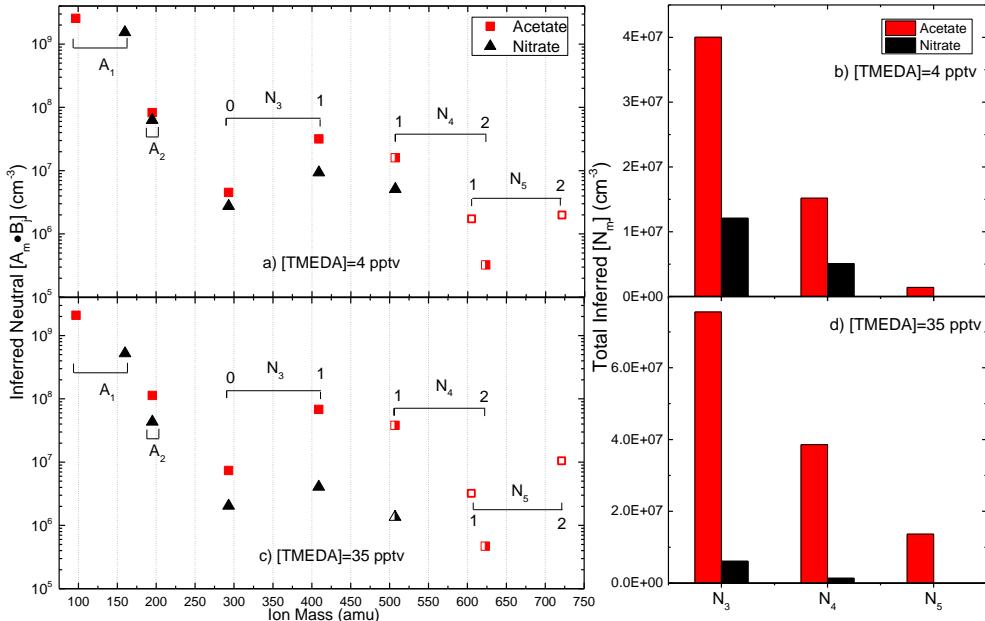

195 Comparing our results to the CLOUD experiments, the amount of clusters detected via nitrate CI using the
 196 Cluster CIMS differ from those detected by nitrate using the CI-APi-ToF (Kürten et al., 2014). They observed more
 197 ion clusters that contained nearly equal number of sulfuric acid and DMA molecules (e.g., $A_3\bullet DMA_2$). Our
 198 experiments suggest that such highly neutralized clusters are not efficiently ionized by our nitrate core ions. We do
 199 not fully understand this difference but longer acid-base reaction times, the amount of ligands on the nitrate core ions,
 200 various inlet designs (e.g., corona discharge vs. our Po-210 or high vs. our low flow rates), temperature (278 K
 201 compared to our 300 K), and ion breakup upon sampling may all play a role.

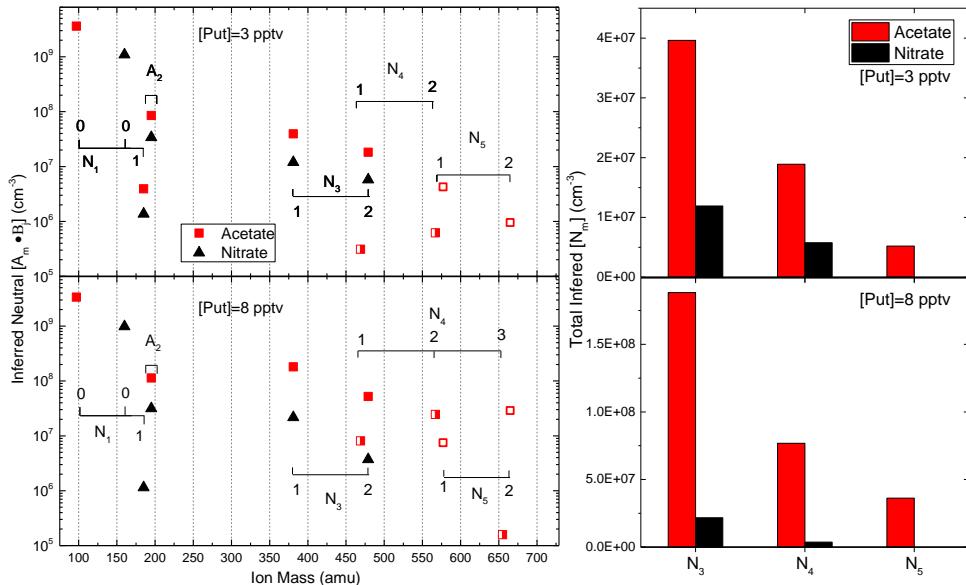

202
 203 **Figure 1 (a and c) Comparison of specific cluster concentrations ($[A_m \bullet B_j]$) using acetate (red squares) and nitrate (black
 204 triangles) reagent ions at two different [DMA] and constant initial sulfuric acid concentration, $[A_1]_0 \sim 4 \times 10^9 \text{ cm}^{-3}$. Each cluster
 205 species is shown at its ion mass. The brackets represent the number of DMA molecules in a cluster with a given number of
 206 sulfuric acid. The half-filled symbols show the tetramers and the outlined symbols are the pentamers. Bar graphs b and d
 207 compare total cluster concentration of a given size ($[N_m]$) between acetate (red) and nitrate (black) for the same [DMA] and
 208 $[A_1]_0$ as a and b respectively.**

 225 triangles) reagent ions at two different $[Put]$ and constant initial sulfuric acid concentration, $[A_1]_0 \sim 4 \times 10^9 \text{ cm}^{-3}$. Each cluster
 226 species is shown at its ion mass. The brackets represent the number of Put molecules in a cluster with a given number of
 227 sulfuric acid. The half-filled symbols show the tetramers and outlined symbols as the pentamers. Bar graphs b and d
 228 compare total cluster concentration of a given size ($[N_m]$) between acetate (red) and nitrate (black) for the same $[Put]$ and
 229 $[A_1]_0$ as a and b respectively.**

230 Chemical ionization efficiency clearly plays a role in both the types and amounts of clusters that can be
 231 detected. However, the concentrations in Figures 1 through 4 were calculated by assuming negligible contributions of
 232 IIC and ion decomposition. The validity of these assumptions was tested by examining the ion behavior with CI
 233 reaction time (t_{CI}) for a variety of bases. Presented in the following sections are ion signal variations with t_{CI} and a
 234 discussion of possible scenarios that explain these observations. To help understand these measurements, we
 235 developed a model to describe these complex series of reactions that govern neutral cluster formation, chemical
 236 ionization, IIC, and ion decomposition. The model combines two box models: one for neutral cluster formation and
 237 one for the ion processes. When compared to observations, the model was useful in identifying the controlling process
 238 for the monomer and dimer but, due to the numerous reactions, only provided general scenarios to explain observations
 239 for the larger clusters.

240 **Monomer, N_1 :**

241 Over the 3 s neutral reaction time in this flow reactor (i.e., the reaction time between neutral sulfuric acid
 242 vapor and the basic gas), initial monomer concentration ($[N_1]$) is depleted as it forms larger clusters/particles and is
 243 lost to walls; N_1 may re-enter the gas phase by evaporation of larger clusters. Two types of N_1 may have significant
 244 abundances in the sulfuric acid and DMA system: A_1 and $A_1 \cdot \text{DMA}$. One computational chemistry study predicts the
 245 latter has an evaporation rate of 10^{-2} s^{-1} (all computed rates at 298 K unless otherwise stated) (Ortega et al., 2012) with
 246 others suggesting an evaporation rate closer to 10 s^{-1} (Nadykto et al., 2014; Bork et al., 2014).

247 Following the neutral clustering reactions, the remaining monomer is readily chemically ionized and the
 248 product ion can decompose and undergo IIC with the monomer or clusters. For example, the decomposition rate of
 249 $A_1 \cdot \text{DMA}$ is predicted to be 10^9 s^{-1} (Ortega et al., 2014). Therefore, whether or not $A_1 \cdot \text{DMA}$ is a significant fraction of the
 250 total monomer concentration, A_1^- is the only ion with significant abundance. This agrees with our experimental
 251 observations.

252 Neutral $[N_1]$ can be estimated from mass spectrometry signals because there is negligible ion breakup in the
253 Cluster CIMS that leads to A_1^- . As discussed above, a number of experiments and the current results have shown this
254 to be the case (Hanson and Eisele, 2002; Eisele and Hanson, 2000; Lovejoy and Bianco, 2000). The signal ratio of the
255 sulfuric acid monomer at 160 amu for nitrate (S_{160}) to the nitrate ion at 125 amu (S_{125}) can be converted to neutral $[N_1]$
256 following Equation 1 (Eisele and Hanson, 2000), where t_{CI} is the CI reaction time.

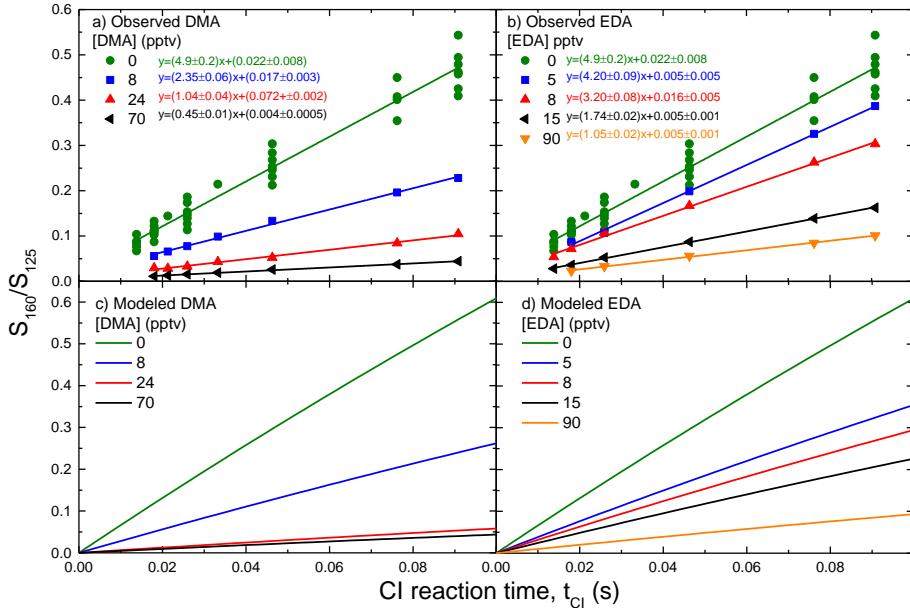

$$\frac{S_{160}}{S_{125}} = k_1 [N_1] t_{CI} \quad \text{Equation 1}$$

257 For $N_1 + HNO_3 \cdot NO_3^-$, $k_1 = 1.9 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ (Viggiano et al., 1997) which is assumed to not depend on whether water or
258 bases are attached onto the monomer. Equation 1 was derived for short t_{CI} where reagent ion and neutral N_1 are not
259 depleted. These assumptions are tenuous at long t_{CI} ; however, the rigorous analytical solution to the population
260 balance equations (derived in the SI and given in Equation S6) shows that Equation 1 is a good approximation: at
261 $t_{CI}=15$ or 18 ms, the differences between Equation 1 and Equation S6 are $\sim 1\%$.

262 Figure 5 (a and b) shows the signal ratios as a function of t_{CI} for DMA and EDA as detected by nitrate CI at
263 equivalent $[A_1]_0 = 4 \times 10^9 \text{ cm}^{-3}$. TMEDA and Put graphs look very similar to EDA (see SI). The green points shown in
264 this figure and subsequent figures provide measurements at base concentration of 0 pptv from eight different days and
265 offer a useful guide for the measurement uncertainty. For all base concentrations as t_{CI} increases, more $[N_1]$ is
266 chemically ionized, leading to higher S_{160}/S_{125} . As $[B]$ increases, the signal ratios and therefore the slopes of the lines
267 decrease. This indicates that $[N_1]$ is depleted during the 3 s neutral reaction time via uptake into large clusters that
268 increase with $[B]$.

269 The model, as mentioned above, was used to interpret the results presented in Figure 5 and subsequent graphs.
270 The neutral cluster concentrations after $[A_1]_0$ and $[B]$ react over the 3 s neutral reaction time are modeled first. This
271 portion of the model also takes into account base dilution from its injection point in the flow reactor (see Jen et al.
272 (2014)), wall loss, and particle coagulation. However, the model does not take into account possible dilution of N_1 by
273 the base addition flow which may affect measured $[N_1]$ as explained in the SI. The neutral model is then coupled to
274 the ion model which simulates chemical ionization and IIC. Ion decomposition is implicitly included by assuming
275 certain cluster types instantly decompose into the observed ion.

276 For the monomer, the model has identical neutral cluster formation pathways for all sulfuric acid and base
277 systems. The acetate vs. nitrate comparison suggests that monomers containing various bases are chemically ionized
278 similarly, with a slight possibility that nitrate may not chemically ionize sulfuric acid monomers that contain a diamine.
279 The modeled reactions pertaining to the monomer are given in Table 1, where k_c is $2 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$. The full list of
280 modeled reactions, including loss of monomer to form larger clusters, is given in the SI.

281

282 **Figure 5** Measured (a,b) and modeled (c, d) sulfuric acid monomer to nitrate signal ratio (S_{160}/S_{125}) as a function of CI
 283 reaction time for DMA (a, c) and EDA (b, d). The measurements were conducted with nitrate as the reagent ion and at
 284 $[A_1]_0 \sim 4 \times 10^9 \text{ cm}^{-3}$. Each color represents a different [B] with the linear regressions for the measurements given in colored
 285 text.

286

Table 1 Summary of possible pathways for neutral monomer formation and chemical ionization

Neutral formation	Nitrate CI and ion decomposition
<u>DMA and Diamines:</u> $A_1 + B \xrightleftharpoons[E_1]{k} A \bullet B$	<u>DMA:</u> $A_1 + NO_3^- \xrightarrow{k_c} HNO_3 \bullet A_1^-$ $A_1 \bullet B + NO_3^- \xrightarrow{k_c} HNO_3 \bullet A_1^- \bullet B$ $HNO_3 \bullet A_1^- \bullet B \xrightarrow{\text{fast}} HNO_3 \bullet A_1^- + B$ <u>Diamines:</u> $A_1 + NO_3^- \xrightarrow{k_c} HNO_3 \bullet A_1^-$ $A_1 \bullet B + NO_3^- \xrightarrow{?} HNO_3 \bullet A_1^- \bullet B$ $HNO_3 \bullet A_1^- \bullet B \rightarrow HNO_3 \bullet A_1^- + B$

287 Figure 5 (c and d) displays the modeled results for DMA and EDA at the same [B] and $[A_1]_0$ as the
 288 measurements presented in panels a and b. The model predicts the linear dependence of S_{160}/S_{125} on t_{CI} as seen in
 289 Equation 1. In addition, the predicted values of S_{160}/S_{125} and their dependence on [B] are in good qualitative agreement
 290 with observations. Including or excluding nitrate CI of $A_1 \bullet$ diamine has little effect on S_{160}/S_{125} because [B] is typically
 291 less than $[A_1]_0$ in these experiments. As a result, the majority of monomers will remain as A_1 even if the evaporation
 292 rate of the $A_1 \bullet B$ (E_1) is very small. Further experiments that quantify the fraction of $A_1 \bullet$ diamine in N_1 are needed to
 293 definitely conclude the efficacy of nitrate in chemically ionizing all N_1 .

294

Dimer, N_2 :

295 Neutral dimers (N_2) largely form by collision of the two types of monomers (A_1 and $A_1 \bullet B$) and, to a much
 296 lesser extent, decomposition of larger clusters. For sulfuric acid+DMA, the N_2 likely exists as $A_2 \bullet DMA$ and $A_2 \bullet DMA_2$,

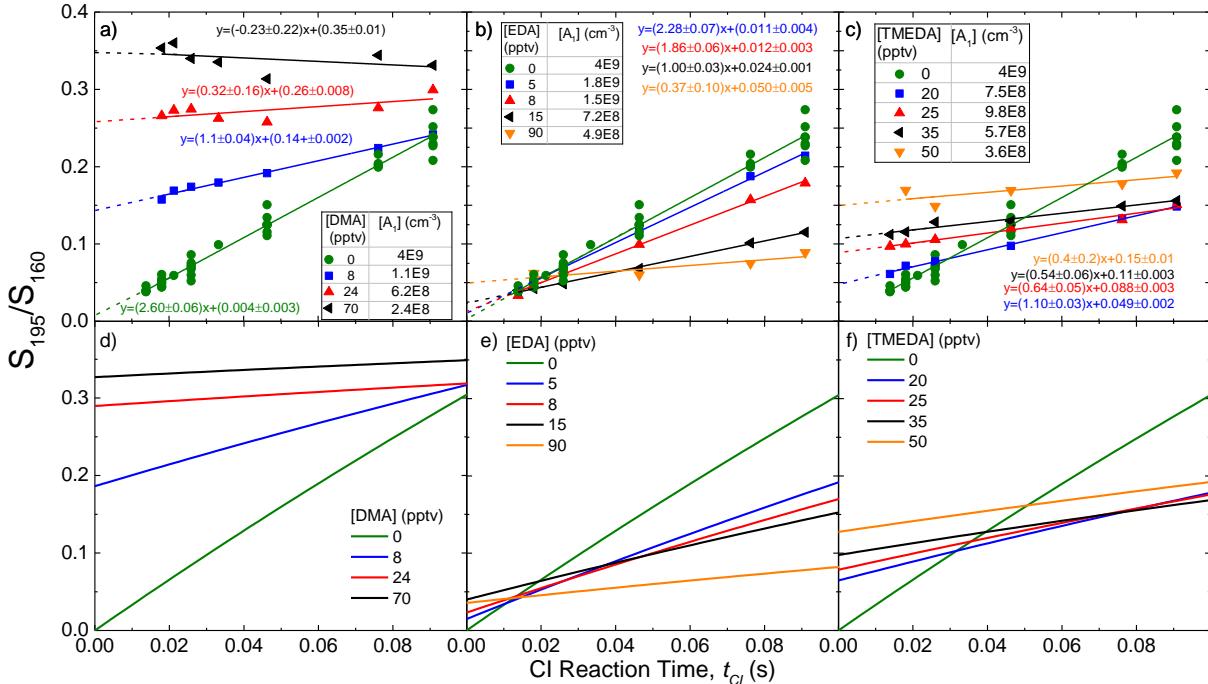

297 with both clusters predicted to have low evaporation rates of $\sim 10^{-5}$ s $^{-1}$ (Ortega et al., 2012) with another study
 298 suggesting a higher evaporation rate of $\text{A}_2\text{-DMA}_2 \sim 10^4$ times higher (Leverentz et al., 2013). Chemically ionizing
 299 these dimers results in ions that undergo IIC and ion decomposition. Computational chemistry predicts that $\text{A}_2^{\cdot}\text{-DMA}_2$
 300 and $\text{A}_2^{\cdot}\text{-DMA}$ have DMA evaporation rates of 10^8 s $^{-1}$ and 10^2 s $^{-1}$, respectively (Ortega et al., 2014). However, the
 301 computed evaporation rate of $\text{A}_2^{\cdot}\text{-DMA}$ may be too low because during the 18 ms CI reaction time used here, all N_2
 302 are detected as A_2^{\cdot} (195 amu). Similarly, the diamine molecule is lost from $\text{A}_2^{\cdot}\text{-diamine}$ as all dimers were detected as
 303 A_2^{\cdot} .

304 A_2^{\cdot} can also be created from IIC between A_1^{\cdot} and N_1 (see Reaction 2) that proceeds with a rate coefficient of
 305 k_{21} . Including both processes in the cluster balance equations leads to the ratio of sulfuric acid dimer (195 amu) to
 306 monomer (160 amu) signal intensities shown in Equation 2. This relationship includes a time-independent term (the
 307 $t_{CI}=0$ s intercept) that is proportional to the neutral dimer to monomer ratio in the sampled gas, and a term due to IIC
 308 that increases linearly with t_{CI} (Chen et al., 2012; Hanson and Eisele, 2002).

$$\frac{S_{195}}{S_{160}} = \frac{k_2}{k_1} \frac{[N_2]}{[N_1]} + \frac{1}{2} k_{21} [N_1] t_{CI} \quad \text{Equation 2}$$

309 The rate constant, k_{21} , is the collisional rate constant of 2×10^{-9} cm 3 s $^{-1}$. Equation 2 was also derived from the assumption
 310 of short t_{IC} . The relation for S_{195}/S_{160} vs. t_{CI} for long t_{CI} is also derived in the SI. Equation 2 is a good approximation
 311 for the more rigorous solution even at long t_{IC} .

312 Figure 6 (a-c) shows measured S_{195}/S_{160} as a function of t_{CI} for DMA, EDA, and TMEDA respectively as
 313 detected by nitrate CI at $[\text{A}_1]_0 = 4 \times 10^9$ cm $^{-3}$. Put is similar to EDA and is presented in Figure 7 (left). For all bases,
 314 increasing the CI reaction time leads to more IIC-dimer. The observed linear increase in the S_{195}/S_{160} ratio for all bases
 315 provides evidence for the influence of IIC on dimer measurements (Equation 2). However, the y-intercepts for DMA
 316 exhibit a pattern that is distinctly different from those observed for the diamines, indicating different trends for the
 317 neutral monomer to dimer concentration ratios. For DMA, the y-intercept increases with increasing [B]. This is due
 318 to higher concentrations of base depleting the monomer and enhancing dimer concentrations. A different trend was
 319 observed for the diamines with the intercepts showing no clear dependence on diamine concentration.

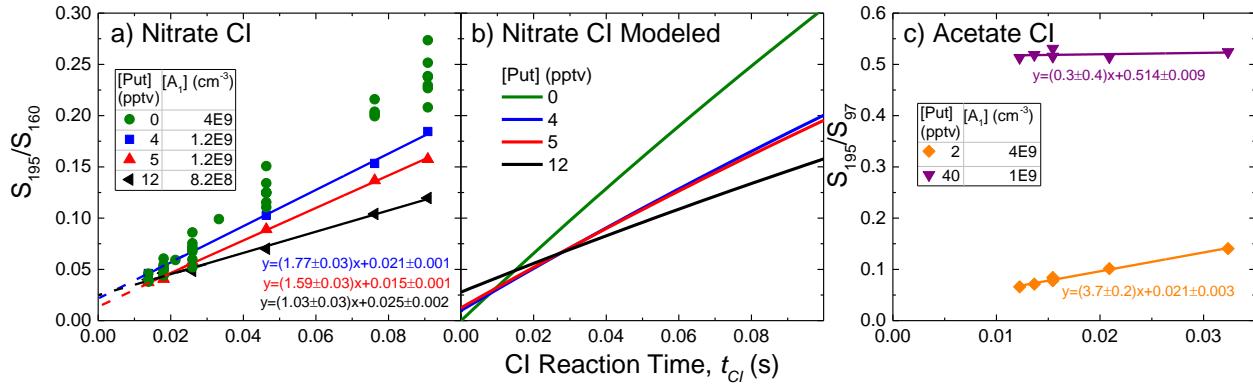

320

321 **Figure 6** Measured sulfuric acid dimer to monomer signal ratio (S_{195}/S_{160}) as a function of t_{CI} for DMA (a), EDA (b), and
 322 TMEDA (c) measured by nitrate CI at $[A_1] \sim 4 \times 10^9 \text{ cm}^{-3}$. The tables in panels a-c provide the measured $[A_1]$ at that [B] after
 323 the 3 s acid-base reaction time. Observations were fitted according to Equation 2 with the y-intercept shown by the dashed
 324 line. Panels d-f present modelled results for each base.

325 There are a number of scenarios that could partly explain the diamine trends. First, the neutral trimer
 326 evaporation rate(s) could be very low such that the formation of trimer and larger clusters will deplete both $[N_2]$ and
 327 $[N_1]$. A_1 evaporation rate from $A_3 \bullet DMA$ is predicted to be $\sim 1 \text{ s}^{-1}$ (Ortega et al., 2012) and likely lower for cluster with
 328 diamines (Jen et al., 2016). The second possibility is A_2^- could be the decomposition product of larger ions such as
 329 $A_3^- \bullet$ diamine forming $A_2^- + A_1 \bullet$ diamine. A third possibility is that $A_2 \bullet$ diamine₂ cannot be readily ionized by nitrate as
 330 compared to $A_2 \bullet DMA_2$ possibly due to differences in cluster configurations and dipole moments. As [diamine]
 331 increases, the fraction of dimers containing two diamines increases, resulting in a growing fraction of N_2 that may not
 332 be ionizable by nitrate. For example, the model predicts $[A_2 \bullet EDA]$ is 10% of $[A_2 \bullet EDA_2]$ when $[EDA] = 90 \text{ pptv}$.

333 The dimer (S_{195}) to monomer signal (S_{97}) ratio for sulfuric acid+Put dimers measured using acetate CI as a
 334 function of t_{CI} was examined to better understand which of these explanations is the most relevant. As mentioned
 335 previously, acetate detects the sulfuric acid monomer as 97 amu, but the detected dimer is at 195 amu for both nitrate
 336 and acetate. Figure 7 shows the ratio of these signals for Put between nitrate (a) and acetate (c). At $[Put] = 40 \text{ pptv}$,
 337 acetate shows a S_{195}/S_{97} y-intercept 25 times higher than the intercepts shown in the nitrate graph. The higher y-
 338 intercepts are most likely due to improved CI efficiency. Decreased detection efficiency of 97 amu and an increased
 339 contribution due to $A_3^- \bullet$ diamine decomposition due to better CI of N_3 by acetate may also contribute (although high
 340 $[A_3^- \bullet$ diamine] in Figure 4 suggests these ions are stable enough during the acetate $t_{CI} = 15 \text{ ms}$). More acetate results
 341 similar to Figure 7 (c) are needed to draw a more definitive conclusion, but these comparisons do suggest that dimers
 342 containing 1-2 diamines are not efficiently chemically ionized by nitrate in these experiments.

343

Figure 7 Measured dimer to monomer signal ratios (S_{195}/S_{160} for nitrate or S_{97} for acetate) as a function of CI reaction time using nitrate (a) and acetate CI (c). In both cases, $[A_1]_0$ was held constant at $4 \times 10^9 \text{ cm}^{-3}$. Panel (b) shows the modeled results for Put. The table inside panel (a) and (c) provide the measured $[A_1]$ after the 3 s acid-base reaction time.

The model adds more clarity on why N_2 containing diamines behave differently than DMA using nitrate CI. For DMA, the best fit to the observations was achieved by assuming all clusters can undergo nitrate ionization and can be formed by IIC. In addition, base evaporation rates from $\text{A}_2\text{-B}_2$ and sulfuric acid evaporation rates from the trimer were set to 0 s^{-1} ; increasing these evaporation rates (up to 10 and 5 s^{-1} respectively) had little effect on the ratio trends. The model also assumed that A_3^-B does not decompose into A_2^- . Figure 6 (d) shows modeling results for DMA. To reproduce S_{195}/S_{160} trends of EDA and Put, the model followed that of DMA except $\text{A}_2\text{-B}_2$ cannot be ionized by nitrate. For TMEDA, the model also assumed $\text{A}_2\text{-TMEDA}_2$ does not form. Modeled results are shown in Figure 6 (e and f) for EDA and TMEDA, respectively, and Figure 7 (b) for Put. The modeled pathways for N_2 are listed in Table 2. For all three diamines, we were unable to reproduce the observations with other combinations of reactions and evaporation rates. The model only matched the observed trends by turning off the CI or formation of $\text{A}_2\text{-diamine}_2$.

However, several of the modeled reactions are simplified versions of multi-step reactions. For example, preventing the formation of $\text{A}_2\text{-TMEDA}_2$ could also mean $\text{A}_2\text{-TMEDA}_2$ forms at the collision rate but instantly decomposes into $\text{A}_2\text{-TMEDA}$. Furthermore, differences between DMA and diamine observations could instead be explained by semi-efficient nitrate CI of $\text{A}_2\text{-diamine}$ because the existence of high $[\text{A}_2\text{-diamine}_2]$ is unlikely due to its high basicity. Preventing $\text{A}_2\text{-diamine}_2$ from forming and semi-efficient CI of $\text{A}_2\text{-diamine}$ could lead to identical results as shown in the model for EDA and TMEDA. Additional thermochemical data (e.g., from more targeted experiments and computational chemistry) are needed to better inform the model. Regardless, our observations and modeling show that dimer's neutral formation pathways and/or the nitrate CI differs between the DMA and diamine systems.

The model also provides an estimate of the fraction of $[\text{A}_2^-]$ formed by IIC at $t_{CI}=18 \text{ ms}$ (used for the nitrate CI experiments). For base concentration of 0 pptv, the model is very similar to what was measured in Figure 6, indicating that A_2^- is almost completely formed by A_1^-+A_1 (i.e., is an IIC artifact) and not by the CI of A_2 . The abundance of A_2^- is low at 300 K (Hanson and Lovejoy, 2006), below detection limit of the Cluster CIM. For DMA, IIC dimers typically account for 1% (less at high [DMA]) of the total dimer signal which agrees with the conclusions drawn in Jen et al. (2015). In contrast, the IIC fraction of A_2^- using nitrate for EDA and Put is $\sim 50\%$, due to the potentially large fraction N_2 not undergoing chemical ionization. The nitrate ion's inability to chemically ionize some of the dimers is further highlighted since IIC is suppressed in the diamine system: less N_1 is available (due to formation of larger clusters) thus both $[\text{A}_1]$ and $[\text{A}_1^-]$ are depressed. IIC-produced A_2^- accounts for $\sim 20\%$ of the total dimer signal for TMEDA. However, these numbers are uncertain due to the assumptions in the model and uncertainties in the measurement. For instance, the model is not sensitive to whether A_1^- can cluster with $\text{A}_1\text{-B}$, which would significantly influence the amount of IIC dimer without significantly affecting S_{195}/S_{160} . IIC contributes much less A_2^- when acetate is used as the reagent ion because acetate detects up to 5 times more total neutral dimer concentration ($[\text{N}_2]$) than

378 nitrate when base is present. Acetate measurements show that IIC produced ~3% of the $[A_2^-]$ when $[Put]=2$ pptv and
 379 near zero when $[Put]=40$ pptv (Figure 7 c).

380 **Table 2 Summary of possible pathways for neutral and ion dimer formation**

Neutral formation	Nitrate CI and ion decomposition reactions	IIC reactions (only A_1^-)
<u>DMA, Put, EDA:</u>	<u>DMA:</u> $A_1 \bullet B + A_1 \xrightarrow{k} A_2 \bullet B$ $A_1 \bullet B + A_1 \bullet B \xrightarrow{k} A_2 \bullet B_2$ $A_2 \bullet B + B \xrightarrow{k} A_2 \bullet B_2$ $A_2 \bullet B_2 \xrightarrow{E_{2B}} A_2 \bullet B + B$	<u>All bases:</u> $A_2 \bullet B + NO_3^- \xrightarrow{k_c} A_2^- \bullet B + HNO_3$ $A_2^- \bullet B \xrightarrow{fast} A_2^- + B$ $A_2 \bullet B_2 + NO_3^- \xrightarrow{k_c} A_2 \bullet B_2^- + HNO_3$ $A_2^- \bullet B_2 \xrightarrow{fast} A_2^- \bullet B$
<u>TMEDA:</u>	<u>Diamines:</u> $A_1 \bullet B + A_1 \xrightarrow{k} A_2 \bullet B$ $A_1 \bullet B + A_1 \bullet B \nrightarrow A_2 \bullet B_2$ $A_2 \bullet B + B \nrightarrow A_2 \bullet B_2$	$A_2 \bullet B + NO_3^- \xrightarrow{k_c} A_2^- \bullet B$ $A_2^- \bullet B \xrightarrow{fast} A_2^- + B$ $A_2 \bullet B_2 + NO_3^- \nrightarrow A_2^- \bullet B_2$

381

382 **Trimer, N_3^- :**

383 Neutral trimers (N_3^-) are primarily formed by combining one of the two types of monomers with one of the
 384 two types of dimers; evaporation of large clusters also contributes. In the sulfuric acid+DMA system, computational
 385 chemistry predicts A_3^- •DMA₂ and A_3^- •DMA₃ are relatively stable, with A_3^- •DMA₃ exhibiting the lowest evaporation
 386 rate (Ortega et al., 2012). Also A_3^- •DMA may be present in significant amounts due to a high production rate via
 387 A_2^- •DMA+A₁. CI of N_3^- leads to ions such as (i) A_3^- •DMA₃ which evaporate at a rate of 10^4 s⁻¹ into A_3^- •DMA₂ and (ii)
 388 A_3^- •DMA₂ and A_3^- •DMA which have predicted DMA evaporation rates of $\sim 10^{-1}$ and 10^{-2} s⁻¹ (Ortega et al., 2014), respectively,
 389 resulting in lifetimes comparable to t_{CI} used here. From Figure 1, nitrate CI resulted in A_3^- •DMA₂ (only at [DMA]=110
 390 pptv), A_3^- •DMA, and A_3^- . The DMA-containing clusters were detected to a much lesser extent than with acetate CI.

391 Acetate CI results help shed light on these processes with much higher $[A_3^-$ •DMA_{1,2}] than with nitrate CI
 392 (Figure 1) which could be due to decomposition of larger ion clusters. The acetate CI results depicted in Figure 1 show
 393 that A_3^- •DMA₂ is the most abundant type of trimer ion, suggesting that the dominant neutral clusters are A_3^- •DMA₂₋₃,
 394 with any A_3^- •DMA₃ quickly decomposing into A_3^- •DMA₂. Neutral A_3^- •DMA₃ is predicted by our model to be dominant
 395 at high [DMA]. This picture is consistent with our postulate that nitrate cannot ionize A_3^- •DMA₃ (and also, possibly,
 396 A_3^- •DMA₂) and thus little A_3^- •DMA_{1,2} is observed using nitrate CI.

397 The trimer ions observed using acetate CI may have contributions from decomposition of large clusters. For
 398 example, A_3^- •DMA₂ could be formed by the decomposition of A_4^- •DMA₂ or A_4^- •DMA₃ via loss of A₁ or A₁•DMA,
 399 respectively. If these types of processes are significant, they might explain some of the differences in the trimer ion
 400 observations between nitrate and acetate CI. Highly aminated tetramer neutrals would be more readily ionized by
 401 acetate and result in larger contributions to the trimer ion signals than compared nitrate CI. Thus, this may be one
 402 drawback to acetate CI: a possible shift downwards in sulfuric acid content in the distribution of ions vs. the neutrals.

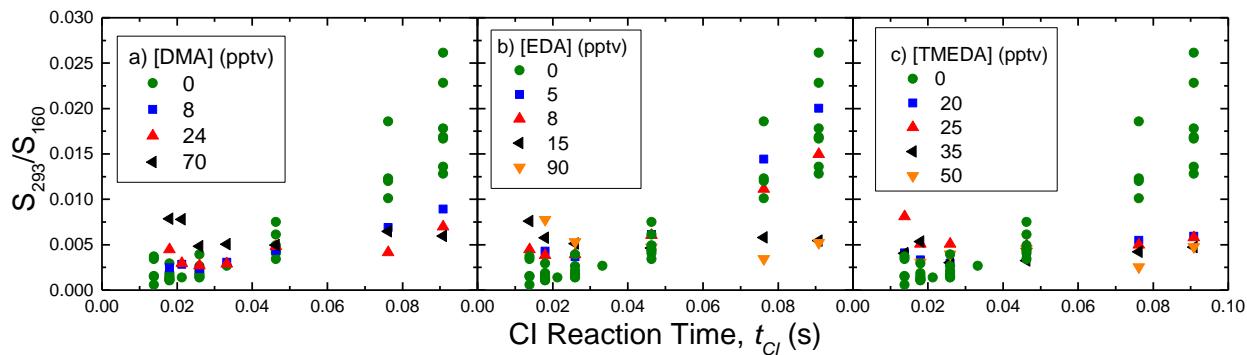

403 The sulfuric acid + diamine system shows nitrate CI detection of A_3^- •diamine₀₋₂ but at much lower
 404 abundances than acetate CI, particularly for EDA. Interestingly, the most abundant trimer ions after acetate CI contain
 405 on average 1 diamine molecule compared to 2 in the DMA system. This is consistent with particle measurements that

406 show one diamine molecule is able to stabilize several sulfuric acid molecules, and thus form a stable particle, while
 407 at least 2 DMA molecules are required for the same effect (Jen et al., 2016). The two amino groups on the diamine
 408 molecule can both effectively stabilize trimers, and this size is stable for the relevant time scales in this flow reactor
 409 (Glasoe et al., 2015;Jen et al., 2016). Therefore, larger clusters can be produced with higher acid to base ratios.

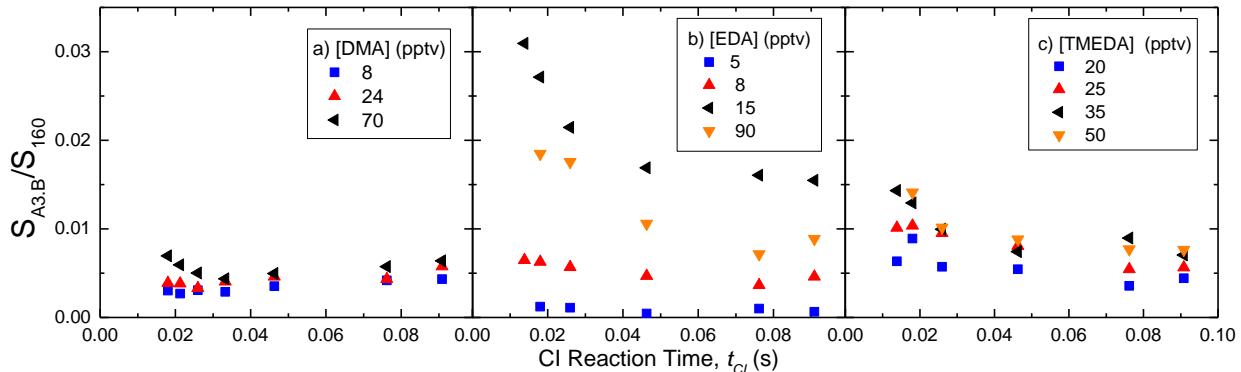

410 To better understand the trimer ion behaviors, we monitored the bare trimer signal (A_3^- , S_{293}) and monomer
 411 signal (S_{160}) as a function of CI reaction time, t_{CI} . Figure 8 shows S_{293}/S_{160} for nitrate CI for DMA, EDA, and TMEDA
 412 at $[A_1]_0=4\times 10^9 \text{ cm}^{-3}$. Note, equivalent measurements for Put are similar to those of EDA. Low values of S_{293}/S_{160} for
 413 all conditions indicate minimal creation of A_3^- from the CI of N_3 . Thus, IIC-produced A_3^- can be a significant fraction
 414 of observed A_3^- . Without base present, IIC is the only way to produce detectable amounts of A_3^- (green circles in
 415 Figure 8).

416 A_3^- can also be formed by the decomposition of larger ions such as $A_3^- \bullet B$. Evidence of this decomposition
 417 can be seen in Figure 9 where $S_{A3 \bullet B}/S_{160}$ measured using nitrate CI is shown as a function of t_{CI} . For diamines at high
 418 concentrations and short t_{CI} , $S_{A3 \bullet B}/S_{160}$ decreases with t_{CI} and can be attributed to decomposition of this ion. Shorter
 419 t_{CI} allows the instrument to capture short-lived ions. $A_3^- \bullet$ diamine decomposes at longer times and could form A_3^- ,
 420 thereby decreasing $S_{A3 \bullet B}/S_{160}$ and increasing S_{293}/S_{160} . However, S_{293}/S_{160} for the diamines does not increase with t_{CI} ,
 421 indicating that $A_3^- \bullet$ diamine likely decomposes into products other than A_3^- . The DMA system also exhibits a very
 422 small decrease of $S_{A3 \bullet B}/S_{160}$ at short t_{CI} , but ratio values are within measurement uncertainties. Thus no conclusion
 423 can be drawn from this decrease of $S_{A3 \bullet DMA}/S_{160}$ at short t_{CI} .

424 Another, more likely scenario to explain these time dependent behaviors for the trimer ion signals is if $A_3^- \bullet B$
 425 decays into A_2^- and a neutral $A_1 \bullet B$ at short t_{CI} . Assuming we have captured most of the initial $A_3^- \bullet B$ signal at the
 426 shortest $t_{CI}=15 \text{ ms}$ in Figure 9 (a-c), the increase in A_2^- due to this mechanism would be small compared to the observed
 427 A_2^- signal. Acetate data for Put (Figure 7 c) provide some evidence supporting this because the slope of the $[Put]=2$
 428 pptv is 3.7 and is higher than the 2.6 slope of $[B]=0$ pptv case. Since A_2^- when $[B]=0$ pptv is primarily produced by
 429 IIC, a higher slope when $[Put]=2$ pptv indicates larger ion decomposition contributing to the A_2^- signal.

430
 431 **Figure 8 Measured bare sulfuric acid trimer to monomer signal ratio (S_{293}/S_{160}) as a function of t_{CI} for DMA (a), EDA (b),
 432 and TMEDA (c) detected by nitrate CI at $[A_1]_0=4\times 10^9 \text{ cm}^{-3}$.**

433
434 **Figure 9 Nitrate measured signal ratio between $A_3 \bullet B$ and sulfuric acid monomer ($S_{A3 \bullet B}/S_{160}$) as a function of t_{CI} for DMA**
435 (a), EDA (b), and TMEDA (c) at $[A_1]_0 = 4 \times 10^9 \text{ cm}^{-3}$.

436 Scenarios deduced from these trimer ion observations and previous computational chemistry studies for the
437 sulfuric acid and DMA system are summarized in Table 3. These reactions have little effect on the modeled dimer
438 results since they introduce minor sources of dimer ions. In contrast, each trimer pathway adds large uncertainty to
439 the modeled trimer behavior. For example, including ion decomposition reactions of larger ions (tetramer and larger),
440 postulated from the acetate CI results, may greatly influence concentration of smaller trimer ions which already exhibit
441 very low signals using nitrate CI. In addition, nitrate inefficient ionization of neutral trimers leads to large uncertainties
442 in modeling the unobserved trimer types. More detailed observations of the chemically neutral trimers and
443 computational chemistry studies on evaporation rates for sulfuric acid+diamine systems will improve future efforts to
444 model these processes.

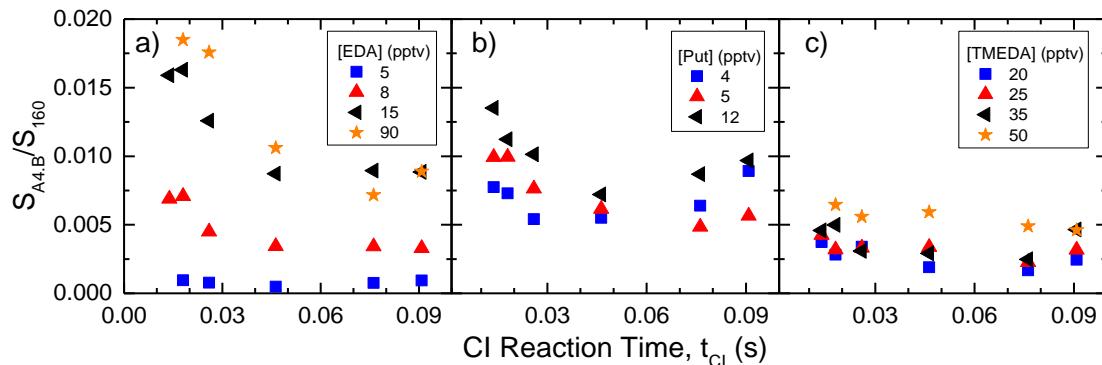

445 **Table 3 Summary of possible pathways for neutral and ion trimers formed from sulfuric acid and DMA, excluding**
446 **decomposition of tetramer and larger ions**

Neutral formation	Nitrate CI and ion decomposition reactions	IIC reactions (only A_1^-)
$A_2 \bullet B + A_1 \xrightarrow{k} A_3 \bullet B$	$A_3 \bullet B + NO_3^- \xrightarrow{k_c} A_3^- \bullet B + HNO_3$	$A_2^- + A_1 \xrightarrow{k_c} A_3^-$
$A_3 \bullet B + B \xrightarrow{k} A_3 \bullet B_2$	$A_3^- \bullet B \xrightarrow{E_d} A_2^- + A_1 \bullet B$	$A_1^- + A_2 \bullet B \xrightarrow{k_c} A_3^- \bullet B$
$A_3 \bullet B_2 + B \xrightarrow{k} A_3 \bullet B_3$	$A_3 \bullet B_3 + NO_3^- \nrightarrow A_3^- \bullet B_3 + HNO_3$	
$A_2 \bullet B_2 + A_1 \bullet B \xrightarrow{k} A_3 \bullet B_2$	$A_3 \bullet B_2 + NO_3^- \nrightarrow A_3^- \bullet B_2 + HNO_3$	
$A_2 \bullet B + A_1 \bullet B \xrightarrow{k} A_3 \bullet B_2$		
$A_2 \bullet B_2 + A_1 \bullet B \xrightarrow{k} A_3 \bullet B_3$		

447
448 **Tetramer, N₄:**
449 Nitrate CI leads to very low amounts of tetramer ions and primarily as $A_4^- \bullet DMA_{1-3}$ and $A_4^- \bullet diamine_{1,2}$.
450 Computational chemistry suggests that the sulfuric acid+DMA tetramer likely exists as $A_4 \bullet DMA_{2-4}$, with $A_4 \bullet DMA_4$
451 dominating the population (Ortega et al., 2012). The acetate data appears to confirm this with $A_4^- \bullet DMA_3$ as the most
452 abundant tetramer ion which likely predominately originated from the decomposition of $A_4 \bullet DMA_4$ upon ionization
453 (Ortega et al., 2014). Nitrate may efficiently chemically ionize $A_4^- \bullet DMA_{1-2}$, however their concentrations after the 3 s
454 neutral reaction time are likely below the detection limit of the Cluster CIMS ($< 10^5 \text{ cm}^{-3}$). Furthermore, the A_4^-
455 $\bullet DMA_{1,2}$ ions may be subject to elimination of $A_1 \bullet DMA$. Nitrate CI results show ~100 times higher $[A_4^- \bullet diamine]$

456 than $[A_4^- \bullet DMA]$ at about equivalent initial reactant concentrations. This suggests that the most stable neutral tetramers
 457 contain fewer diamine molecules than DMA. In addition, the acetate CI results for the diamines show the majority of
 458 N_4 contain 1 diamine, further supporting the conclusions drawn in Jen et al. (2016) that only one diamine molecule is
 459 needed to form a stable particle.

460 Due to the very low observed concentration of $A_4^- \bullet DMA$, we focus on the ions of the diamine systems. The
 461 stability and behavior of $A_4^- \bullet$ diamine can be examined by looking at nitrate detected signal ratios of $A_4^- \bullet$ diamine and the
 462 monomer ($S_{A4 \bullet \text{diamine}}/S_{160}$) as a function of CI reaction time, given in Figure 10. Similar to $A_3^- \bullet EDA$, $S_{A4 \bullet EDA}/S_{160}$ and
 463 $S_{A4 \bullet Put}/S_{160}$ decreases with time at short t_{CI} , indicating that they decompose with a lifetime shorter than a few tens of
 464 ms. $S_{A4 \bullet TMEDA}/S_{160}$ also shows a decrease at short t_{CI} , but it is less evident. It could have a fast decay rate leading to a
 465 few ms lifetime, and our measurements would have mostly missed them. Nonetheless, decomposition of $A_4^- \bullet$ diamine
 466 likely entails evaporation of N_1 or N_2 instead of a lone diamine from the cluster as $[A_4^-]$ was below detection limit of
 467 the Cluster CIMS using nitrate. At long CI reaction time, $S_{A4 \bullet EDA}/S_{160}$ remained constant, indicating negligible
 468 contribution of IIC to $A_4^- \bullet EDA$ signal. In contrast, $S_{A4 \bullet Put}/S_{160}$ and $S_{A4 \bullet TMEDA}/S_{160}$ increase at long t_{CI} . This could be
 469 due to IIC or larger ion decomposition.

470
 471 **Figure 10** Nitrate measured signal ratio between $A_4^- \bullet B$ and sulfuric acid monomer ($S_{A4 \bullet \text{diamine}}/S_{160}$) as a function of CI
 472 reaction time for EDA (a), Put (b), and TMEDA (c).

473 **Pentamer, N_5 :**

474 Nitrate CI did not detect any pentamer (N_5), but pentamer was detected using acetate CI. In the diamine
 475 system, acetate detected N_5 with fewer diamine molecules (1-2) than DMA (4). However, $A_5^- \bullet EDA_{>3}$, $A_5^- \bullet TMEDA_{>1}$,
 476 and $A_5^- \bullet Put_{>2}$ fall outside the Cluster CIMS mass range of 710 amu. Thus, we may not have measured the complete
 477 pentamer population. The most abundant N_5 is $A_5^- \bullet DMA_4$ and it increases in both concentration and in fraction of N_5
 478 population with increasing [DMA]. This ion could be the result of the loss of a DMA molecule after CI of $A_5^- \bullet DMA_5$.
 479 This would follow similar trends predicted by computation chemistry for smaller clusters. However, since
 480 $[DMA] \ll [A_1]_0$ (i.e., $[B]/[A_1]_0$ is high) and stable particles need ~ 2 DMA to form (Glasoe et al., 2015), $[A_5^- \bullet DMA_5]$
 481 as high as 10^7 cm^{-3} would not be expected. The presence of $A_5^- \bullet DMA_4$ could also then be the result of large ion
 482 decomposition via evaporation of A_1 or $A_1 \bullet DMA$. Measurements of ions larger than 700 amu are needed to better
 483 understand how they evaporate upon acetate CI and what fraction of the pentamers are not ionizable by nitrate.

484 **Conclusion:**

485 This study presents measurements of the behavior of neutral and ionized sulfuric acid clusters containing
 486 various bases. The results show the complexities of the coupled neutral cluster formation pathways with the ion
 487 processes (e.g. chemical ionization, ion-induced clustering, and ion decomposition). We provide various scenarios to
 488 describe the observed trends. Our most definitive conclusions are

489 1) Nitrate very likely does not chemically ionize all types of sulfuric acid dimers containing diamines. The model
490 indicates $A_2 \bullet \text{diamine}_2$ cannot be chemically ionized by nitrate. However, the model did not consider semi-efficient
491 nitrate CI of $A_2 \bullet \text{diamine}$ which could also explain our observations.

492 2) Nitrate only chemically ionizes a small fraction of trimer and larger clusters in both the DMA and diamine with
493 sulfuric acid systems. Measurements suggest that the more chemically neutral clusters are not chemically ionized
494 by nitrate but are by acetate.

495 3) Acetate and nitrate CI measurements of sulfuric acid+DMA clusters generally agree with the qualitative trends
496 of neutral and ion cluster predicted from computational chemistry (Ortega et al., 2012;Ortega et al., 2014).
497 However, these measurements suggest that $A_3^- \bullet B$ decomposes into A_2^- and $A_1 \bullet B$.

498 4) Nitrate measurements of $A_3^- \bullet B$ and $A_4^- \bullet B$ show that these ions decompose at roughly the same time scales as the
499 CI reaction time at room temperature. In principle, ionization of neutral clusters leads to potentially large artifacts
500 even before they are sampled into a vacuum system. These decomposition reactions will likely affect the
501 calculated concentrations of the neutral clusters.

502 5) In an acid-rich environment where $[B]/[A_1] < 1$, A_2^- and A_3^- are primarily produced via IIC pathways and contribute
503 negligible amounts to overall dimer and trimer signals when any of these bases are present and at our 18 ms CI
504 reaction time. If some fraction of the dimer is not chemically ionized by nitrate, then IIC-produced A_2^- is a
505 significant fraction of the dimer signal.

506 Additional computed neutral and ion evaporation rates and a more complex model combined with
507 multivariable parameter fitting would provide more clarity to these results. In addition, more acetate CI measurements
508 of ion signal ratios as a function of CI reaction time are needed to provide more details on specific ion behaviors.
509 However, measurements using the acetate ion (which includes acetate, acetate•water, and acetic acid•acetate) exhibit
510 high backgrounds in the low masses, leading to up to a factor of 5 uncertainty in measured monomer concentration
511 ($[N_1]$) and a factor of 2-3 for dimer concentration ($[N_2]$). A higher resolution mass spectrometer is needed to resolve
512 the background signals and reduce the uncertainties.
