Reply to Reviewer #1

Minor comment 1: "1.47-48. Fix this awkward sentence as follows, …significant columnar SO2 increases, exceeding on the average 2 DU relative to an unperturbed pre-volcanic 10-day baseline, with a mean close to zero and σ = 0.46, as calculated..."

Answer to 1: The sentence has been modified as suggested.

Minor comment 2: "2.22-23. Suggest … quantities of both ash and SO2 are released which in the case of ash can result in air travel disruptions…"

Answer to 2: The sentence has been modified as suggested.

Minor comment 3: "7.39-8.5. The authors need to explain what the ground based measurements are in this statement, "… the columnar SO2 measurements over Europe were also compared with measurements from ground level European stations from the European Environment Agency databases (AirBase) covering…". I have no idea what "measurement" the columnar so2 measurements are being compared to."

Answer to 3: The columnar SO2 measurements are compared to surface SO2 measurements. The text has been revised and it now reads as follows: "Only for the case of the Bárðarbunga eruption in 2014, the columnar SO2 measurements over Europe were also compared with surface SO2 measurements from ground based European stations. The surface SO2 data were obtained from the European Environment Agency databases (AirBase; http://www.eea.europa.eu/data-and-maps/data/aqereporting-1#tab-european-data) covering the bimonthly period September-October 2014."

Minor comment 4: "8.21-35. Authors should explain why the STL product is not used, since it seems that would be the correct altitude for explosive volcanic eruptions versus volcanic degassing for TRM. I was surprised when STL was not mentioned further after the explanation of what it was."

Answer to 4: The TRM retrievals are recommended by Ialongo et al. (2015) to be used for volcanic degassing at all altitudes. On the other hand, STL data are intended for use with explosive volcanic eruptions where the volcanic cloud is placed in the upper troposphere / stratosphere (UTLS). The reviewer correctly points this out, and in the revised manuscript we show the results from both TRM and STL products. The STL calculations have been added to the figures and in the text, and the results are almost identical as described in the revised text.

Minor comment 5: "Section 3.1 The 2014 Bárðarbunga case – What is difficult to understand about this case is the timing of the ejected material from the volcano. The dispersion modeling is from 18-26 Sept. The back trajectories shown are 5 days from about 20 Sept., so a similar period. In contrast the eruption is indicated to occur at day 0 in figures 4 and 5 with the plume not appearing until 20 days later. How does the reader reconcile this significant time difference? Did the outgassed so2 hang around Iceland for 15 days prior to being dispersed? I doubt it. Was the volcano continuing to outgas for a number of weeks? The authors need to be clear and not mark the eruption as a one day event if that is not the case. If that is the case then the authors need to explain why the so2 was located over Iceland 15 days later."

Answer to 5: Bárðarbunga was continuously active during September – October 2014 but it was only during 18-26 September when meteorological conditions favoured transport towards Europe as shown by back trajectories analyses (see Figure left below). Previous emissions (1-17 September 2014) travelled towards different directions (e.g. Atlantic Ocean, Arctic) and could have not been detected by the European Brewer and surface networks (see Figure to the right below). This has been clarified in the revised text.

The eruption was not a one day event. To clarify this we have added the following line in the captions of Figures 4, 5: "The arrow marks the starting date of the eruption (beginning on 31 August 2014 which continued to be active throughout the whole bimonthly period and beyond)."

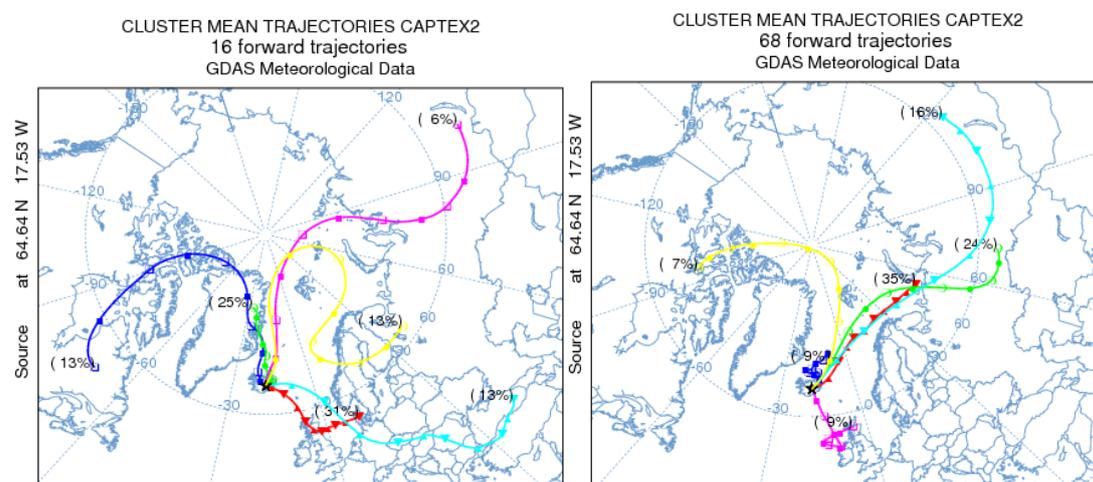

Figure left: Cluster analysis of the HYSPLIT 120 hours forward trajectories from Bárðarbunga for the period 18-21 September 2014. Figure right: Cluster analysis of the HYSPLIT 120 hours forward trajectories from Bárðarbunga for the period 1-17 September 2014.

Minor comment 6: "Figure 9. The positive so2 signal at Taipei on 06/19 is compromised by the equivalent negative excursion on 07/17. Can the authors explain this?"

Answer to 6: The positive SO2 signal at Taipei and the negative excursion are not connected to each other. The positive SO2 signal was due to the volcanic SO2 plume by Nabro as evidenced from the back trajectories analyses in figure 9.

Minor comment 7: "12.38. "The increase in SO2 due to the passage of the Nabro volcano plume over the Canary Islands is significant using both methods, showing an offset between them (Figure 11)." What is meant by "showing an offset between them"? Do the different zeroing methods produce the offset, does the volcanic plume produce the offset, is the offset introduced to separate the lines, …?"

Answer to 7: Both Brewer lines (data calibrated with two different methods at Izana) are free from offsets by subtracting from the data the non-perturbed pre-volcanic 10-day baseline. The text and Figure 11 have been revised.

Minor comment 8: "Fig. 12 and 13.20. This figure has the same problem as Figs. 4 and 5. The mark indicating the eruption is misleading. First the text states that the eruption first occurred on 14 April. The figure legend claims the time frame is April-May so the reader assumes day 0 corresponds with April 1, but that would make the eruption occurring on 4 April. The text goes further to claim the eruption has three phases so it occurs on a number of days in April/May leaving the figure misleading again since it indicates an eruption on just one day. The authors could make this clear with appropriately labelled ordinates indicating what day 0 is, or better, use the actual dates of the month for simplicity, then add a mark on each day when there was significant effluent from Eyjafjallajökull."

Answer to 8: The labels on the abscissa of Fig. 12 (and in all other figures) have been corrected to show the actual dates of the month as suggested. The arrow in Fig. 12 marks the beginning of the eruption of Eyjafjallajökull on 14 April.

Minor comment 9: "13.36-14.5. It is surprising that back trajectories are not shown for Uccle and DeBilt, in fact no back trajectories are shown for Eyjafjallajökull, whereas a number of such trajectories were shown for Bárðarbunga. It appears that if there is no increase in so2 then the authors don't bother to calculate a back trajectory. That makes sense in most cases, but not when stations are as close as Uccle and DeBilt. The authors should consider adding back trajectories here to demonstrate that indeed one station was outside and one inside the plume on the same date. It would be a nice confirmation of the reliability of the back trajectories and the localized nature of the volcanic clouds."

Answer to comment 9: This is a useful comment and in the revised text we replace lines 13.36-37 with the following section:

"We should note here that volcanic clouds can be rather narrow plumes with diameters on the order of a few tens kilometers (e.g. Stohl et al., 2011; Webley et al., 2012; Thorsteinsson et al., 2012; Kristiansen et al., 2012; Kokkalis et al., 2013) and thus it is possible that a detected volcanic layer at a specific station is not observed by neighbouring stations. The

measurements at Uccle and De Bilt that are located at a horizontal distance of 150 km are different during the Eyjafjallajökull episode and provide a formidable example. On 2 May 2010 the mean daily SO_2 is 5.8 DU at De Bilt and -0.2 DU at Uccle. As seen at the corresponding back trajectories for that day in Figure 13, air masses originating from Iceland arrive at De Bilt at heights 6-7 km and have been probably transporting the volcanic cloud over that station. In contrast similar back trajectories on the same day for the case of Uccle indicate transport of air masses from Iceland but at lower heights (3-4 km) that were probably not affected by the volcanic emissions. In another case of transport on 11 May 2010, Uccle was outside of the plume (see Figure 13) while the mean daily SO_2 for De Bilt was 0.9 DU. On 18 May 2010, both De Bilt and Uccle stations detected a volcanic cloud with SO_2 daily means of 1.7 DU and 1.2 DU respectively. To summarize, in spite the proximity of Uccle and De Bilt the transport heights and trajectories can have a different result in transporting volcanic gases."

The above response, new Fig. 13 (back trajectories for Eyjafjallajökull) and references have been added in the text as appropriate. The previous Fig. 13 (Kasatochi) now becomes Fig. 14.

Abstract. This study examines the adequacy of the existing Brewer network to supplement other networks from ground and space to detect SO_2 plumes of volcanic origin. It was found that large volcanic eruptions of the last decade in the Northern Hemisphere have a positive columnar SO_2 signal seen by the Brewer instruments located under the plume. It is shown that a few days after the eruption the Brewer instrument is capable of detecting significant columnar SO_2 increases, exceeding on the average ~~exceeding~~ 2 DU relative to ~~a considered as~~an unperturbed pre-volcanic 10-day baseline ~~10 day period~~, with a mean close to zero and σ = 0.46, as calculated

1

from the 33 Brewer instruments under study. Intercomparisons with independent measurements from ground and space as well as theoretical calculations corroborate the capability of the Brewer network to detect volcanic plumes. For instance, the comparison with OMI and GOME-2 SO_2 space-borne retrievals shows statistically significant agreement between the Brewer network data and the collocated satellite overpasses in the case of Kasatochi eruption. Unfortunately, due to sparsity of satellite data the significant positive departures seen in the Brewer and other ground networks following Eyjafjallajökull, Bárðarbunga and Nabro eruptions could not be statistically confirmed by the data from satellite overpasses. A model exercise from the MACC (Monitoring Atmospheric Composition and Climate) project shows that the large increases of SO_2 over Europe following the Bárðarbunga eruption in Iceland were not caused by local pollution sources or ship emissions but were clearly linked to the volcanic eruption. Sulfur dioxide positive departures in Europe following Bárðarbunga could be traced by other networks from the free troposphere down to the surface (AirBase and EARLINET). We propose that by combining Brewer data with that from other networks and satellites, a useful tool aided by trajectory analyses and modelling could be created which can be used also to forecast high SO_2 values both at ground level and in air flight corridors following future eruptions.

1 Introduction

Volcanic eruptions are an important source of natural emissions of sulfur dioxide (SO_2) into the troposphere and the stratosphere. Ash particles and gases injected into the atmosphere by large volcanic eruptions can affect solar radiation and climate (e.g. Robock, 2000), air quality (e.g. Schmidt et al., 2015) and may also impact local environments (e.g. Durant et al., 2010). Volcanic emissions (e.g. ash and SO_2) can reach different heights in the atmosphere and can be transported in different directions (e.g. Prata et al., 2010). Thomas and Prata (2011) have shown that the eruption can be divided into an initial ash rich phase, a lower intensity middle phase and a final phase where considerably greater quantities of both ash and SO_2 are released which in the case of ash can result even toin air travel disruptions (e.g. Flentje et al., 2010). These effects make the ash and SO_2 in volcanic plumes important parameters to be studied, monitored and forecasted on small and larger spatial scales. Our study focuses on volcanic columnar SO_2 amounts because of the existence of the rather continuous set of direct sun measurements with the Brewer network.

Measurements of SO_2 are important for tracking and assessing impacts of emissions from pollution sources and in quantifying natural SO_2 emissions by volcanoes. Pollution sources typically result in a few Dobson Units (DU, 1 DU = $2.69 \cdot 10^{26}$ molec$\cdot$km^{-2}) increases of column SO_2 amounts unless observations are made near a source. The Brewer network is useful for plume tracking because it can track SO_2 columnar amounts from a large number of stations and wide geographical extent. The primary application of the ground-based Brewer spectrophotometer is to measure total ozone column by using UV spectrophotometry. Direct sunlight intensities are measured at five wavelengths (between 306 and 320 nm; see also Sect. 2.1) to simultaneously calculate ozone and SO_2 column integrals (Kerr et al., 1980). These instruments have been used extensively to monitor stratospheric ozone (e.g. WMO Scientific Assessment of Ozone Depletion reports 2011, 2014) and have a long history of studying atmospheric SO_2 columns (e.g. De Backer and De Muer, 1991; Bais et al., 1993; Fioletov et al., 1998; Zerefos et al., 2000; Zerefos et al., 2009; Ialongo et al., 2015). Ground-based measurements of

2

atmospheric SO_2 using the Brewer instrument have played an important role in the development and validation of satellite-based SO_2 measurements (Schaefer et al., 1997; Spinei et al., 2010; Rix et al., 2012; Ialongo et al., 2015) used primarily for detecting and tracking volcanic emissions. Since the Brewer instruments are located at stationary ground-based monitoring sites, a volcanic plume of SO_2 must pass over the site if useful data are to be obtained. Validation of satellite measurements by the Brewer instrument also requires that a satellite overpass is available when the plume is over the ground based site (Kerr, 2010).

There have been various initiatives during recent years that used satellite measurements of SO_2 to monitor volcanic eruptions in support of aviation safety, e.g. ESA's Support to Aviation Control Service (SACS) (Brenot et al., 2014). These initiatives together with modelling forecasting tools provide valuable information to the established Volcanic Ash Advisory Centers (VAAC). Satellite SO_2 data have been available in the past from various satellite instruments (e.g. GOME, SCIAMACHY). Currently operational data are available from UV measurements (e.g. GOME-2 (Global Ozone Monitoring Experiment-2), OMI (Ozone Monitoring Instrument) and OMPS (Ozone Mapping Profiler Suite)) and from infrared measurements (e.g. IASI (Infrared Atmospheric Sounding Interferometer) and AIRS (Atmospheric Infrared Sounder)).

In the present work we investigate the efficiency of the existing Brewer network in the Northern Hemisphere to detect volcanic SO_2 plumes during the past decade. The main focus is to show the sensitivity of the Brewer network in detecting SO_2 plumes of volcanic origin in synergy with other ground based observations, satellite data and dynamic transport calculations. The Brewer spectroradiometric measurements are compared to collocated satellite measurements from OMI and GOME-2 as described in the next paragraph. This paper did not include analyses of the SO_2 measurements from IASI and AIRS since both instruments are IR spectroradiometers. We compared Brewer measurements against the OMI and GOME-2 data that are derived using information from differential optical absorption in the UV spectrum, which is also at the base of the Brewer measurement methodology. In the case of Brewer-IASI or Brewer-AIRS comparison we would also have to consider differences in the spectroscopy and the corresponding retrieval algorithm concepts, which would require further analysis which is beyond the scope of this paper.

Table 1 lists in chronological order all major volcanic eruptions in the Northern Hemisphere between 2005-2015 with volcanic explosivity scale index (VEI) of at least 4 (Newhall and Self, 1982; Robock et al., 2000; Zerefos et al., 2014). The study also provides a separate analysis for the Bárðarbunga eruption, which although not rated 4 has been already studied with the Brewer at Sodankylä by Ialongo et al. (2015).

As seen from Table 1, chronologically, the first case was the volcanic eruption at Mount Okmok, Alaska (53.43^o N, 168.13^o W, 1073 m above sea level (asl), 12 July 2008, Prata et al., 2010) followed by the Kasatochi eruption, Alaska (52.17^o N, 175.51^o W, 300 m asl, 7-8 August 2008, e.g., Kristiansen et al., 2010; Krotkov et al., 2010; Waythomas et al., 2010) which was detected over large areas of the Northern Hemisphere. Okmok and Kasatochi volcanoes in Alaska erupted a short time span of less than a month and therefore we decided to study the evolution of the Brewer SO_2 columnar measurements following the latter volcanic eruption (Kasatochi). The third eruption took place at Sarychev in Russia (48.1^o N, 153.2^o E, 1496 m asl, 12-17 June 2009, Haywood et al.,

3

2010). The evolution of the SO_2 volcanic plume from Sarychev was mostly observed over the North Pacific, North America and North Atlantic (Haywood et al., 2010). There was only one North American Brewer station (Saturna Island) in the path of the plume from Sarychev eruption. The record shows SO_2 columns of 8.6 DU detected on 19 June 2009 and 3.7 DU on 20 June 2009. This volcanic eruption is not investigated any further in this paper. The next eruption on the list, Eyjafjallajökull in Iceland (63.63^o N, 19.62^o W, 1666 m asl, from 14 April to 23 May 2010), resulted in interruption of the air traffic over NW Europe (e.g. Flemming and Inness, 2013). The fifth eruption Grímsvötn 2011 (64.42^o N, 17.33^o W, 1725 m asl, 21 May 2011) was studied by Flemming and Inness (2013), and by Moxnes et al. (2014). This eruption provided an interesting example of a clear separation of the volcanic SO_2 plume (transported mostly northwestward) while the fine ash was transported mostly southeastward. Unfortunately the volcanic plume did not overpass any Brewer station and therefore we do not include any results post Grímsvötn eruption. The sixth eruption recorded features the Nabro in Africa (13.37^o N, 41.70^o E, 2218 m asl) that occurred on 12-13 June 2011 (e.g., Bourassa et al., 2012; Sawamura et al., 2012; Clarisse et al., 2014). We present here a case study that described detection of the Nabro volcanic SO_2 plume over ground based stations. The plume was clearly detected by the Brewer instrument over Izaña (and poorly from space), then over Taiwan by both Brewer and satellite instruments, and finally at Mauna Loa, Hawaii (mostly by the Brewer instrument). The seventh eruption was Tolbachik, Russia (55.83^o N, 160.33^o E, 3.611 m asl) on 27 November 2012 (e.g. Telling et al., 2015). As in the case of Grímsvötn, the plume has not passed over any Brewer station that was verified by trajectory analysis. The next eruption on the list is the volcanic eruption from Bárðarbunga, Iceland (64.64^o N, 17.56^o W, 2005 m asl) that was observed between 31 August 2014 and 28 February 2015 (e.g. Schmidt et al., 2015). This last eruption, although not yet rated on the VEI scale, has been extensively studied in view of the observed increased SO_2 concentrations that have been observed all the way through troposphere and reaching down to the surface in Europe (Ialongo et al., 2015; Schmidt et al., 2015).

The capability of the Brewer network to measure columnar SO_2 amounts above the local air pollution levels is also presented and discussed. The qualitative evidence that the plume can be detected in many single cases by the Brewer network has been quantitatively tested by calculating correlation coefficients with collocated satellite data. Only in the case of Kasatochi 2008 eruption it was possible to test the sensitivity of SO_2 abundance measured by the Brewers and from space. Correlations between the Brewer and collocated satellite SO_2 data from the Aura OMI and GOME-2 are presented in the section 3 where the correlation coefficients were found to be statistically significant at a confidence level of 99%. For the other eruptions unfortunately due to the sparsity of satellite data no firm conclusions can be drawn as discussed in section 3.

The paper is structured in the following order, Section 2 describes the data sources and the methods of analysis of the columnar SO_2 measurements by the Brewer spectrophotometers (hereinafter simply referred to as the "Brewers"). Section 3 presents the analysis of the Brewer measurements during four of the volcanic eruptions listed in Table 1, along with satellite data and dynamic volcanic plume transport simulations. The conclusions are provided in Section 4.

2 Data and methods

4

2.1 Ground based data

Sulfur dioxide in the atmosphere can be measured from ground-based instruments, by instrumentation onboard the spacecraft and can be estimated with help of models. The Brewer is an automated, diffraction-grating spectrophotometer that provides observations of the sun's intensity in the near UV range. The spectrophotometer measures the intensity of radiation in the ultraviolet absorption spectrum of ozone at five wavelengths (306.3 nm, 310.1 nm, 313.5 nm, 316.8 nm and 320.1 nm) with a resolution of 0.6 nm. These data are used to derive the total ozone column (Kerr et al., 1980). Because sulfur dioxide has strong and variable absorption in this spectral region, the Brewer spectrophotometer has additionally been proposed to derive SO_2 columns (Kerr et al., 1980). About two hundred Brewer spectrophotometers around the world contribute high-precision ozone data to the global ozone monitoring network (Kumharn et al., 2012). The existing Brewer network also delivers frequent SO_2 columnar measurements as well, which can be used for analyses, but with caution. This is because the signal to noise ratio for the SO_2 absorption is usually quite low and therefore well calibrated instruments are required to monitor nominal SO_2 columnar amounts (Koukouli et al., 2014). Details on the method with which SO_2 is measured by the Brewer spectrophotometer can be found in Kerr et al. (1980; 1985; 1988) and De Backer and De Muer (1991). According to Fioletov et al. (2016) the uncertainty of the Brewer direct sun (DS) SO_2 measurements is about 1 DU and is typically insufficient for air quality applications. A more accurate method (with an uncertainty as low as 0.13 DU) based on Brewer "group-scan" spectral direct sun radiation measurements at 45 wavelengths from 306 to 324 nm was developed (Kerr, 2002), but not implemented for routine operations due to its complexity (Fioletov et al., 2016). Although the Brewer instrument has difficulties in detecting low columnar SO_2 concentrations, in extreme cases, such as volcanic eruptions, the SO_2 levels typically rise well above the instrumental noise and can be identified with the Brewer instrument as shown in this paper and in Fioletov et al. (1998).

Before proceeding to the analysis of Brewer measurements, the methodology to derive columnar SO_2 is first presented. To determine ozone and SO_2 column amounts, the measured raw photon counts at the five operational channels in the Brewer instrument are converted to radiation intensity. The Beer-Lambert absorption law is applied at each wavelength λ, and the measured intensity of direct sunlight is given by the formula:

$$\log I_\lambda = \log I_{0\lambda} - \beta_\lambda \mu_R - \delta_\lambda \mu_p - \alpha_\lambda O_3 \mu - \sigma_\lambda SO_2 \mu \qquad (1)$$

where I_λ is the measured radiation intensity at wavelength λ, $I_{0\lambda}$ is the measured extra-terrestrial spectrally resolved intensity at λ, β_λ is the Rayleigh scattering coefficient at λ, δ_λ is the particulate scattering coefficient at λ, α_λ is the ozone absorption coefficient (cm^2/molecules) at λ, O_3 is the total ozone column (molecules/cm^2), σ_λ is the SO_2 absorption coefficient at λ, SO_2 is the column amount of sulfur dioxide, μ_R, μ_p and μ are the optical path lengths (air masses) corresponding to the effective heights of molecules, particles, and ozone respectively.

According to the Brewer retrieval algorithm, the following ratios are formed:

$$F = F_0 - \Delta\beta\mu_R - \Delta\alpha O_3\mu \qquad (2)$$

5

and

$$F' = F_0' - \Delta\beta'\mu_R - \Delta\alpha'O_3\mu - \Delta\sigma'SO_2\mu \tag{3}$$

where F is the weighted ratio of direct sun measurements at 4 (or 6 for double Brewer) spectral channels, $F = logI_2 - 0.5\,logI_3 - 2.2\,logI_4 + 1.7\,logI_5$, F_0, $\Delta\beta$, and $\Delta\alpha$ are the same linear combinations for $logI_{0\lambda}$, β_λ, and α_λ. The F' is the SO_2 ratio, $F' = logI_1 - 4.2\,logI_4 + 3.2\,logI_5$ and F_0', $\Delta\beta'$, $\Delta\alpha'$ and $\Delta\sigma'$ the corresponding linear combinations for $logI_{0\lambda}$, β_λ, α_λ, σ_λ. Both of these functions have weights which eliminate the effects of particulate scattering, while the function F is weighted to remove SO_2 absorption effects as well. The extra-terrestrial constants F_0 and F_0' are determined from a long series of intercomparison measurements as well as zero air mass (μ) extrapolations.

The total ozone column is determined by the formula

$$O_3 = \frac{F_0 - F - \Delta\beta\mu_R}{\Delta\alpha\,\mu} \tag{4}$$

and the SO_2 by the formula

$$SO_2 = \frac{1}{A}\left(\frac{F_0' - F' - \Delta\beta'\mu_R}{\Delta\alpha'\,\mu} - O_3\right) \tag{5}$$

where A is the ratio of the SO_2 absorption coefficient to the O_3 absorption coefficient, $A = 2.44$.

From the above described operational Brewer algorithm it is evident that the estimation of columnar SO_2 is the result of the difference between two columnar terms $(O_3 + SO_2)$ and O_3. Both terms have uncertainties (weighting functions, calibrations, random errors, systematic errors). Systematic negative values could be the result of a systematic offset in the measurements that can be related to the calibration of the instrument (usually optimized only for the ozone measurements). Randomly varying positive and negative values around zero, suggest that the signal of SO_2 is small (and thus the difference of two terms should be close to zero) but since both terms have uncertainties, negative values are possible indicating that the amount of SO_2 in the atmosphere is below the detection limit of the instrument and could be considered as noise. In this work we have repeated our analysis excluding the negative values and the results remained the same i.e. a positive increase after a major volcanic eruption was confirmed as described in the following sections. Finally, we need to point out that perturbations by ash present in the volcanic plumes have been shown not to affect the Brewer SO_2 measurements. This is based on the result of Pappalardo et al., 2013 paper based on EARLINET observations following the Eyjafjallajökull eruption in which they found that the Ångström exponent of the volcanic ash optical depth is close to zero. This indicates that the effect of ash in the UV and visible region on the aerosol extinction is almost independent from wavelength. The Brewer SO_2 measurements taken in a narrow wavelength band in the UV are therefore not expected to be influenced by the presence of volcanic ash considering the weights already applied in the operational Brewer algorithm.

In this study we analysed twenty three stations located in Europe, six Brewer stations in Canada, two in the USA and one in Taiwan, whose geographical positions are shown in Figure 1. SO_2 measurements were averaged over a large number of instruments and datasets during periods following volcanic eruptions. Random errors in the measurements of individual Brewer stations are reduced significantly by the averaging processes to calculate regional means.

Daily SO_2 columns at Churchill, Goose, Edmonton, Regina, Saturna Island and Toronto in Canada, Taipei in Taiwan, Boulder and Mauna Loa in the US were obtained from the World Ozone and Ultraviolet Radiation Data Centre (WOUDC; http://www.woudc.org/) and the NOAA-EPA Brewer Spectrophotometer UV and Ozone Network (NEUBrew; http://www.esrl.noaa.gov/gmd/grad/neubrew/). The data have been checked for quality assurance/quality control by the individual data providers. It is important to note the participation of the most of the European Brewer data providers in a recent EU COST Action (EUBREWNET, http://www.eubrewnet.org/cost1207/) programme. Its focus is at establishing a coherent network of European Brewer Spectrophotometer monitoring stations in order to harmonise operations and develop approaches, practices and protocols to achieve consistency in quality control, quality assurance and coordinated operations.

In our analysis only direct sun (DS) measurements satisfying the following criteria have been used: a Brewer DS measurement was included if and only if for every measurement cycle of 5 sets of measurements (from which also total columnar ozone is derived) the standard deviation of O_3 and SO_2 was less than 2.5 DU, the total columnar ozone was between 250 DU and 450 DU, and the solar zenith angle was less than 73.5 degrees. To exclude erratic data of SO_2 from our analysis, values exceeding ±6σ of the mean of all SO_2 individual Brewer measurements were considered erroneous and were not included in the calculations. Therefore the range of analysed values were limited to a maximum of ± 35 DU for an individual measurement (i.e. 6σ, with σ being equal to 5.8 as estimated from all available sub-daily SO_2 values). Then we calculated daily SO_2 columns at each station only if at least three individual measurements passed these criteria for each day. Brewers are useful because they provide more than one observation per day. For plumes which change rapidly, more than one observation per day would be useful, especially to complement satellites which typically have just one local overpass.

Daily sulfur dioxide (SO_2) columns were analysed in four bimonthly periods, namely August-September 2008, April-May 2010, June-July 2011 and September-October 2014, which include the volcanic eruptions of Kasatochi (2008), Eyjafjallajökull (2010), Nabro (2011) and Bárðarbunga (2014), respectively. For the case of Kasatochi, Eyjafjallajökull and Bárðarbunga we analysed daily SO_2 columns at 30 sites (listed in Table 2), while for the case of Nabro, whose impact was mostly seen over low latitudes in the N.H. (e.g., Bourassa et al., 2012), we analysed SO_2 columns at three low latitude sites in the Northern Hemisphere, namely Izaña, Mauna Loa and Taipei.

Only for the case of the Bárðarbunga eruption in 2014, the columnar SO_2 measurements over Europe were also compared with surface SO_2 measurements from ground level based European stations. The surface SO_2 data

7

were obtained from the European Environment Agency databases (AirBase; http://www.eea.europa.eu/data-and-maps/data/aqereporting-1#tab-european-data) covering the bimonthly period September-October 2014. Only rural background stations, i.e stations in class 1-2 according to the Joly-Peuch classification methodology for the surface sulfur dioxide (Joly and Peuch, 2012), located at a distance of less than 150 km from the nearest Brewer station, were used in the analysis. A total of 7 stations in Europe (see Table 3) fulfilled the above mentioned criteria and were included in the current analysis. Observed data from the AirBase network were available in hourly resolution, from which we calculated daily surface SO_2 values. We note here that SO_2 in the troposphere over Western Europe is very low (e.g. Zerefos et al., 2009; Wild, 2012) and therefore plumes from volcanic eruptions are easy to detect against a lower background level.

2.2 Satellite Data

The columnar SO_2 records from remote sensing spectrophotometers over Europe, Canada, USA and Taiwan were compared with space-borne measurements from a) the Ozone Monitoring Instrument (OMI) aboard the EOS-Aura (e.g. Ialongo et al., 2015) satellite and b) the Global Ozone Monitoring Experiment-2 (GOME-2) aboard the MetOp-A (e.g. Rix et al., 2009) satellite. We use MetOp-A instead of MetOp-B because it covers a longer time period. Both OMI and GOME-2 satellite SO_2 data products were downloaded from the Aura Validation Data Center (AVDC) (available from: http://avdc.gsfc.nasa.gov/index.php?site=245276100). GOME-2 level 2 overpass data have been processed with the GOME Data Processor (GDP) version 4.7. We analysed station overpass data for the various mid-latitude stations listed in Table 2 and for the low latitude stations at Mauna Loa, Izaña and Taipei. The available OMI version 1.2.0 overpass (collection 3) data analysed in this study include pixels within 50 km radius from the nearest Brewer site and is not affected by OMI row anomalies. The available GOME-2 level 2 overpass data include pixels within 100 km radius from the Brewer sites.

For the case of OMI, the SO_2 data are provided from October 2004 to the present. There are four SO_2 products: (1) the Planetary Boundary Layer SO_2 column (PBL), corresponding to a centre of mass altitude (CMA) at 0.9 km, (2) the lower tropospheric SO_2 column (TRL) corresponding to CMA of 2.5 km, (3) the middle tropospheric SO_2 column (TRM), usually produced by volcanic degassing, corresponding to CMA of 7.5 km, and (4) the upper tropospheric and stratospheric SO_2 column (STL), usually produced by explosive volcanic eruptions, corresponding to CMA of 17 km. Details on OMI SO_2 columns can be found in various studies (Levelt et al., 2006; Yang et al., 2007; Fioletov et al., 2011; McLinden et al., 2012; Fioletov et al., 2013; Li et al., 2013; Ialongo et al., 2015). In this study, we primarily made use of the product for the middle tropospheric SO_2 column (TRM) following the recommendation that the TRM retrievals should be used for volcanic degassing at all altitudes, because the PBL retrievals are restricted to optimal viewing conditions and TRL data are overestimated for high altitude emissions (>3km) (Ialongo et al., 2015). Also, we analysed the STL data which are intended for use with explosive volcanic eruptions where the volcanic cloud is placed in the upper troposphere / stratosphere. The standard deviation of TRM retrievals in background areas is reported to be about 0.3 DU in low and mid-latitudes and about 0.2 DU for the STL retrievals. This is similar to the standard deviations (indicative of typical uncertainties of the measurements) that we find for the TRM and STL retrievals in the four bimonthly periods under this study. For the best data quality, we used data from the scenes near the centre of the OMI swath (rows

4-54) as recommended by Ialongo et al. (2015) who found that data from the edges of the swath tend to have greater noise.

For GOME-2, we analysed the total SO_2 columns from April 2007 to the present. The standard deviation found in our study for the GOME-2 retrievals is the order of 0.4 DU. We analysed satellite SO_2 measurements whenever O_3 column was between 250 and 450 DU and solar zenith angle was less than 73.5 degrees. We used SO_2 data defined as having a cloud radiance fraction (across each pixel) less than 50%, as they were found to have smaller standard deviation than all sky data. Moreover, a range of SO_2 values between -35 and 35 DU was used to screen for outliers. In cases of multiple daily data matched to the station overpass, all available measurements within a radius of 50 (100) km from the Brewer site in the case of OMI (GOME-2) are averaged.

Finally, both for the satellite and the Brewer data we have considered that during a ten-day period prior to any eruption both the surface and the satellite data sets represent a baseline reference from which subsequent departures after the eruption should be tested as to their significance. Therefore, we calculated averages and standard deviations (σ) of departures from the unperturbed pre-volcanic period, for the three studied periods of volcanic importance at each station, only if at least 25 daily values were available. The bimonthly averages for each station in the examined periods are presented in Table 4a. Table 4b shows the mean and standard error (σ/√N) of all bimonthly averages in each studied volcanic period. Averaging the departures from the pre-volcanic baseline for all Brewer stations and for all bimonthly periods gives a mean SO_2 columnar departure of 0.10 ± 0.03 DU. This estimate is on the same order of magnitude as the corresponding statistics for OMI (TRM) SO_2 column departures (0.05 ± 0.02 DU), OMI (STL) (0.04 ± 0.01 DU) and that measured by GOME-2 (0.09 ± 0.02 DU). The standard deviation of the bimonthly averages relative to their baselines, which was calculated from a large sample of data, was taken here as an approximation of the typical uncertainties in the columnar SO_2 measurements performed by the group of Brewers, OMI and GOME-2 instruments following volcanic eruptions.

2.3 Modelling tools

Dispersion of volcanic emissions is simulated with the Lagrangian transport model FLEXPART (Stohl et al., 2005; Brioude et al., 2013). The model is driven by hourly meteorological fields from the Weather Research and Forecasting (WRF) atmospheric model (Skamarock et al., 2008) at a horizontal resolution of 45×45 km. The initial and boundary conditions for the WRF model are taken from the National Center for Environmental Prediction (NCEP) final analysis (FNL) dataset at 1°×1° resolution. The sea surface temperature (SST) is initialised from the NCEP 1°×1° analysis. A total of 40,000 tracer particles are assumed for each release in FLEXPART simulations. The use of 1-hourly WRF meteorological fields at 45x45 km spatial resolution allows a more detailed representation of the volcanic plume dispersion but implies also a significant increase in computational time. To overcome this computational time cost, source-receptor relationships between station measurements and volcanic activity are also analysed with the use of HYSPLIT model trajectories (Stein et al., 2015) of long range transport driven by the 3-hourly meteorological dataset Global Data Assimilation System (GDAS) at a resolution of 1°×1°.

3 Results and discussion

3.1 The 2014 Bárðarbunga case

Bárðarbunga was continuously active during September – October 2014 but it was only during 18-26 September when meteorological conditions favoured transport towards Europe as shown by back trajectories analyses. A detailed description of the transport of Bárðarbunga plumes towards the station of Hohenpeissenberg is provided using the FLEXPART Lagrangian particle dispersion model offline coupled with the WRF_ARW atmospheric model. The simulation period is 18-26 September 2014. We assume a constant SO_2 release rate of 119 kilotons per day as reported by Gíslason et al. (2015) from near the source SO_2 measurements during the first weeks of the eruption. Similar emission rates are also suggested by Schmidt et al. (2015) through comparisons between NAME simulations (UK Met Office's Numerical Atmospheric-dispersion Modelling Environment) and OMI satellite retrievals. The emission height is set between 0 and 3500 m above ground level, consistent throughout the simulation period. The establishment of an anticyclonic flow over the British Isles on 21 September 2014 (not shown here) resulted in the separation of the volcanic SO_2 field into two distinct plumes (Figure 2a). On 22 September the primary plume (plume 1) becomes stagnant over the topographic barrier of the Alps (Figure 2b). The secondary plume is advected southwards by the intense northerly winds over the North Sea. The two plumes overlap at about 09:00-11:00 UTC. Taking a closer look at the surface SO_2 values sampled during this event by surface air quality stations in the Netherlands, several days of enhanced SO_2 were discovered, which indicate an area of stagnation or blocking of the flow. Trajectory calculations performed at the Royal Netherlands Meteorological Institute (KNMI) correspond well to the calculations shown in Figure 2, but also show that the air parcels stayed over Northern Europe for some time after a very fast flow over the North Sea, which agrees with the spikes found in the surface SO_2 records observed over the Netherlands during a period of several days.

The high SO_2 concentrations, which were recorded almost simultaneously at stations over Europe in various sites during the period 21-29 September 2014, are thus associated with the activity of Bárðarbunga volcano (Ialongo et. al., 2015; Table A1 see Appendix A). This is also supported by the back trajectories analysis performed with the HYSPLIT dispersion model that is shown in Figure 3. All back trajectories start at 12:00 UTC on the day of maximum SO_2 observations for each one of the Brewer stations and indicate that the arrival of air masses originated from Iceland.

As shown in Figure 4a, the SO_2 plume was detected by the Brewer instruments located in the passage of the volcanic SO_2 plume and from different ground based networks. However, no co-incident measurements were available from the OMI and GOME-2 overpasses at the time of the high SO_2 excursions. Also it should be noted here that no enhanced SO_2 columns were detected by the Brewers located outside of the geographical area covered by the volcanic plume (Fig. 4b). In all volcanic cases we have applied a criterion according to which each daily average from either OMI or GOME-2 should be calculated if and only if more than half of the individual overpasses had data at a given day.

The eruption took place at the beginning of September 2014 and several European countries experienced high concentrations of SO_2 at ground level during the rest of September. Figure 5 shows the response of ground-level AirBase stations under the plume located within 150 km from the nearest Brewer station plotted together with the co-incident Brewer SO_2 column measurements. Interestingly, it suggests that the highest amount of the SO_2

10

column measured by the majority of the Brewers during 21 September 2014 due to the volcano reached the surface with a time lag of about one day. The high volcanic concentrations were successfully measured by the ground-based Airbase network. Due to strong European efforts over the last decades to reduce SO_2 emissions, high concentrations of SO_2 are now quite rare in Western Europe (e.g. Vestreng et al., 2007) except in the areas affected by industrial or shipping emissions. In-situ air quality stations observed high values of SO_2 at the ground level in the coast of France, in the United Kingdom, the Netherlands and Germany between 21 and 25 September 2014. This all points towards a volcanic episode with a large spatial extent.

As can be seen from Figure 4a, the highest SO_2 column departures from the pre-volcanic baseline were observed from 21 to 22 September 2014. The mean SO_2 column measured by the Brewers under the plume was 2.4 ± 0.8 DU, which was five times greater than the mean column of SO_2 measured by the Brewers outside of the plume (-0.1 ± 0.1 DU) by 2.5 DU on average. The "error bars" show the standard deviation of the daily SO_2 values of all stations during the non-perturbed 10 day period prior to the volcanic eruption. These differences provide rough estimates of the additional SO_2 loading induced by the volcanic eruption over Europe which exceeds 3σ. Comparison between satellite data and Brewer are limited for interpretation because satellite measurements are sparse, represent an average SO_2 column over a relatively large satellite pixel, while the Brewer observations are designed to provide a local point measurement. In spite of the sparsity of OMI observations post Bárðarbunga volcanic eruption, satellite data were used for assimilation in the SO_2 analyses and forecasts produced with the MACC (Monitoring Atmospheric Composition and Climate) system (http://atmosphere.copernicus.eu/). This near-real-time forecasting system assimilates satellite observations to constrain modelling forecasts (Inness et al., 2015; Flemming et al., 2015). The OMI instrument aboard the AURA satellite provided information about concentrations of volcanic SO_2 emitted by the Icelandic Bárðarbunga volcano on 20 September; these observations were assimilated in 2014 by the MACC system in cases of volcanic eruptions, i.e. when OMI values exceeded 5 DU. As shown in Figure 6 (the charts of total column SO_2 are taken from the website http://atmosphere.copernicus.eu/) the subsequent forecasts capture the transport of the plume of volcanic SO_2 southward, while spreading over the continent on 21 and 22 September. The plume stretched all the way from Finland through Poland, Germany and France, to southern England. A parallel forecast, for which no OMI data were used (Fig. 6, right), did not show any elevated SO_2 values, confirming that 'normal' emissions of SO_2 (including shipping and industrial activities) could not explain the observed situation.

Finally, it should be mentioned here that the thin aerosol layer that has been detected by the PollyXT lidar (Engelmann et al., 2015) over Leipzig at around 2-3 km on 23 and 24 of September 2014 was mostly associated with volcanic ash advection (Figure 7). A corresponding cluster analysis of all 155 hourly HYSPLIT back trajectories during this period and for the heights of the layer detected by the lidar (~2.5-3.5km) is shown in Figure 8. The increased wind shear that is evident between these heights does not allow a robust characterization of the air masses. However, the source contribution of about 20% from Icelandic air masses supports the volcanic origin of the detected plume. During volcanic eruptions, ash and SO_2 may be injected to different altitudes and may follow different trajectories for long-range transport. EARLINET lidars can provide alerts on volcanic ash dispersion over Europe, especially when the systems are employed with depolarization capabilities (e.g. Pappalardo et al., 2013). For the Brewer network capabilities and the Hohenpeissenberg station, Figures 7

11

and 8 demonstrate that similar approach can be applied to contribute towards an early warning synergistic tool, as evidenced in the Bárðarbunga case study. The role of the Brewer stations in this system will be the early detection of SO_2 plumes transported over continental areas that would trigger the associated forecasting systems (models and networks).

3.2 The 2011 Nabro Volcano plume

A major eruption of Mt. Nabro, a 2218 m high volcano on the border between Eritrea and Ethiopia (13.37° N, 41.7° E), occurred on 12–13 June, 2011. The volcanic eruption injected ash, water vapour and an estimated 1.3–2.0 Tg of SO_2 into the upper troposphere and lower stratosphere (Fairlie et al., 2014 and references therein). In the first phase of the eruption, the main transport pattern of emitted SO_2 followed the strong anticyclonic circulation over the Middle East and Asia associated with the Asian summer monsoon at that time of year (Clarisse et al., 2014 and references therein). In the first month after the eruption stratospheric aerosols were mainly observed over Asia and the Middle East, and by day 60 covered the whole Northern Hemisphere. Estimated aerosol altitudes from various instruments were between 12 and 21 km (Clarisse et al., 2014). By July 2011 Nabro had cumulatively emitted 5 to 10 percent of what was released by Mount Pinatubo in 1991 (~20 Tg) ranking it among the largest SO_2 emissions in the tropical stratosphere (up to at least 19 km) since Pinatubo (Krotkov et al., 2011). Sulfur dioxide signals of volcanic origin were detected both by Brewer and satellite measurements over East Asia where the volcanic SO_2 plume was transported, as demonstrated in Figure 9 and 10a. Measurements were taken by Brewer in Taipei, Taiwan, Asia. This is also evident from the back trajectories analysis performed with the HYSPLIT dispersion model for Taipei (Taiwan) as shown in Figure 10a. The analysis indicates that the upper tropospheric air masses arriving at Taipei on June 19, when the peak in SO_2 is observed, originate from Africa.

The Nabro volcanic plume was mainly transported to the East Asia and was detected by various satellite instruments which provide better spatial coverage than the Brewers. A special case study focuses on discrepancies found between ground based and satellite observations of the volcanic SO_2 plume. Brewer located in Tenerife, Spain detected an increase in the SO_2 column, which was not clearly detected by the OMI and GOME-2 satellite overpasses.

More specifically, Figure 10b shows back trajectories from Izaña (Tenerife) during 19-29 June 2011 at 15, 17.5 and 20 km heights. It appears that the upper tropospheric-lower stratospheric air masses arriving at Tenerife during 19-29 June originated from Nabro. In June 2011 the Nabro volcano ash plume was detected by the Micropulse Lidar (MPL) located at Santa Cruz de Tenerife (The Canary Islands, Spain). The volcanic plume height ranged from 12 km on 19 June to 21 km on 29 June (Sawamura et al., 2012). Figure 11 shows the columnar SO_2 departures from the unperturbed 10 day pre-volcanic baseline measured by the Brewer at Izaña following Nabro. The daily mean SO_2 ~~record~~ departures (Figure 11) show~~s~~ a ~~0.5~~0.3 DU increase at the beginning of the event (19 June), reaching ~~0.75~~0.6 DU on 29 June when the layer is found at higher altitude. The signal is not strong and is near the error of 0.5 DU estimated for SO_2 measurement (Stanek, personal communication) but the observations are consistent (independent of the ozone and air mass), since at Izaña about 100 O_3/SO_2 measurements per day are performed resulting to reduced standard errors associated with daily means as

12

compared to individual observations. The Langley calibration is tracked between calibrations by measurements of the internal lamp (Langley and lamp are shown in Supplement Figure S1). The increase in SO_2 due to the passage of the Nabro volcano plume over the Canary Islands is significant using both methods, showing an offset between them (Figure 11). It is clearly shown that the zero-calibrated Brewer SO_2 data do not compare well with OMI and GOME-2 levels. Instead, the Langley calibrated Brewer data compare better with OMI and GOME-2 retrievals.

In this case the Brewer at Izaña has been able to detect an SO_2 plume at high altitude from a volcano located 7,000 km from the Canary Islands, indicating that the Brewer network is sensitive enough to be incorporated in columnar SO_2 monitoring from volcanic eruptions in worldwide networks.

The case of the 2011 Nabro eruption shows an example of the importance of the Brewer spectrophotometers in measuring and detecting changes in SO_2 amounts in the atmosphere due to volcanic eruptions, in cases where signal in the satellite overpasses is low. This is true for the case of Izaña (Tenerife) where it appears that OMI and GOME-2 did not clearly detect increases in SO_2 column of volcanic origin between 19 June and 1 July as it was the case with the Brewer instrument (Figure 11). During some days between 19 June and 1 July, the Brewer SO_2 columns at Izaña rose above the uncertainty of 0.5 DU for the Brewer SO_2 measurements at this station, whereas the satellite SO_2 columns stayed mostly within the uncertainty of 0.4 DU estimated for OMI (TRM) and GOME-2 satellite retrievals.

These findings can provide clues on the detection limits of such events from a well calibrated Brewer network and a space-borne instrument. They need further clarification with more Brewers and a larger number of cases.

3.3 The case of the 2010 Eyjafjallajökull volcanic eruption

The Eyjafjallajökull volcano, Iceland (63.63$^{\rm o}$ N, 19.6215$^{\rm o}$ W; 1666 m asl) erupted explosively on 14 April 2010 and continued to emit ash and gas until 24 May (Flentje et al., 2010; Thomas and Prata, 2011; Stohl et al., 2011; Flemming and Inness, 2013). Despite the relatively modest size of the eruption, the prevailing wind conditions advected the volcanic plume toward the south-east leading to unprecedented disruption to air traffic in Western Europe. This caused significant financial losses for the airlines and highlights the importance of efficient volcanic cloud monitoring and forecasting. Results demonstrate that the eruption can be divided into an initial ash rich phase (14-18 April), a lower intensity middle phase (19 April until early May) and a final phase (4-24 May) where considerably great quantities both ash and SO_2 were released (Thomas and Prata, 2011).

Figure 12 shows the responses of Brewer stations under the volcanic SO_2 plume and the average of Brewer stations outside of the plume together with OMI and GOME-2 satellite observations. We determined 9 10 stations being under the plume in 2010 and 11 10 stations being outside of the plume based on the analysis of forward and backward trajectories of air masses following the volcanic eruption. The stations determined to be under the plume in 2010 (shown in Figure 12a) are Sodankylä Sodankÿla, Obninsk, Manchester, De Bilt, Uccle, Belsk, Reading, Hohenpeissenberg, Davos and Arosa. The stations determined to be outside of the plume are Vindeln, Oslo, Norrkoeping, Copenhagen, Uccle, Hradec Kralove, Aosta, Kislovodsk, Rome, Thessaloniki and

Athens (Figure 12b). ~~It may seem surprising that Uccle and De Bilt fall in different categories as they are closely located, but the data did not show increased SO₂ at Uccle during days when increased SO₂ was measured at De Bilt.~~

We should note here that volcanic clouds can be rather narrow plumes with diameters on the order of a few tens kilometers (e.g. Stohl et al., 2011; Webley et al., 2012; Thorsteinsson et al., 2012; Kristiansen et al., 2012; Kokkalis et al., 2013) and thus it is possible that a detected volcanic layer at a specific station is not observed by neighbouring stations. The measurements at Uccle and De Bilt that are located at a horizontal distance of 150 km are different during the Eyjafjallajökull episode and provide a formidable example. On 2 May 2010 the mean daily SO_2 is 5.8 DU at De Bilt and -0.2 DU at Uccle. As seen at the corresponding back trajectories for that day in Figure 13, air masses originating from Iceland arrive at De Bilt at heights 6-7 km and have been probably transporting the volcanic cloud over that station. In contrast similar back trajectories on the same day for the case of Uccle indicate transport of air masses from Iceland but at lower heights (3-4 km) that were probably not affected by the volcanic emissions. In another case of transport on 11 May 2010, Uccle was outside of the plume (see Figure 13) while the mean daily SO_2 for De Bilt was 0.9 DU. On 18 May 2010, both De Bilt and Uccle stations detected a volcanic cloud with SO_2 daily means of 1.7 DU and 1.2 DU respectively. To summarize, in spite the proximity of Uccle and De Bilt the transport heights and trajectories can have a different result in transporting volcanic gases.

In Table A1 of Appendix A, we present the dates when the examined Brewer stations were either under or outside of the volcanic SO_2 plume. Careful analysis of the trajectories of the volcanic plumes in 2010 and 2014 helped verify these analyses. The distinction between stations outside of the plume and stations under the plume was done as follows: whenever SO_2 at each station measuring exceeded 2 DU (2σ) back trajectories were calculated and the origin was compared to the location of the volcanic eruption. All these stations have been considered to be under the SO_2 plume. All other stations, for which columnar SO_2 amounts were within 2σ and were not originating from the area of the eruption, were considered to be outside of the volcanic SO_2 plume.

As we can see from Figure 12, the columnar SO_2 departures at stations located under the passage of the volcanic SO_2 plume exceeded 0.3 DU (reaching 1.5 DU in some cases) whereas at stations located outside of the plume, the columnar SO_2 departures did not exceed 0.3 DU. Moreover, during the explosive phase 2 there were three main periods in which the volcanic aerosol content was observed by EARLINET over Europe: 15-26 April, 5-13 May and 17-20 May. These periods were determined from measurements of the integrated backscatter at 532 nm in the volcanic layers (Pappalardo et al., 2013). We estimate high SO_2 columnar departures measured by the Brewers under the plume during ~~these three periods~~14 April and 23 May 2010 up to 6.0 DU (e.g. Arosa, 18 May 2016).

We note here that the ash cloud caused further disruptions to air transportation on 4-5 May and 16-17 May 2010, particularly over Ireland and the UK. The average SO_2 columnar departures measured by the Brewers under the plume in the UK (Manchester and Reading) during these two periods were estimated to 1.1 ± 0.3 DU and 1.5 ±

0.4 DU respectively. These amounts were higher than the amounts measured outside of the plume (-0.1 ± 0.2 DU and -0.1 ± 0.1 DU, accordingly) almost by 1.4 DU on average.

3.4 An eruption of larger scale importance – The 2008 Kasatochi case

The eruption of Kasatochi volcano on 7-8 August 2008 injected large amounts of material and SO_2 into the troposphere and lower stratosphere of the northern middle latitudes during a period of low stratospheric aerosol background concentrations. The Kasatochi volcano in the central Aleutian Islands of Alaska (52.17^o N, 175.51^o W) erupted three times between 2201 UTC on 7 August and 0435 UTC on 8 August 2008 (Bitar et al., 2010). Aerosols from the volcanic eruption were detected by lidar in Halifax shortly after the eruption (Bitar et al., 2010). The total mass of SO_2 injected into the atmosphere by the eruption is estimated at 1.7 Tg, with about 1 Tg reaching the stratosphere (above 10 km asl) (Kristiansen et al., 2010).

We have studied the columnar SO_2 amounts following the Kasatochi eruption in August 2008 from ground based and satellite data. Figure 13 14 shows the columnar SO_2 departures from the unperturbed 10 day pre-volcanic period over Canada/USA and Europe during the bimonthly period August-September 2008 as measured by the Brewers in comparison with the satellite observations by OMI and GOME-2.

The SO_2 plume was clearly seen by the Brewers in Canada/USA (Figure 13 14) and it was also detected by the majority of the Brewers in Europe with a delay by about 3 days. The total SO_2 columnar departures averaged over Canada during the period 12-20 August 2008 are estimated to 0.9 ± 0.2 DU. Accordingly over Europe, we estimate a mean SO_2 columnar departure of 1.0 ± 0.1 DU during the period 15-22 August 2008. This number gives a rough estimate of the average volcanic SO_2 column measured by the Brewers over Europe. We note here that the e-folding time of the Kasatochi SO_2, i.e. the time where the volcanic SO_2 amount decayed, was estimated to be about 8-9 days (Krotkov et al., 2010).

The high amounts of SO_2 and the variability of SO_2 measured in Europe by the Brewers after the eruption of Kasatochi in August 2008 are in line with OMI (TRM) and GOME-2 satellite observations. More specifically, OMI (TRM) shows an average SO_2 columnar departure of 0.5 ± 0.1 DU during the period 15-22 August 2008, OMI (STL) an average SO_2 columnar departure of 0.4 ± 0.1 DU and GOME-2 an average SO_2 columnar departure of 0.8 ± 0.1 DU respectively.

The Brewer data have been correlated with those from OMI and GOME-2. The Pearson's correlation coefficients between the three datasets were all highly statistically significant (>99%). The correlation between SO_2 from the Brewers and SO_2 from GOME-2 at 19 stations averaged over Europe is +0.86 (t-value = 12.54, p-value < 0.0001, N = 59). Accordingly, the correlation between Brewer and OMI (TRM) SO_2 data is +0.86 (t-value = 11.77, p < 0.0001, N = 50) and between GOME-2 and OMI (TRM) data is +0.92 (t-value = 16.32, p < 0.0001, N = 48). Same correlations are found for the Brewer-OMI (STL) and GOME-OMI (STL) data pairs. These correlations were calculated from 60 daily averages during the Kasatochi volcanic eruption in August-September 2008. The statistical tests gave significant results and verified the capability of the Brewers in detecting natural SO_2 emitted by volcanoes when the volcanic plume of SO_2 passes over the ground sites. We note here that there is a general

consistency between all three datasets (Brewers, OMI and GOME-2) on the changes in SO_2 column following the Kasatochi volcanic eruption.

Table 5 summarises the correlation coefficients between the mean columnar SO_2 measured by all Brewers over Europe and provided by the satellite products of OMI and GOME-2 during the globally extended Kasatochi event. The correlation coefficients have high statistical significance explaining more than 70% of the total variance between the columnar SO_2 measurements from ground and space in the case of Kasatochi. However, the discrepancies found between satellite and Brewer observations during the other volcanic eruptions could be impacted by sparsity of coincident measurements, and thus cannot confirm or deny Kasatochi case findings at high significance levels.

4 Conclusions

In this work we provide evidence that the current network of Brewer spectroradiometers is capable of identifying columnar SO_2 plumes of volcanic origin. The study is based on the results from the three largest volcanic eruptions (VEI $\geq$4) in the past decade when elevated SO_2 plumes have passed over Brewer stations in the Northern Hemisphere. The analysis included a fourth eruption, namely Bárðarbunga, because it has perturbed the SO_2 regime over large parts of Europe and extended from the free troposphere down to the surface. Back and forward trajectory analysis have been used to aid in identifying and selecting measurements taken under and outside of the volcanic SO_2 plume. When the plume was overpassing a site, the SO_2 signal was found to be quite high, exceeding 3σ of daily values relative to the average levels taken during the unperturbed measurements over ten days preceding each eruption. On the average the mean SO_2 columnar amount to be attributed to the volcano is estimated to be on the order of 2 DU as discussed in section 3. In addition to the Brewer network, comparisons were made with other instruments (e.g. surface SO_2 sensors) that were located under the volcanic SO_2 plumes. Moreover, satellite measurements of columnar SO_2 from OMI and GOME-2 collocated with the Brewer network were used for comparisons.

From the results discussed in section 3 some general remarks can be put forward concerning SO_2 levels and detection time after the eruption. Starting with the Kasatochi eruption, as it appears from Figure 1314, the plume can be detected 4 days after the eruption over Canada and the US and about 7 days over Europe with an average amplitude on the order of 2 DU compared to the unperturbed ten day pre-volcanic period (baseline). All estimates are based obviously on measurements taken under the plume. The Kasatochi eruption provided a formidable example for a volcanic SO_2 plume to be observed not only by the ground based instruments, but from space-borne as well (OMI and GOME-2). Relative to the undisturbed period before Kasatochi the amplitude of the signal is 2 DU for GOME-2 and 1.5 DU for OMI. The results for the other volcanic eruptions are similar for the Brewer network, but unfortunately because of the sparsity of satellite overpassing the Brewer stations the satellite data concur with those from the Brewers only in Kasatochi. Based on the above discussion it appears that currently no single network can independently and fully monitor the evolution of volcanic SO_2 plumes. Among a few reasons are lack of measurements during peak values, complications from meteorological events, ejection heights and exposure conditions. The evidence presented here points that combination of observations

16

from various instruments, aided by chemical transport models and operated in synergy could address such a complex issue.

The combination of the above discussed observation and modelling tools can assist in detecting existing volcanic plumes, but also in forecasting their evolution, which can have importance not only to the air traffic warning but also to air pollution in the lower layers of the atmosphere. Therefore, an automated source receptor modelling tool could be proposed as follows: a modelling system based on FLEXPART and HYSPLIT backward-trajectory simulations could be automatically triggered whenever high SO_2 values are detected at a Brewer station above a specific threshold (e.g. 3σ of station's daily values) or when a lidar instrument detects highly depolarizing layers that were not advected from a geographical location over a desert. The operational use of such a synergistic activity could provide near-real-time and forecasting information on the evolution of volcanic episodes and also develop a comprehensive database of measurements useful to improve model forecasts. This new well-tuned and organised synergistic activity of monitoring networks, observations and modelling from ground and space could create a challenging monitoring tool for volcanic and other extreme emissions, which form the basis towards a new regional SO_2 columnar forecasting facility.

5 Data availability

SO_2 columns at Churchill, Goose, Edmonton, Regina, Saturna Island and Toronto in Canada, Taipei in Taiwan, Boulder and Mauna Loa in the US were obtained from the World Ozone and Ultraviolet Radiation Data Centre (WOUDC; http://www.woudc.org/, last access: 10 October 2016) and the NOAA-EPA Brewer Spectrophotometer UV and Ozone Network (NEUBrew; http://www.esrl.noaa.gov/gmd/grad/neubrew/, last access: 10 October 2016). OMI and GOME-2 satellite SO_2 data products were downloaded from the Aura Validation Data Center (AVDC) (available from: http://avdc.gsfc.nasa.gov/index.php?site=245276100, last access: 10 October 2016). Surface SO_2 concentrations over Europe were acquired from the European Environment Agency databases (AirBase) (http://www.eea.europa.eu/data-and-maps/data/aqereporting-1#tab-european-data, last access: 10 October 2016).

Appendix A

Table A1. Dates in which the Brewers were determined to be under or outside of the volcanic SO_2 plume, based on analysis of back trajectories of the volcanic plumes in 2010 and 2014. The distinction between stations outside of the plume and stations under the plume was done as follows: At each station measuring SO_2 exceeding 2 DU (2σ) we calculated back trajectories and found that their origin was at the volcanic eruption. All these stations have been considered to be under the SO_2 plume. All other stations, for which columnar SO_2 amounts were within 2σ and were not originating from the area of the eruption, were considered to be outside of the volcanic SO_2 plume. During the Kasatochi eruption all Brewers were considered to be under the volcanic SO_2 plume.

Station	LAT (deg)	LON (deg)	ALT (m)	2010	2014
Sodankylä	67.36	26.63	180	20/4	27/9 and 29/9

Formatted Table

(*) missing values are those possessing < 25 days of data in each bimonthly period, or no data.

10

Table 5. Correlation coefficients between the mean columnar SO$_2$ measured by the brewers in Europe and provided by the satellite products of OMI and GOME-2 during the volcanic eruptions of Kasatochi (2008), Eyjafjallajökull (2011) and Bárðarbunga (2014) for stations located under the volcanic SO$_2$ plume.

Europe	August-September 2008	April-May 2010	September-October 2014
Brewers and GOME-2	**0.86** [59] (p<0.0001)	**0.31** [54] (p=0.02336)	**0.44** [39] (p=0.00496)
Brewers and OMI (TRM)	**0.86** [50] (p<0.0001)	(*) [~~16~~23]	(*) [~~16~~15]
Brewers and OMI (STL)	**0.86** [50] (p<0.0001)	(*) [23]	(*) [15]
GOME-2 and OMI (TRM)	**0.92** [48] (p<0.0001)	(*) [~~15~~21]	(*) [15]
GOME-2 and OMI (STL)	**0.93** [48] (p<0.0001)	(*) [21]	(*) [15]

Bold: all the above correlations are significant at confidence level 95% or greater (t-test).
(*): missing correlations are those possessing less than 30 days of data in each bimonthly period. In brackets: number of pairs.

26
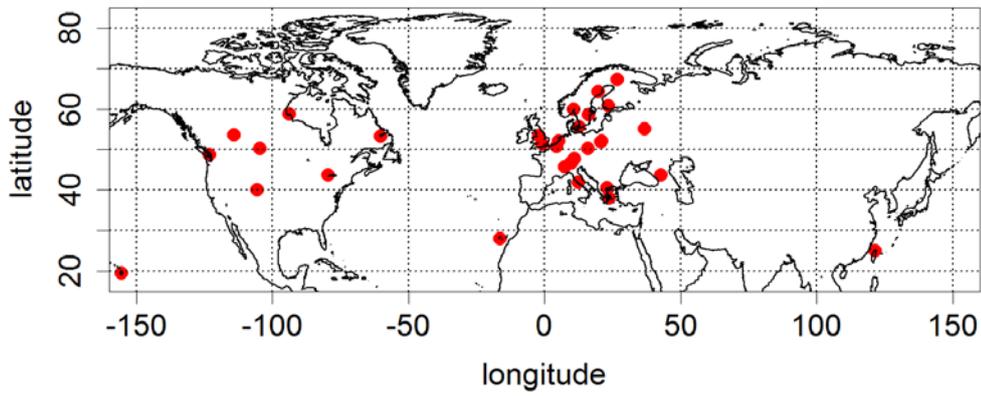

5   **Figure 1. All stations with accessible SO$_2$ column data from Brewers analysed in this study as listed in Table 2.**
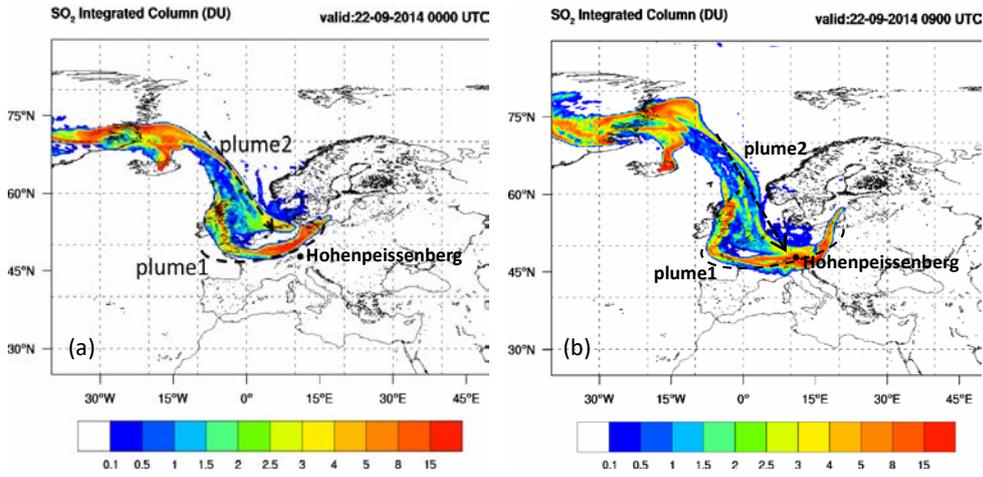

Figure 2. Integrated column of SO$_2$ (DU) from Bárðarbunga emissions as simulated with FLEXPART-WRF model, a) 22 September 2014 00:00 UTC; b) 22 September 09:00 UTC. Dashed lines indicate the orientation of the two distinct plumes overlapping over central Europe.

Bárðarbunga 120h backward trajectories (from Brewer Stations)
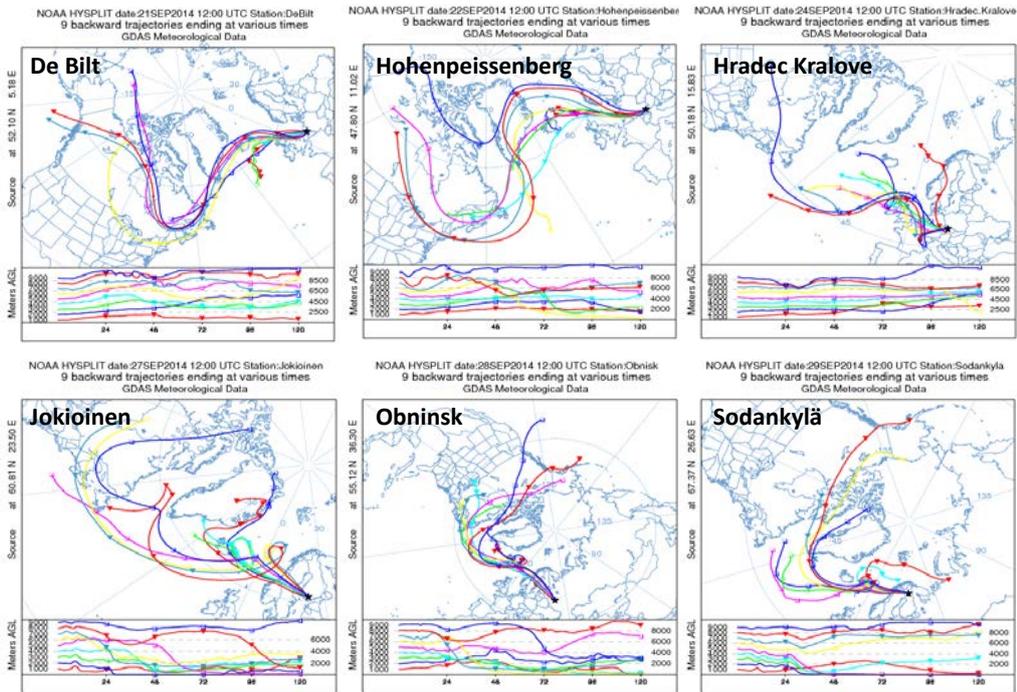

Figure 3. HYSPLIT 120 hours back trajectories of air masses arriving on the day of maximum SO₂ records for each one of the Brewer stations at De Bilt, Hohenpeissenberg, Hradec Kralove, Jokioinen, Obninsk and Sodankylä.

(a) **SO₂ column departures (September-October 2014)**

(b) **SO₂ column departures (September-October 2014)**

(a) SO₂ column departures (September-October 2014)

Brewers ● OMI (TRM) ◆ GOME-2 ▲

Europe (13 stations) under the plume

(b) SO₂ column departures (September-October 2014)

Brewers ● OMI (TRM) ◆ GOME-2 ▲

Europe (8 stations) outside of the plume
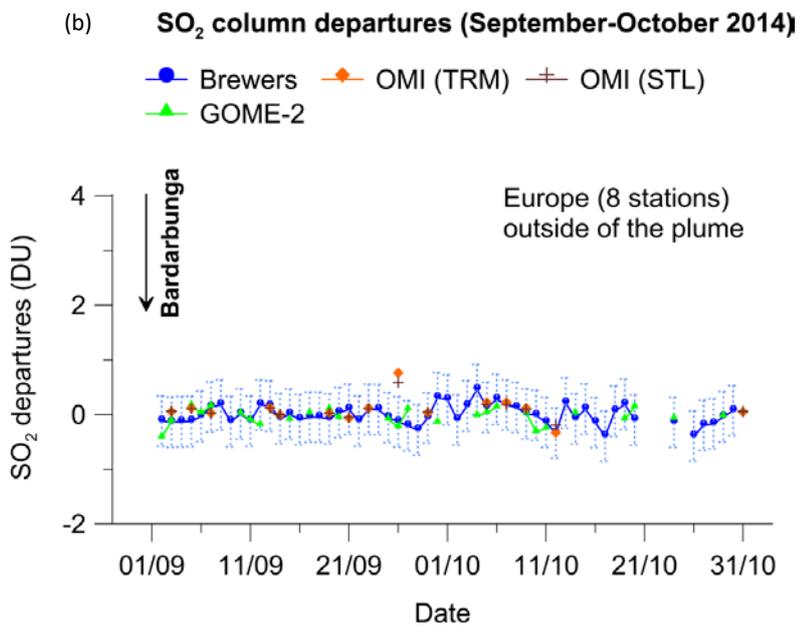

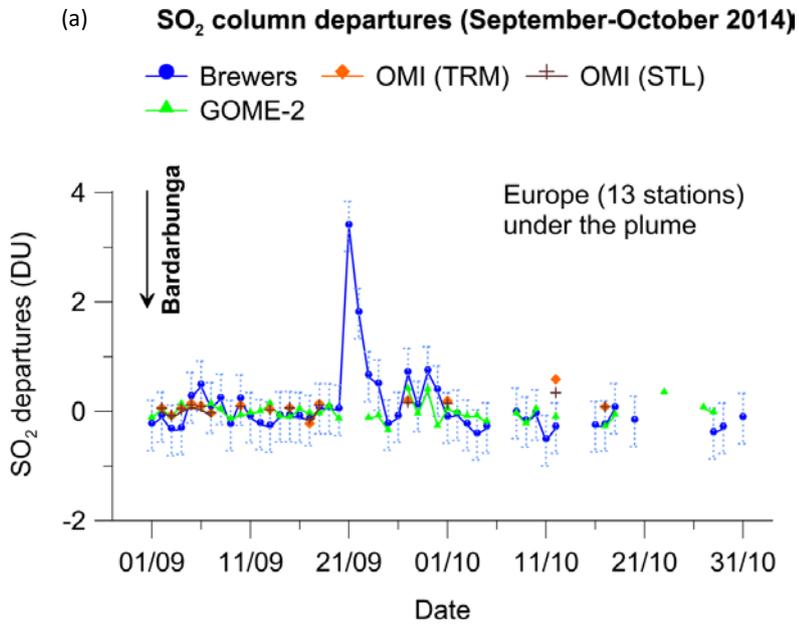

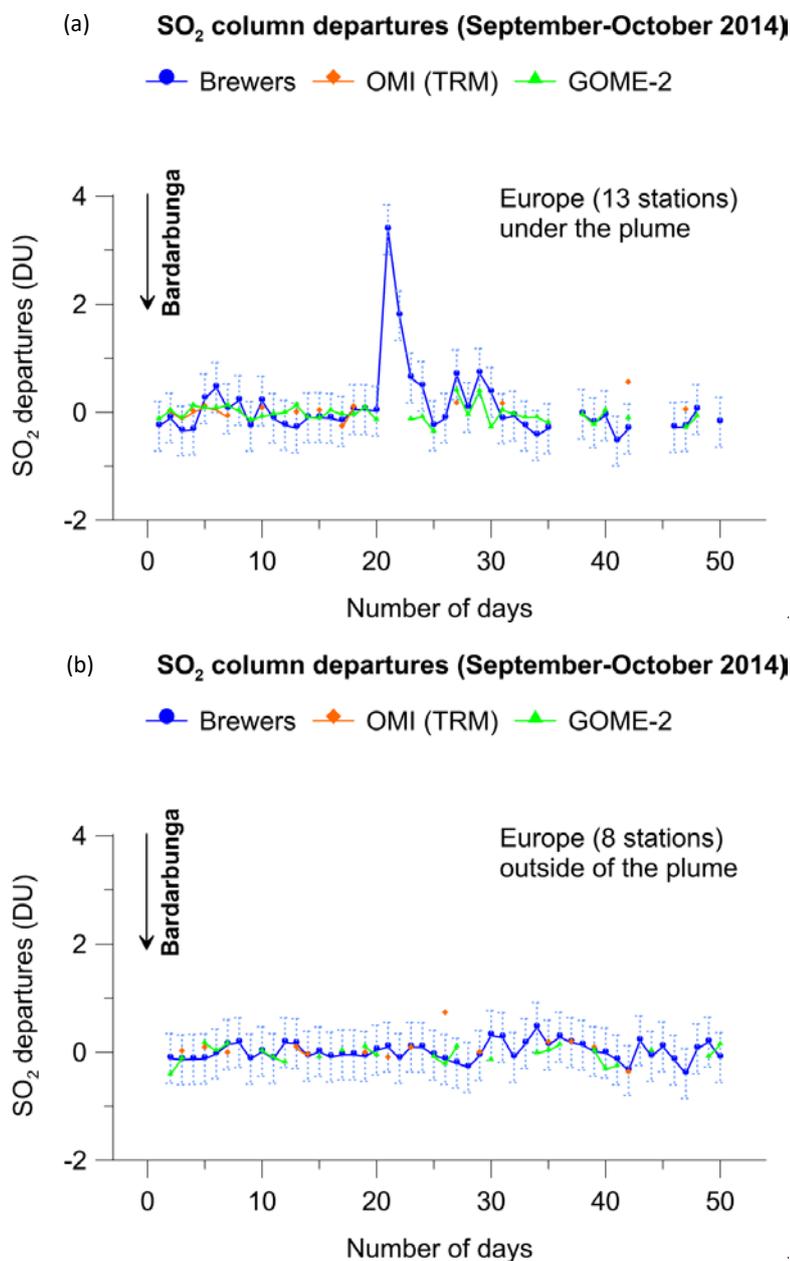

Figure 4. Mean SO₂ column departures from the unperturbed 10 day pre-volcanic baseline measured by Brewers, OMI (TRM, STL) and GOME-2 during September-October 2014 over Europe following the 2014 Bárðarbunga volcanic eruption for: (a) stations under the volcanic SO₂ plume, and (b) stations outside of the plume. The error bars for the Brewer observations show the standard deviation of all daily values during the unperturbed 10 day period prior to the volcanic eruption. Brewer stations under the plume are: Sodankylä~~Sodankÿla~~, Vindeln, Jokioinen, Oslo, Norrkoeping, Copenhagen, Obninsk, Manchester, De Bilt, Reading, Uccle, Hradec Kralove, Hohenpeissenberg and Aosta. Stations outside of the plume are: Warsaw, Belsk, Davos, Arosa, Kislovodsk, Rome and Athens. Each daily average from either OMI or GOME-2 was calculated if and only if more than half of the individual overpasses had data at a given day. The arrow marks the starting date of the eruption (beginning on 31 August 2014 which continued to be active throughout the whole bimonthly period and beyond).
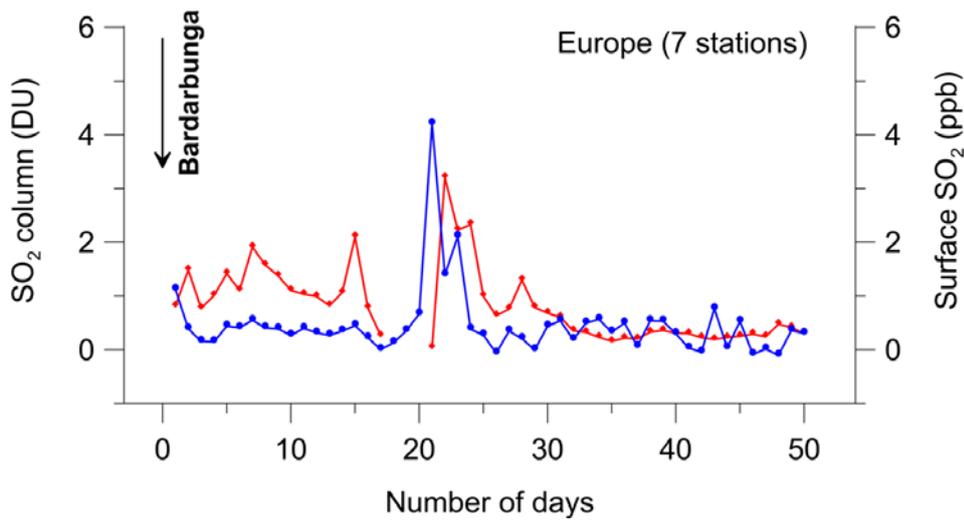

Figure 5. Mean surface SO₂ measured by Airbase class 1-2 stations located within 150 km from 7 nearest Brewer stations in Europe as listed in Table 3. The arrow marks the starting date of the eruption (beginning on 31 August 2014 which continued to be active throughout the whole bimonthly period and beyond).
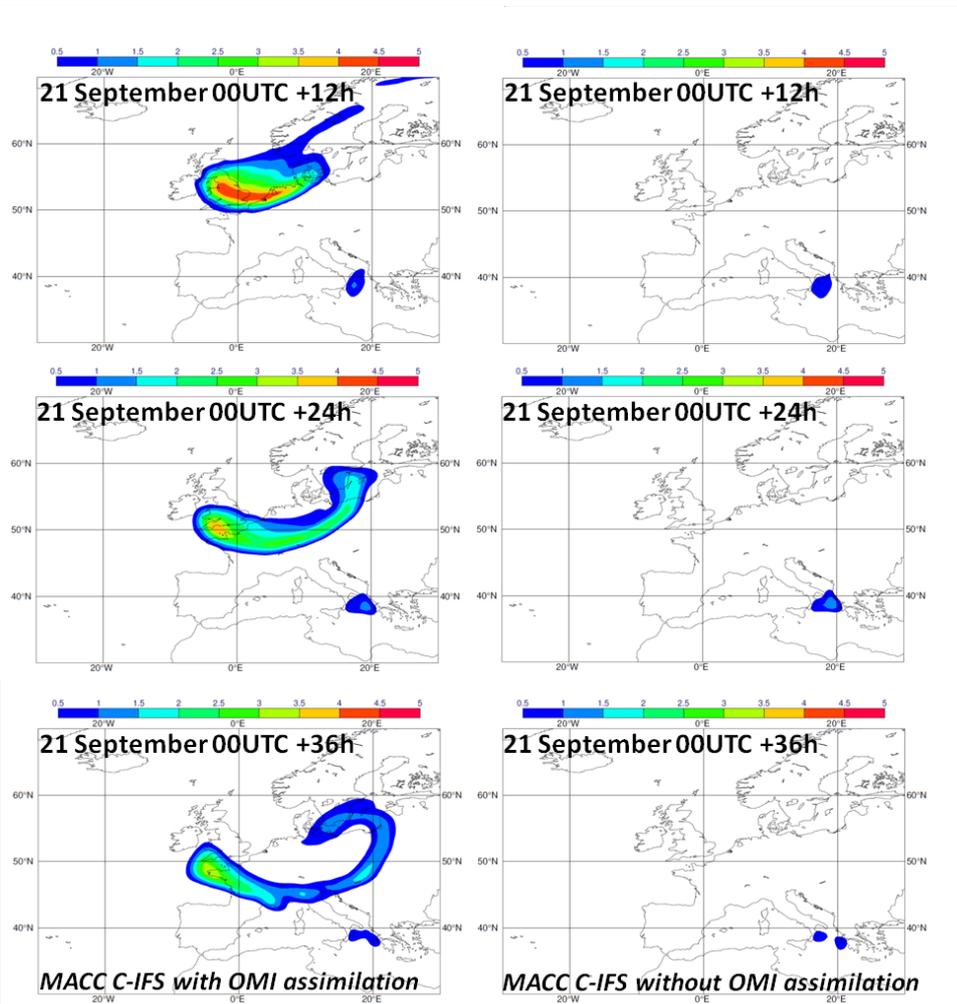

Figure 6. Charts of forecasted total column SO$_2$ produced within the MACC system for 21 September 2014 with OMI data assimilation (left) and without OMI data assimilation (right).

Figure 7. Range corrected signal at 1064 nm from the PollyXT lidar in Leipzig on 23 September 2014 (up) and 24 September 2014 (down). The red rectangular indicates the location of the volcanic ash layer.
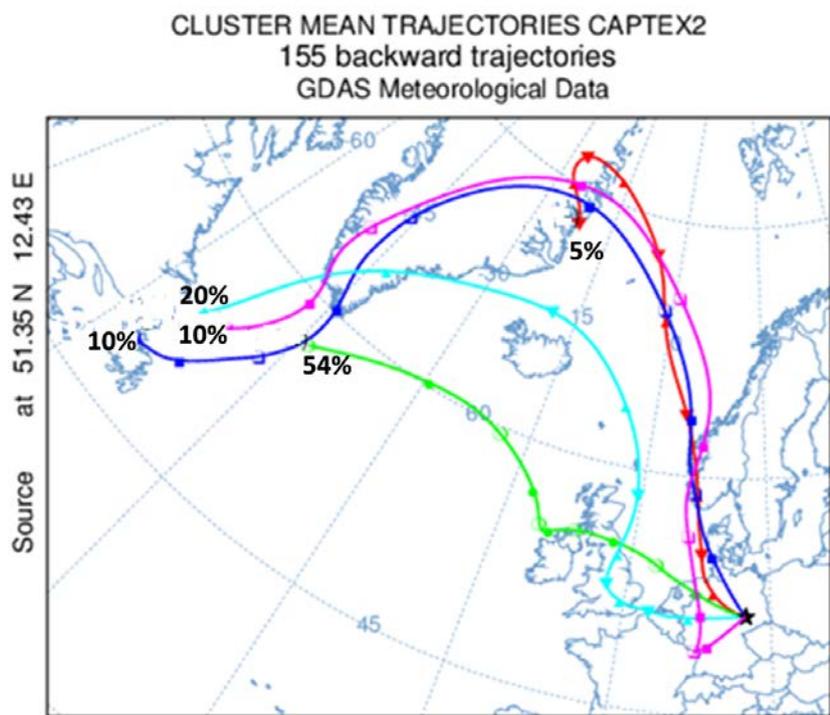

Figure 8. Cluster analysis of the HYSPLIT back trajectories that arrive every hour (from 23 September 12:00 UTC up to 24 September 18:00 UTC) at 2.5-3.5 km height over Leipzig. A 54% cluster percentage means that there is 54% chance that the SO$_2$ arriving anywhere between 2.5-3.5 km over Leipzig originates from the specific direction.
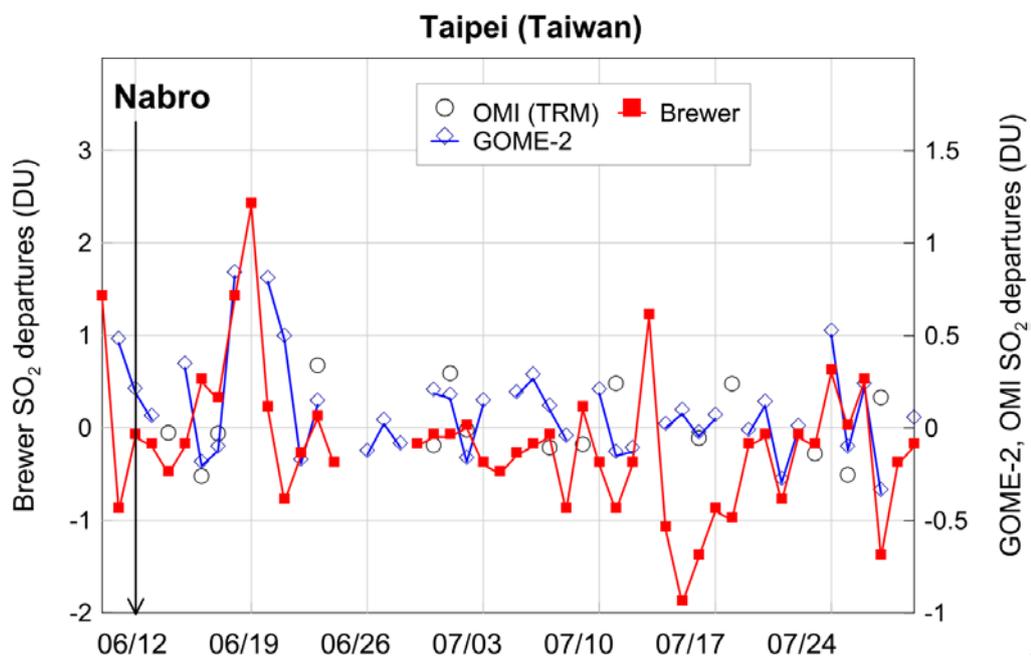

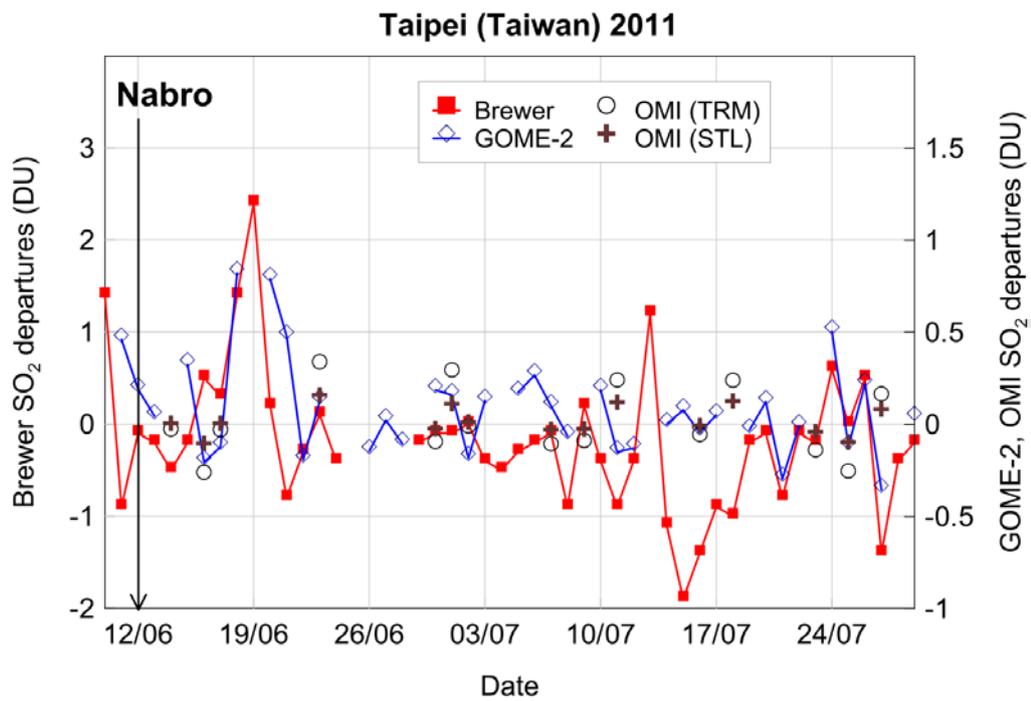

Figure 9. SO₂ column departures from the unperturbed 10 day pre-volcanic baseline measured by Brewer, OMI (TRM, STL) and GOME-2 over Taipei, Taiwan, during June-July 2011 following the 2011 Nabro volcanic eruption (on 12 June 2011).
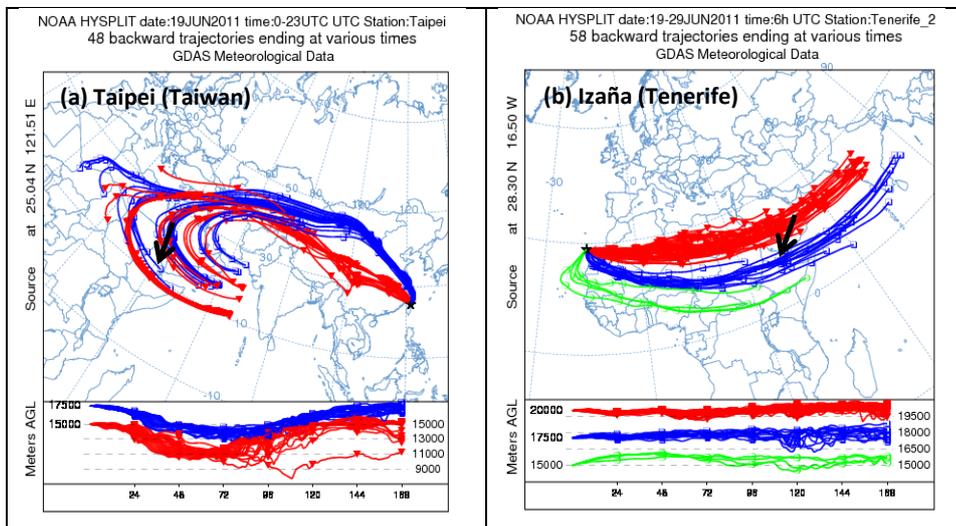

Figure 10. HYSPLIT back trajectories of air masses (a) from Taipei (Taiwan) on 19 June 2011, (b) from Izaña (Tenerife) for days 19-29 June 2011. Nabro's location is indicated by the black arrow.

Izana Observatory SO$_2$ 2011
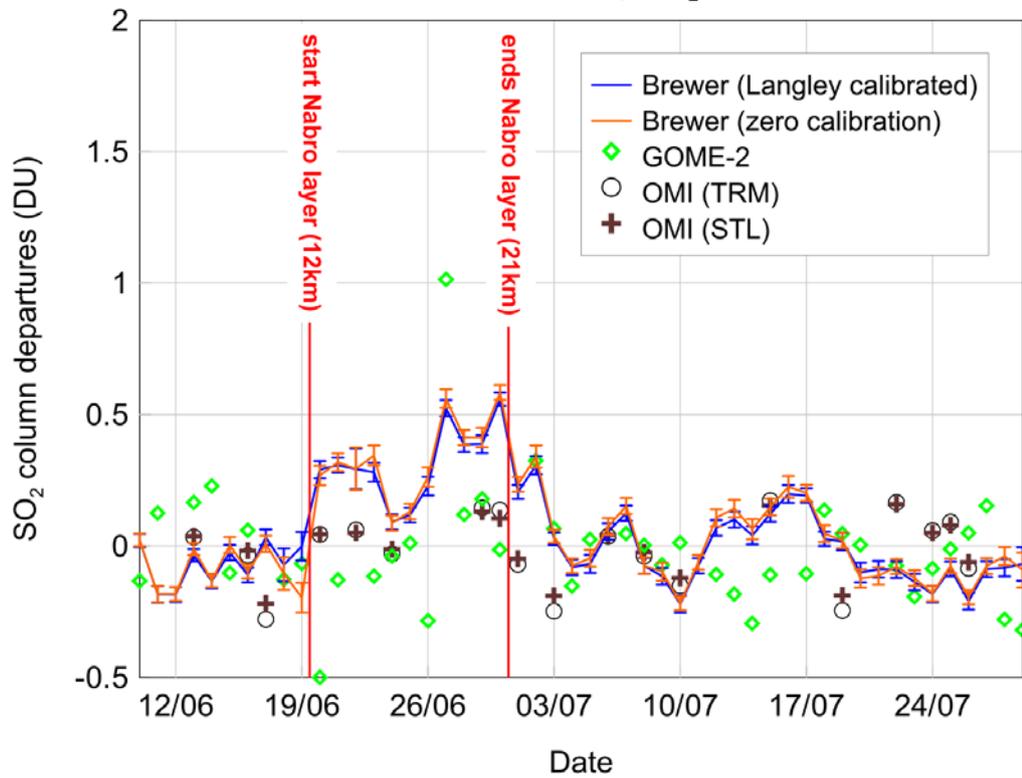

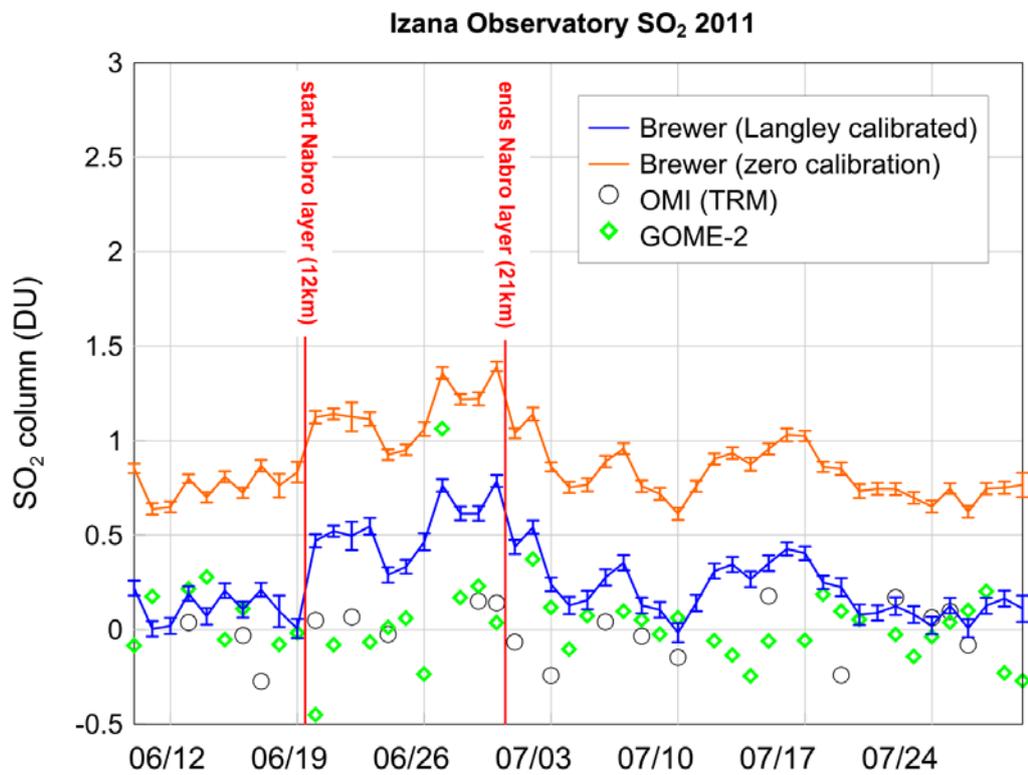

Figure 11. SO₂ column departures from the unperturbed 10 day pre-volcanic baseline measured by the Brewer, OMI (TRM, STL) and GOME-2 over Izaña, Tenerife, during June-July 2011 following the 2011 Nabro volcanic eruption. SO₂ calculations by the Brewer were performed using the Langley calibration and the zero calibration at Izaña (assuming SO₂=0 during the days 06 and 07 of June 2011) following the 2011 Nabro volcanic eruption. Also shown are SO₂ columns from OMI (TRM) and GOME 2 overpasses over Izaña Observatory during June July 2011.

(a) SO₂ column departures (April-May 2010)

Legend: Brewers, OMI (TRM), OMI (STL), GOME-2

Europe (10 stations) under the plume

Eyjafjallajokull

(b) SO₂ column departures (April-May 2010)

Legend: Brewers, OMI (TRM), OMI (STL), GOME-2

Europe (10 stations) outside of the plume
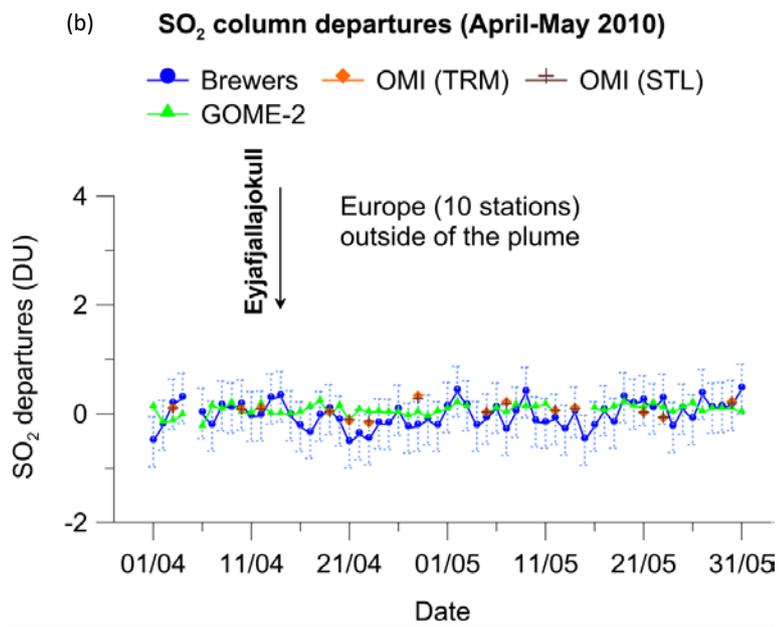

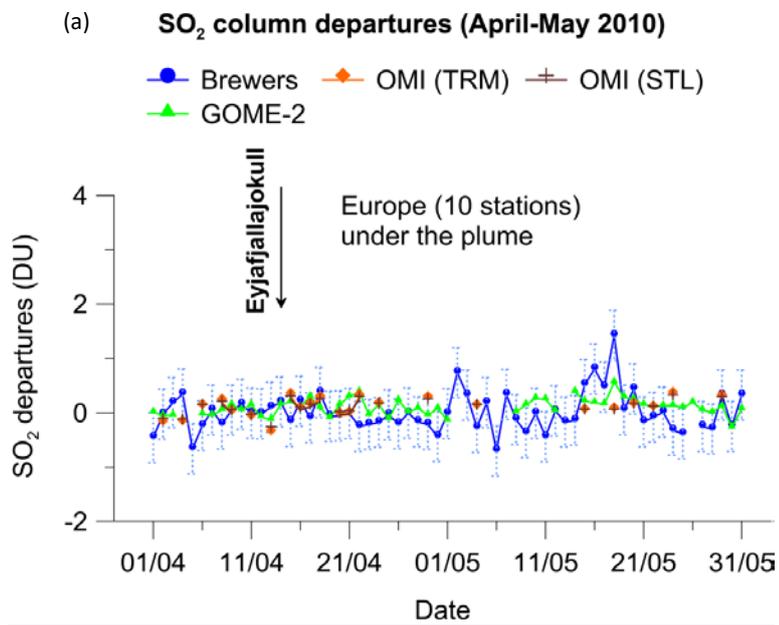

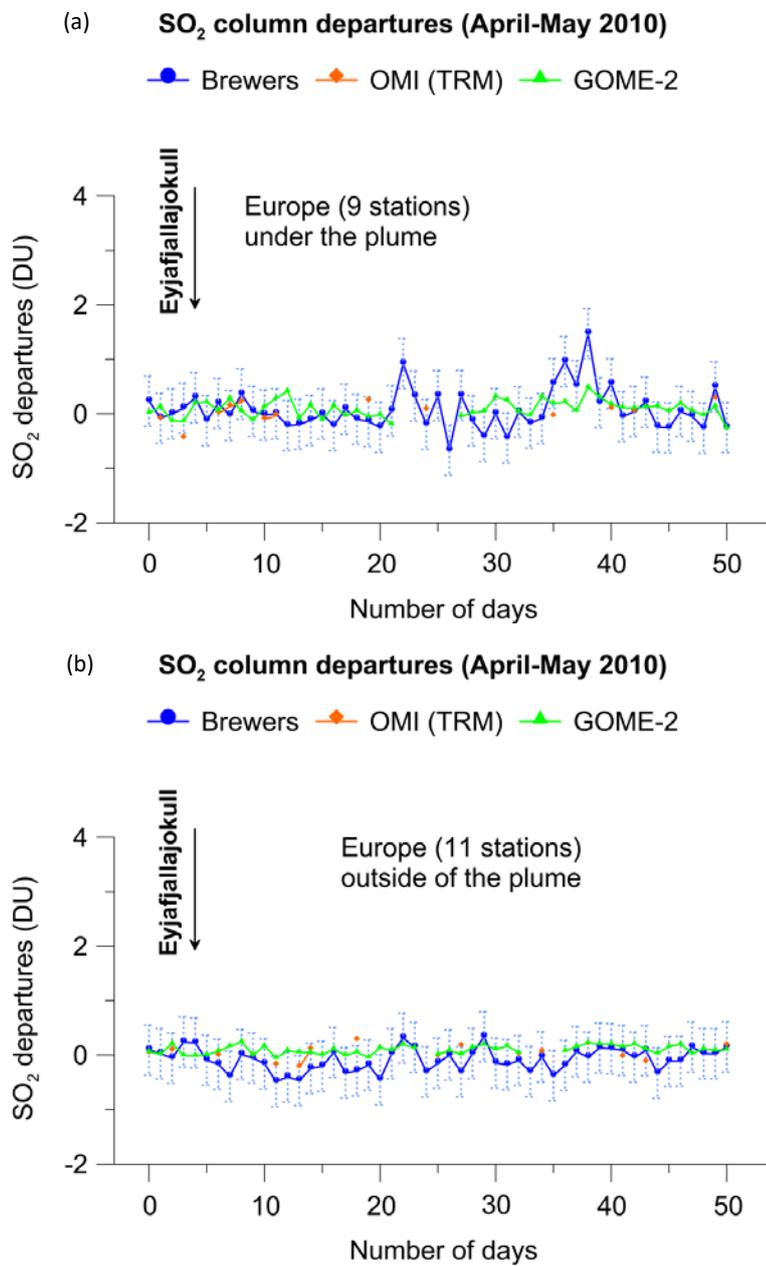

Eyjafjallajokull

Figure 12. Mean SO₂ column departures from the unperturbed 10 day pre-volcanic baseline measured by Brewers, OMI (TRM, STL) and GOME-2 during April-May 2010 over Europe following the 2010 Eyjafjallajökull volcanic eruption for: (a) stations under the volcanic SO₂ plume, and (b) stations outside of the plume. The error bars for the Brewer observations show the standard deviation of all daily values during the unperturbed 10 day period prior to the volcanic eruption. Brewer stations under the plume are: Sodankylä~~Sodankÿla~~, Obninsk, Manchester, De Bilt, Uccle, Belsk, Reading, Hohenpeissenberg, Davos and Arosa. Stations outside of the plume are: Vindeln, Oslo, Norrkoeping, Copenhagen, ~~Uccle,~~ Hradec Kralove, Aosta, Kislovodsk, Rome, Thessaloniki and Athens. Each daily average from either OMI or GOME-2 was calculated if and only if more than half of the individual overpasses had data at a given day. The arrow marks the starting date of the eruption (beginning on 14 April until 24 May 2010).

**SO₂ column departures (August-September 2008)**

Figure ~~13~~14. Mean SO$_2$ column departures from the unperturbed 10 day pre-volcanic baseline measured by Brewers, OMI (TRM**, STL**) and GOME-2 during August-September 2008 over Europe and Canada/USA following the 2008 Kasatochi volcanic eruption. The error bars for the Brewer observations show the standard deviation of all daily values during the unperturbed 10 day period prior to the volcanic eruption. Stations in Europe include: **Sodankylä**~~Sodankÿla~~, Vindeln, Jokioinen, Norrkoeping, Copenhagen, Manchester, De Bilt, Belsk, Reading, Uccle, Hradec Kralove, Hohenpeissenberg, Davos, Arosa, Aosta, Kislovodsk, Rome, Thessaloniki and Athens. Stations in Canada/USA include: Churchill, Edmonton, Goose Bay, Regina, Saturna Island, Toronto, Boulder and Mauna Loa. Each daily average from either OMI or GOME-2 was calculated if and only if more than half of the individual overpasses had data at a given day. **The arrow marks the date of the eruption (7 August 2008).**
