## 12 Abstract

13  
14 To better understand the influence of monsoonal climate and transport of atmospheric mercury (Hg) in  
15 southwestern China, measurements of total gaseous mercury (TGM, defined as the sum of gaseous elemental  
16 mercury, GEM, and gaseous oxidized mercury, GOM), particulate bound mercury (PBM) and GOM were  
17 carried out at Ailaoshan Station (ALS, 2450 m a.s.l.) in southwestern China from May 2011 to May 2012. The  
18 mean concentrations ( $\pm$ standard deviation) for TGM, GOM and PBM were  $2.09\pm 0.63$  ng m<sup>-3</sup>,  $2.2\pm 2.3$  pg m<sup>-3</sup>  
19 and  $31.3\pm 28.4$  pg m<sup>-3</sup>, respectively. TGM showed a monsoonal distribution pattern with relatively higher  
20 concentrations ( $2.22\pm 0.58$  ng m<sup>-3</sup>,  $p=0.021$ ) during the Indian summer monsoon (ISM, from May to September)  
21 and the East Asia summer monsoon (EASM, from May to September) periods than that ( $1.99\pm 0.66$  ng m<sup>-3</sup>) in  
22 the non-ISM period. Similarly, GOM and PBM concentrations were higher in the ISM period than in the  
23 non-ISM period. This study suggests that the ISM and the EASM have a strong impact on long-range and  
24 transboundary transport of Hg between southwestern China and South and Southeast Asia. Several high TGM  
25 events were accompanied by the occurrence of northern wind during the ISM period, indicating anthropogenic  
26 Hg emissions from inland China could rapidly increase TGM levels at ALS due to strengthening of the EASM.  
27 Most of the TGM and PBM events occurred at ALS during the non-ISM period. Meanwhile, high CO  
28 concentrations were also observed at ALS, indicating that a strong south tributary of westerlies could have  
29 transported Hg from South and Southeast Asia to southwestern China during the non-ISM period. The biomass  
30 burning in Southeast Asia and anthropogenic Hg emissions from South Asia are thought to be the source of  
31 atmospheric Hg in remote areas of southwestern China during the non-ISM period.

36

## 37 **1 Introduction**

38 Mercury (Hg), because of its volatility and long residence time in atmosphere, can transport a long distance  
39 with air mass from anthropogenic Hg emission regions to remote areas (Schroeder and Munthe, 1998;Pirrone  
40 et al., 2010). The monsoonal climate **has the potential to** strongly affect the transport and distribution of  
41 atmospheric Hg in monsoon regions, such as East and South Asia. The onset of ISM in May causes air masses,  
42 originating from the Indian Ocean, to overpass South and Southeast Asia, and move northeastwardly to  
43 mainland China. Air pollutants such as SO<sub>2</sub> and CO also travel into Mainland China via air transport caused by  
44 the ISM (Xu et al., 2009;Bonasoni et al., 2010;Lin et al., 2013). In addition, the south tributary of westerlies,  
45 which passes over northern India and Myanmar into southwestern China, can also carry air pollutants to  
46 southwestern China and Tibetan plateau (Loewen et al., 2007;Xu et al., 2009;Yao et al., 2012). In East Asia,  
47 EASM is the dominant monsoon. During the monsoon period (from May to September), the warm and moist  
48 air masses from the Pacific Ocean sweep through the coastal area of China into inland China, and then move  
49 across southwestern China and the eastern Tibetan plateau. During the non-ISM period (from October to April),  
50 the dry and cold air masses from Siberia and Central Asia move through Mainland China into the Pacific  
51 Ocean via the westerlies (Hsu, 2005;Fan et al., 2013;Yu et al., 2015). The monsoonal wind changes play an  
52 important role in the transport of regional Hg emissions in Southeast and East Asia (Sheu et al., 2010a;Tseng  
53 et al., 2012;Lee et al., 2016).

54

55 An increasing number of studies have indicated that pollutant emissions and transport originate from  
56 developing countries in South and Southeast Asia (Wang et al., 2009;Lawrence and Lelieveld, 2010;Bonasoni  
57 et al., 2010;Wang et al., 2015), home to more than a billion people with strong energy demands, **can impact**  
58 **other regions**. These areas are regarded as important source regions of many air pollutants that pose significant  
59 health risk locally and regionally (Rajgopal, 2003;Lelieveld et al., 2001). Previous studies indicated that Hg  
60 emissions within South and Southeast Asia, including southwestern China, **have** significant impacts on the  
61 distribution and deposition of atmospheric Hg in South and East Asia (Pirrone et al., 2009;Mukherjee et al.,  
62 2009;Sheu et al., 2013;Fu et al., 2015;Zhang et al., 2012). These influences have raised concerns **about** high  
63 atmospheric Hg levels in India and Southwestern China, and increased Hg contents in the snow packs of Hindu  
64 Kush Himalayan-Tibetan glaciers (Loewen et al., 2005;Loewen et al., 2007;Kang et al., 2016). Previous  
65 studies reported that the open biomass burning in forests and agricultural waste burning in Southeast Asia are  
66 major sources for atmospheric Hg, aerosols and persistent organic pollutants in the region, which are subject to  
67 **transboundary** transport (Reid et al., 2013;Chang et al., 2013;Zhang et al., 2010;Sheu et al., 2013;Zhang et al.,  
68 2015;Wang et al., 2015). However, studies with respect to Hg emissions in South and Southeast Asia and the  
69 associated transboundary transport mediated by monsoonal weather are still lacking.

70

71 In this study, we conducted comprehensive measurements of TGM, GOM and PBM at Ailaoshan Station

72 (ALS), a remote site in Southwestern China. ALS is located in the subtropical mountainous region of Yunnan  
73 province and is close to South and Southeast Asia. The air flow to ALS is mainly controlled by the Indian  
74 monsoon climate with plenty of rainfall (85% of the total annual rainfall occurred during the ISM period) and  
75 also can be affected by EASM during the spring through early fall. In the winter, the weather is controlled by  
76 dry and cold monsoon circulation including westerlies and the cold Siberian current (Liu et al., 2003b; Yuhong  
77 and Yourong, 1993; Zhao et al., 2006). Therefore, ALS is as a unique location for studying the long-range and  
78 transboundary transport of Hg influenced by the ISM and the EAMS.

79

80 In this paper, we present the observations of TGM, GOM and PBM during the ISM and non-ISM periods at  
81 ALS, and discuss the transboundary transport characteristics using backward trajectory analysis. We also  
82 assess the potential contributing sources of Hg, and analyze the pathways of transboundary transport. This  
83 study is part of the Global Mercury Observation System (GMOS, <http://www.gmos.eu/>), **which aims to**  
84 **establish a global mercury monitoring network for ambient concentrations and deposition of Hg through**  
85 **ground-based observational platforms, oceanographic and aircraft campaigns** (Sprovieri et al., 2013)

86

## 87 **2 Materials and methods**

### 88 **2.1 Measurement site descriptions**

89 This study was conducted at Ailaoshan Mountain National Natural Reserve (24°32'N, 101°01'E) which lies in  
90 the Yunnan province of southern China, a protected forest section covering 5100 ha on the northern crest of a  
91 pristine evergreen broad-leaved forest on Mt. Ailao (23°35'–24°44' N, 100°54'–101°01' E). The forest altitude  
92 ranges from 2450 to 2650 m. above sea level (a.s.l.). The climate is influenced by both ISM and EASM during  
93 warm seasons with plenty of rainfall (Table 1). On the contrary, the dry and cold monsoon circulation from the  
94 south tributary of westerlies control the climate of Mt. Ailao in the winter (Table 1). Annual mean air  
95 temperature and rainfall in the study area are 11.3 °C and 1947 mm, respectively (You et al., 2012). Mt. Ailao  
96 is regarded as the largest tract (504 km<sup>2</sup>) of natural evergreen broad-leaved forest and one of China's most  
97 important natural areas which has remained relatively undisturbed by human influences due to poor access  
98 (Liu et al., 2003a). Situated about 160 km to the south of Kunming, the capital of Yunnan province, ALS is  
99 relatively isolated from large anthropogenic Hg sources. The nearest populated center is Jingdong County  
100 (Population: 36500, 1200 a.s.l.), located 20 km to the south. Hg emissions in the Jingdong area is relatively  
101 low, ranging between 5-10 g km<sup>-2</sup>, as displayed in Fig.1.

102

### 103 **2.2 Sampling methods and analysis**

#### 104 **2.2.1 Measurements of atmospheric TGM, GOM and PBM**

105 From May 2011 to May 2012, TGM (GEM+GOM) in ambient air was measured every 5 minutes with an  
106 automated mercury vapor analyzer, Tekran Model 2537A (Tekran Inc., Toronto, Canada), which is widely used  
107 for monitoring atmospheric Hg. The automated instrument collects Hg on gold cartridges and then thermally

108 desorbs and detects the Hg by Cold Vapor Atomic Fluorescence Spectroscopy (CVAFS). The Tekran 2537A  
109 performs automatic calibration for TGM every 73 hours using an internal permeation source. To evaluate these  
110 automated calibrations, manual external injections using Tekran 2505 with known concentrations of Hg were  
111 performed every 4 months. PBM ( $\leq 0.2 \mu\text{m}$ ) were collected using a 47 mm diameter Teflon filter (pore size 0.2  
112  $\mu\text{m}$ ). To prevent the effect of Hg emission from ground and GOM sorption, the A Teflon sampling line with its  
113 inlet 5 m above the ground and heat preservation (50 °C) was employed at the sampling site. To mitigate the  
114 influence of low atmospheric pressure on the pump's strain, a low sampling rate of 0.75 L min<sup>-1</sup> (at standard  
115 temperature and pressure)(Fu et al., 2008b;Swartzendruber et al., 2009;Zhang et al., 2015).

116  
117 GOM and PBM was measured using a denuder-based system. The quartz denuders can collect GOM while air  
118 passes through the KCl-coated surfaces. However, GOM and PBM have extremely low concentrations and  
119 complex chemical reactivities in the atmosphere, and their chemical compounds are not well known. Several  
120 previous studies reported that different GOM compounds (HgCl<sub>2</sub>, HgBr<sub>2</sub> and HgO) have different collection  
121 efficiencies for the KCl-coated denuder surface, as high relative humidity can passivate KCl-coated denuder  
122 and make GOM recoveries decrease (Huang et al., 2013a;Gustin et al., 2015;Huang and Gustin, 2015). In this  
123 study, the measurements of GOM and PBM were achieved by a manual method. The procedure of  
124 sampling and analysis of the manual method is analogous to the Tekran speciation system using identical  
125 denuders to the Tekran system with KCl coating (Gustin et al., 2015), differing only by manual operation.  
126 Details regarding the measurement system and the quality assurance routines are presented in earlier  
127 works (Xiao et al., 1997;Landis et al., 2002;Feng et al., 2000;Fu et al., 2012c;Zhang et al., 2015).

128  
129 Four sampling campaigns were carried out for PBM and GOM measurements: August 17–24, 2011, December  
130 3–17, 2011, April 12–19, 2012, and July 11–21, 2012. The selected periods represented the ISM period (May  
131 to September) and non-ISM period (October to April) observations. Before sampling, the denuders were  
132 pre-cleaned by pyrolysis to obtain the filed blanks, which was at  $1.2 \pm 0.7 \text{ pg}$  (N=12) for denuders. The quartz  
133 fiber filter was heated at 900 °C for 30 minutes for pre-cleaning. A somewhat higher field blank ( $6.2 \pm 2.7 \text{ pg}$ ,  
134 N=20) was observed and used to correct the PBM concentrations by subtracting the mean blank from the  
135 detected Hg. In this study, data QA procedure followed the GMOS Standard Operation Procedure and Data  
136 Quality Management (D'Amore et al., 2015).

### 137 138 **2.2.2 Meteorological data and backward trajectory calculation**

139 Meteorological parameters, including rainfall (RF), wind direction (WD), wind speed (WS), air temperature  
140 (AT) and relative humidity (RH), were provided by the local weather station from ALS. In order to identify the  
141 influence of long-range transport on the measured Hg at the study site, three-day backward trajectories were  
142 calculated using HYSPLIT and the Global Data Assimilation System (GDAS) meteorological data archives of

143 the Air Resource Laboratory, National Oceanic and Atmospheric Administration (NOAA). The meteorological  
 144 data are of  $1^\circ \times 1^\circ$  spatial resolutions at 6-hour intervals. All the backward trajectories ended at the sampling  
 145 site at an arrival height of 500 m above the ground. The backward trajectories were calculated at 1-hour  
 146 intervals, and cluster analysis of the trajectory endpoints was performed to determine the regional transport  
 147 pathway. To distinguish the larger sources from moderate sources, a weighing algorithm based on measured  
 148 concentrations (concentration weighted trajectory (CWT)) was applied in this study. In this procedure, each  
 149 grid cell received a source strength obtained by averaging sample concentrations that have associated  
 150 trajectories that crossed that grid cell as follows:

$$151 \quad C_{ij} = \frac{1}{\sum_{l=1}^M \tau_{ijl}} \sum_{l=1}^M C_l \tau_{ijl}$$

152  $C_{ij}$  is the average weighted concentration in the grid cell  $(i,j)$ .  $C_l$  is the measured Hg concentration,  $\tau_{ijl}$  is the  
 153 number of trajectory endpoints in the grid cell  $(i,j)$  associated with the  $C_l$  sample, and  $M$  is the number of  
 154 samples that have trajectory endpoints in grid cell  $(i,j)$ . A point filter is applied as the final step of CWT to  
 155 eliminate grid cells with few endpoints. Weighted concentration fields show concentration gradients across  
 156 potential sources. This method helps determine the relative significance of potential sources (Hsu et al.,  
 157 2003; Cheng et al., 2013).

158

### 159 **3 Results and discussion**

#### 160 **3.1. General distribution characteristics of TGM, GOM and PBM**

161 The highly time-resolved long-term data set of TGM concentrations in ambient air at ALS is displayed in Fig.  
 162 2, and the mean TGM concentration over the sampling period was  $2.09 \pm 0.63 \text{ ng m}^{-3}$  with a higher level ( $2.22$   
 163  $\text{ng m}^{-3}$ ) during the ISM period than that during the non-ISM period ( $1.99 \text{ ng m}^{-3}$ ) (Table 1). The TGM mean  
 164 concentration at ALS was slightly higher than that of the global background ( $1.5\text{-}1.7 \text{ ng m}^{-3}$  in the Northern  
 165 Hemisphere and  $1.1\text{-}1.3 \text{ ng m}^{-3}$  in the Southern Hemisphere (Lindberg et al., 2007; Slemr et al., 2015; Venter et  
 166 al., 2015), and higher than those ( $1.58$  to  $1.93 \text{ ng m}^{-3}$ ) observed in some remote areas in northern America and  
 167 Europe (Kim et al., 2005; Sprovieri et al., 2010). Compared to the background concentrations observed at the  
 168 Shangri-La Baseline Observatory in Yunnan province ( $2.55 \pm 0.73 \text{ ng m}^{-3}$ , (Zhang et al., 2015), at Mt. Leigong  
 169 in Guizhou province ( $2.80 \pm 1.51 \text{ ng m}^{-3}$ , (Fu et al., 2010b) and at Mt. Gongga in Sichuan province ( $3.98 \pm 1.62$   
 170  $\text{ng m}^{-3}$ , (Fu et al., 2008a), the mean TGM level at ALS was lower. However, the mean TGM level at ALS was  
 171 higher than those observed at Mt. Changbai ( $1.60 \pm 0.51 \text{ ng m}^{-3}$ ) in Northeast China and at Mt. Waliguan  
 172 (WLG) Baseline Observatory ( $1.98 \pm 0.98 \text{ ng m}^{-3}$ ) in the Tibetan plateau (Fu et al., 2012a; Fu et al., 2012b).  
 173 Interestingly, most peaks of high TGM concentrations at ALS frequently appeared during the ISM period (Fig.  
 174 2). This differed from the previous results at Mt. Gongga and Mt. Leigong of southwestern China but was  
 175 similar to the results at Shangri-La. There were also several peaks that appeared during the non-ISM period,  
 176 which could have been caused by different sources than those during the ISM period. The sampling site is  
 177 located adjacent to South Asia and Southeast Asia, and Hg emissions from biomass burning in South Asia and

178 Southeast Asia would inevitably contribute to the elevated TGM concentrations at ALS during the non-ISM  
179 period (Wang et al., 2015). Southwestern China is one of the largest Hg emission areas in China, and coal  
180 combustion and non-ferrous metal (especially zinc) smelting activities are the two main Hg sources. It was  
181 reported that total Hg emission from Guizhou, Sichuan and Yunan provinces reached about 128 tons in 2003  
182 (Wu et al., 2006), and the large amount of Hg emissions contributed to the elevation of TGM concentrations in  
183 this area. Since Guizhou, Sichuan and Yunan provinces are located in the upper wind direction of the sampling  
184 site to EASM, Hg emission from these areas can be transported to ALS and result in the elevation of TGM  
185 concentrations.

186  
187 Fig. 3 displays the distribution frequency of TGM above and under the average ( $2.09 \text{ ng m}^{-3}$ ) based on wind  
188 direction including Northeast (NE), Southeast (SE), Southwest (SW) during the ISM and non-ISM period. It is  
189 clear that SW was the predominating wind direction, and there was no Northwest (NW) during the entire study  
190 period. The SW frequency was highest when high and low TGM levels occurred during the ISM period or  
191 non-ISM period, and the SW frequency showing low TGM was higher than that of high TGM. This could be  
192 the reason why the average TGM level from SW was not high. The air flows originating from South Asia and  
193 Southeast Asia could contribute to high TGM concentrations at ALS. Contrarily, NE and SE frequency had a  
194 relatively lower trend than SW, but high TGM frequency from NE and SE were both high during the ISM  
195 period. This should be the result from the strengthening of EASM during the ISM period. However, during the  
196 non-ISM period, the cold and dry air flow from the south tributary of westerlies could have swept over South  
197 Asia and Southeast Asia and moved to ALS with high wind speed (Fig. 4). This dry air flow could have also  
198 taken the air masses of high Hg levels emitted from biomass burning in South Asia and Southeast Asia to ALS  
199 and caused a rapid increase of TGM level at ALS. In addition, cold air flows could also transport Hg emitted  
200 from inland China to ALS due to the strengthening of the cold Siberian current during the non-ISM period.  
201 Therefore, there were some high TGM events in December and March at ALS (Fig. 4).

202  
203 For GOM and PBM, which on average accounted for <2% of the TGM, there were also seasonal trends. Both  
204 species had the highest levels in autumn while GOM was lowest in the winter and PBM was lowest in the  
205 spring. The lowest GOM level was observed in the summer, which increased consistently to reach the highest  
206 value ( $3.4 \pm 3 \text{ pg m}^{-3}$ ) in autumn. Similarly, PBM displayed the same distribution in seasonal variation, with the  
207 highest PBM level in autumn ( $46.3 \pm 28.8 \text{ pg m}^{-3}$ ). Meanwhile, the AT, RF and RH were also higher during the  
208 ISM period than those during the non-ISM period. However, unlike TGM, the GOM and PBM were closely  
209 linked with atmospheric Hg chemistry, meteorological patterns, and numerous other factors. Thus, there are  
210 several likely factors that contribute to these trends, including a greater number of sources during the ISM  
211 period, and changing ecological or meteorological conditions. Previous studies in the Mt. Gongga and Mt.  
212 Leigong area suggested that enhanced coal and biomass burning played a significant role in elevated TGM  
213 concentrations during cold seasons (Fu et al., 2008a; Fu et al., 2010a). Enhanced coal and biomass burning

214 during cold seasons is generally driven by the need for residential heating in China. However, in the southern  
215 Yunnan province, the air temperature is high during the non-ISM period. Thus, the domestic use of coal is not  
216 dominant for residential heating, but rather the agricultural activity in the region including the crop harvesting  
217 and the burning of straw. This was probably one of most important reasons for the highly elevated GOM and  
218 PBM level at ALS in autumn.

219

### 220 **3.2 Seasonal variation of TGM, GOM and PBM influenced by monsoonal climate**

221 Table 1 shows seasonal statistics of daily averages for Hg species and select meteorological parameters which  
222 were determined on a seasonal basis and for the year-long dataset. TGM during the ISM period was  
223 statistically higher than during the non-ISM period (Table S1). Meanwhile, AT, RF and RH had a distribution  
224 with the highest level during the ISM period, and SW frequency had decline with increase of SE and NE  
225 frequency during the ISM period. This suggests the EASM could also influence the climate at ALS during the  
226 ISM period, which was consistent with TGM concentration that the site is impacted by regional sources  
227 including biomass burning and monsoonal long-range transboundary transport.

228

229 To assess the monsoonal variation of TGM concentrations, the distribution of monthly mean TGM  
230 concentrations at ALS is shown in Fig. 4. The TGM concentrations during the ISM period were higher than  
231 those during the non-ISM period. The highest monthly concentration was observed in May with a mean value  
232 of  $2.46 \text{ ng m}^{-3}$ , and the lowest monthly mean concentration of  $1.45 \text{ ng m}^{-3}$  was observed in November.  
233 Although there were relatively higher TGM levels in December and January during the non-ISM period, this  
234 pattern was generally different from the most common pattern in the Northern Hemispheric which has a  
235 summer minimum and winter maximum TGM distribution pattern as observed in many previous studies  
236 (Kellerhals et al., 2003;Kock et al., 2005;Fu et al., 2010a). There were several possible reasons for this  
237 monsoonal distribution pattern of TGM concentrations on ALS.

238

239 Firstly, the increase of TGM concentrations during the ISM period could be due to the interaction of the  
240 EASM and the ISM, promoting the air masses with high TGM from the areas of anthropogenic Hg emissions  
241 to ALS. Generally, ALS is located on the low latitude highlands of Yunnan in southwestern China which is  
242 subject to the interactions between the EASM and the ISM, although most of time, the air flow of Yunnan is  
243 mainly controlled by the ISM during the ISM period. However the strengthening of the EASM or the  
244 weakening of the ISM can also spur the EASM to control this area and bring precipitation during the ISM  
245 period (Fan et al., 2013). Therefore, the TGM level should be sensitive to the strengthening/weakening of the  
246 two monsoons. Once the air flow from high Hg source regions (Sichuan, Guizhou and Chongqing) is  
247 transported to ALS with the strengthening of the EASM, TGM levels at ALS can increase rapidly. However,  
248 anthropogenic Hg emissions from inland China could increase the TGM background level with the raid of  
249 westerlies and cold Siberian current during the non-ISM period. Previous studies discussed the seasonal

250 change of TGM at the background sites of southwestern China and found that increased domestic coal  
251 consumption and an increase in household heating was the main cause of elevated TGM concentrations  
252 observed in winter (Fu et al., 2008a;Fu et al., 2010a). Additionally, the biomass burning in Southeast Asia  
253 could also be an important reason for high TGM level at ALS during the non-ISM period. Intense biomass  
254 burning originating from Southeast Asia typically occurred in late winter and spring (Huang et al., 2013b).  
255 This could be the cause of the high TGM at ALS along with the long-range transboundary transport in the  
256 spring (Wang et al., 2015).

257  
258 Monsoonal distribution patterns and mean TGM, GOM and PBM concentrations based on the four sampling  
259 campaigns in ALS are shown in Fig. 5. Mean concentration of the three Hg species showed a monsoonal  
260 variation with higher levels during the ISM period than during the non-ISM period. This suggests that regional  
261 anthropogenic emissions are important Hg sources in southwestern China. During the ISM period, not only  
262 was air flow originating from the Indian Ocean dominating, but air flow that occasionally originated from the  
263 Pacific Ocean also intruded the study site, which passed through central and southwestern China, one of the  
264 most Hg-polluted regions. Moreover, the TGM, GOM and PBM levels from the north were higher than those  
265 from the south to ALS (Fig. S1). Thus, the air masses likely captured large amounts of Hg during transport and  
266 caused elevated atmospheric TGM concentrations at ALS during the ISM period.

267  
268 Fig. 6 shows pollution roses of TGM, GOM and PBM at ALS during the ISM period and during the non-ISM  
269 period respectively. The wind direction at the study site was dominantly SW. This reflects that the  
270 predominant monsoon influencing the ALS site is the ISM and westerlies. During the ISM period, most of the  
271 TGM, GOM and PBM events were from SW, slightly fewer were from NE, and both SW and NE exhibited  
272 higher TGM, GOM and PBM events. This indicates SW and NE were the two primary directions of high Hg  
273 sources during the ISM period. However, during the non-ISM period, almost all TGM, GOM and PBM events  
274 were from SW. This indicates that strong westerlies were the primary winds during the non-ISM period. These  
275 westerlies could take the GEM and PBM from South Asia and Southeast Asia into southwestern China. Thus,  
276 the dependence of atmospheric Hg on wind was likely attributed to an interplay of regional sources and the  
277 long-range transboundary transport of the GEM and PBM.

278  
279 Indeed, GOM concentrations were extremely low at ALS. Marine air masses during the ISM period likely  
280 diluted the atmospheric TGM in the study area. The high RF and low WS can promote the wet deposition of  
281 GOM and PBM. Therefore, in the summer, RH was very high, but the GOM and PBM were very low at ALS.  
282 A new study reported that high RH could reduce the collection of GOM by the KCl-coated denuder (Huang,  
283 Gustin et al. 2015). This could be another reason why the GOM was low in summer. Additionally, low GOM  
284 and PBM could be also related to rapid deposition of Hg due to the high altitude montane environment and  
285 luxuriant virgin forest cover of Mt. Ailao. A previous study already found that the increasing occurrence and

286 extension of fog and cloud droplet interception can enhance the uptake of Hg by foliage (Zhang et al., 2013).  
287 We will study the possible reasons why the GOM level is exceedingly low in ALS via continuous long-term  
288 monitoring for GOM in the future.

289

### 290 **3.3 Transboundary transport of Hg facilitated by monsoons**

291 The backward trajectories arriving at ALS over the study period were grouped into five clusters, which are  
292 shown in Fig. 7. Most of these backward trajectories consisted of air masses that originated from the South  
293 Asia and Southeast Asia, passing over India, Bengal Bay, the Indo-China peninsula and the southern Yunnan  
294 province of China. Just 4.7% of air masses originated from inland China and then passed over Sichuan,  
295 Guizhou, Yunnan provinces and the city of Chongqing, China. For the five types of air masses, air masses in  
296 cluster 1 displayed very low TGM concentrations ( $1.86 \text{ ng m}^{-3}$ ) for all the air masses, although their  
297 frequencies were the highest (38.55%). Similarly, the mean TGM concentration in cluster 3 was  $1.92 \text{ ng m}^{-3}$ ,  
298 which was also considerably low and had second highest frequency (23.03%). This suggest that Hg emitted in  
299 South Asia could not have largely contributed to the high TGM levels at ALS. Air masses in cluster 4 showed  
300 a high TGM concentration of  $2.42 \text{ ng m}^{-3}$ , which originated over the South China Sea and passed over northern  
301 Vietnam and Laos and the southern Yunnan and Guangxi provinces of China, which are generally areas of less  
302 anthropogenic emissions other than biomass burning during the non-ISM period. However, the air masses in  
303 cluster 5 were also polluted with Hg, with a mean concentration of  $2.20 \text{ ng m}^{-3}$ , which is higher than those of  
304 clusters 1, 3 and 4. Air flows likely originated in Bengal Bay and passed over Myanmar since most  
305 anthropogenic emissions in Myanmar are centralized in southern Myanmar, and intense biomass burning in the  
306 area during the non-ISM period perhaps contributed to a slightly high TGM level of these air masses. Cluster 2  
307 displayed the highest TGM concentrations ( $2.65 \text{ ng m}^{-3}$ ). Air masses in cluster 2 passed over the inland China  
308 region, which is the most densely populated and heavily Hg-polluted area in China due to industrial and  
309 domestic coal combustion, smelting industries, cement production, biomass burning, etc. Sichuan, Guizhou,  
310 Chongqing and the northwestern Yunnan provinces, respectively, were contributing Hg source provinces in  
311 China. Although only 4.70% of air masses were from the southwestern China region, the TGM concentrations  
312 of these air masses were the highest, which could be an important reason for elevated TGM levels at ALS.

313

314 The Tibetan plateau and Yunnan-Guizhou plateau are located in north of ALS, which is a monitoring site at  
315 high elevation. To the south of ALS, the geography consists of a montane area plain of low elevation. Thus,  
316 the air masses at ALS were from different directions and of different heights, which may have affected the  
317 TGM level in the air masses as they passed over different anthropogenic emission regions. Fig. S2 compares  
318 the three-dimensional height of all the wind clusters arriving at ALS. The height of cluster 1 from India was  
319 the highest. Such transport pattern tends to more effectively dilute Hg emissions from low altitude surface to  
320 ALS. Thus, in non-ISM period, the south tributary of westerlies passed over India does not lead to elevated  
321 TGM concentrations at ALS. Additionally, due to the high TGM concentration in the air in southwestern

322 China, the TGM level of any air masses coming from the northeast of ALS should be increased at ALS  
323 regardless of height. Contrarily, cluster 3 had a high height but low level TGM because its air masses  
324 originated and passed over the area of low anthropogenic emission region.

325

### 326 **3.4 Impacts of Hg emission from industrial sources and biomass burning**

327 Fig. 8 shows the seasonal trend analysis using the average of the daily TGM values, RF distribution, WS and  
328 WD during the study period along with IMI (Indian monsoon index) at ALS. In general, May to September  
329 represent the normal ISM period. The IMI, however, also illustrates the onset in of the ISM in May and its  
330 retreat at the end of September. During the ISM period, the mean TGM is  $2.22 \text{ ng m}^{-3}$ , which is slightly higher  
331 than  $1.99 \text{ ng m}^{-3}$  during the non-ISM period, and most of the RF events appeared during the ISM period. More  
332 crucially, some high-frequency NE and east wind events occurred during the ISM period. Once the WD shifted  
333 from SW to NE, the TGM level rapidly increased in addition to relatively lower RF and WS. This indicates  
334 that the strengthening of EASM can move the air masses with high TGM levels from inland China to ALS, but  
335 when the NE air flow climbed over the Yunnan-Guizhou plateau, the speed of air mass movement decreased  
336 and carried less RF. However, during the non-ISM period, the high TGM events did not accompany the  
337 appearance of NE. The WD was primarily SW other than a few SE at the end of March, and the WS was  
338 higher than the level during the ISM period. This indicates that the south tributary of westerlies could control  
339 the climate and carry air masses from South Asia and Southeast Asia. High TGM events were also evident  
340 with SW and SE during the non-ISM period, which could be due to Hg emission from biomass burning in  
341 South Asia and Southeast Asia.

342

343 Therefore, five special high TGM events were accompanied by an exceeding variation of WD and WS to  
344 analyze the reasons of high TGM appearance. As Fig. 8 shows, five extreme peaks of high TGM were  
345 displayed from June 23-29 and July 10-18, 2011, September 28 to October 9 and December 23-31, 2011, and  
346 March 23-29, 2012, respectively. On June 23, the air masses from India began to increase TGM concentrations,  
347 and with the strengthening of the EASM, the TGM level increased gradually and peaked with low RF and WS  
348 on June 26. The air masses that had just swept Chongqing, Sichuan, Guizhou and eastern Yunnan provinces,  
349 including Kunming city, where there is high Hg emission because of industrial activities (Fig. 1). Thus the air  
350 flow from these areas could suddenly increase the TGM level at ALS due to the long-range transport. Once the  
351 air flow from EASM faded away, the ISM would control the ALS area again, the air flow would shift to  
352 southwest, and the TGM level would return to average levels (Fig. 9a). The same variation appeared from July  
353 10-18 during the ISM period. TGM levels increased on July 10 and were highest ( $3.65 \text{ ng m}^{-3}$ ) from July 14-16  
354 with the strengthening of EASM. When WD shifted to SW, TGM was back to its base level (Fig. 9b). In fact,  
355 during the ISM period, this sort of peak appeared many times (Fig. 2), the reason for these peaks being similar  
356 to the two peaks in June and July.

357

358 However, on September 28, due to the fadeaway of ISM and the strengthening and incursion of air flow from  
359 EASM as well as the cold Siberian current, a high TGM event was initiated as the air flow shifted from SW to  
360 NE (Fig. 10). When the air flow swept Chongqing, Sichuan, Guizhou and eastern Yunnan province again from  
361 September 30 to October 5, the TGM level increased to its highest level ( $3.18 \text{ ng m}^{-3}$ ), then gradually  
362 decreased with the shift in air flow that swept northern Vietnam and Laos. These high TGM events happened  
363 during the transitional period from the ISM period to the non-ISM period, which indicates that the high Hg  
364 emission from inland China had severely influenced the TGM level at ALS. As previously discussed, the  
365 strengthening of the EASM or the weakening of ISM caused the air flow with high TGM originating from  
366 inland China to be transported to ALS, which contributed to extremely high TGM concentrations.

367

368 During the non-ISM period, with the fading of the ISM and EASM, the south tributary of westerlies grew  
369 stronger as the dry and cold air flow swept over South and Southeast Asia and arrived in southwestern China to  
370 control the climate. Hence, industrial sources likely contributed to the high level TGM concentrations in this  
371 study site. In Fig. 11, when air masses entered from important Southeast Asia industrial regions (e.g. Hanoi,  
372 Haiphong et al.), the TGM level was highest ( $3.13 \text{ ng m}^{-3}$ ) while TGM concentrations decreased 11% with the  
373 entrance of the strong wind from the Bay of Bengal. In addition, fire events were also observed along the  
374 backward trajectories. Moreover, the high correlation ( $R^2=0.89$ ) between TGM and CO was identified in Fig.  
375 12. However, the TGM/CO ratio was  $0.01124 \text{ ng g}^{-1} \text{ ppb}^{-1}$  ( $1.80 \text{ E-6 mol mol}^{-1}$ ), which is more than 10 times  
376 higher than the reported world average biomass burning ratio but was close to ratios observed in Taiwan in  
377 October ( $1.28 \text{ E-6}$ , verified from anthropogenic plumes) Sheu et al. (2010b);(Friedli et al., 2009). Therefore, in  
378 this event, the major contributor should be the industrial sources from Southeast Asia. Fig. 13 shows that  
379 biomass burning is an important source for TGM. On March 23, the high TGM concentrations began to arise  
380 because of the fire events that occurred in northeastern India and north Myanmar. TGM levels were highest  
381 ( $4.53 \text{ ng m}^{-3}$ ) when the air flow shifted and swept inland China. When the air flow shifted from east to  
382 southwest and swept south Myanmar from March 25-28, a period of were high-frequency fire events, the TGM  
383 concentrations maintained a high level ( $3.11 \text{ ng m}^{-3}$ ). However, when the air flow shifted to northern Myanmar,  
384 the TGM level returned to low levels ( $2.01 \text{ ng m}^{-3}$ ), indicating that biomass burning originating from Southeast  
385 Asia could also rapidly input and increase the TGM levels in southwestern China during the non-ISM period.  
386 Different from Fig. 12, the TGM/CO ratio decreased by half in Fig. 14 and was comparable with reported  
387 biomass burning ratios ( $3.00 \text{ E-7}$ ) in Canada and the USA (Sigler et al., 2003). Moreover, the close  
388 correlations between TFRP (total fire radiative power), which provides information on the measured radiant  
389 heat output of detected fires, and CO ( $R^2=0.98$ ) and TGM ( $R^2=0.45$ ) verify the above hypothesis (Wooster et  
390 al., 2005).

391

### 392 **3.5 Potential source regions of atmospheric Hg**

393 Fig. 15a shows the possible source regions and pathways of atmospheric TGM at ALS during the ISM period

394 identified by the CWT analysis. Sichuan, Guizhou, Chongqing, Yunnan and Guangxi provinces in  
395 southwestern China as well as in Southeast Asia as well as northern Laos, Cambodia, Thailand and Vietnam  
396 were likely source regions of high atmospheric TGM at ALS during the ISM period. Southwestern China,  
397 including Sichuan, Chongqing, Guizhou, and Yunnan provinces, is an important anthropogenic source region  
398 of China (Wang et al., 2006;Feng and Qiu, 2008;Wu et al., 2006;Jiang et al., 2006). In fact, several capital  
399 cities including Kunming, Guiyang and Chongqing are located about 200 to 800 km north of ALS. These  
400 capital cities may be the source of much of the Hg emissions during atmospheric transport. The identified  
401 source areas correspond very well with the anthropogenic Hg emission inventories in East and South Asia. The  
402 potential area identified in Southeast Asia is also classified as a high anthropogenic Hg emission region by Hg  
403 emission inventories (Pacyna et al., 2010;Pirrone et al., 2010;Li et al., 2009), and the biomass burning in  
404 Southeast Asia could cause high Hg emissions. During the non-ISM period, as displayed in Fig. 15b, Northern  
405 India is an important urbanized and industrialized area that may produce high anthropogenic Hg emission rates,  
406 as there are a number of large scale industries and coal-fired power plants in India (Burger Chakraborty et al.,  
407 2013;Pervez et al., 2010). Additionally, the biomass burning in Southeast Asia should be a large contributor of  
408 high TGM levels at ALS (Wang et al., 2015). A small region in eastern Myanmar and northern Laos and  
409 Thailand was also identified as a potential source region and pathway for TGM at ALS. The high CWT values  
410 in this area may be primarily due to high Hg emission rates because of biomass burning during the non-ISM  
411 period.

412  
413 Indeed, the emission of Hg from biomass burning includes forest fire and agricultural waste burning in  
414 Southeast Asia and southwestern China and could also play an important role in TGM distribution and  
415 transboundary transport at ALS. Southeast Asia and southwestern China are large tropical rain forest areas.  
416 During the ISM period, the air had a very high RH and the highest RF. Because the fire events in Southeast  
417 Asia and southwestern China were not frequent and the biomass burning for agriculture was not prevalent, less  
418 Hg from biomass burning was released into the atmosphere. As shown in Fig. S3a, fire events in Southeast  
419 Asia and southwestern China during the ISM period (mainly from June to September 2011) exhibited a much  
420 lower frequency, indicating that the significant impact of TGM transport was primarily from anthropogenic Hg  
421 emissions. Nevertheless, during the non-ISM period (mainly from December 2011 to April 2012),  
422 high-frequency fire events in Southeast Asia and southwestern China were observed (Fig. S3b). Hg emissions  
423 from fire events peaked when the most intense biomass burning occurred in Southeast Asia and Southwest  
424 China. This increased TGM level at ALS once air masses from these areas were transported to ALS.

#### 425 426 **4 Conclusions**

427 This study made at ALS suggests a significant impact of monsoonal climates on the distribution and  
428 long-range transport of atmospheric Hg in southwestern China and shows a pronounced monsoonal variation  
429 with a high TGM level during the ISM period and a low TGM level during the non-ISM period. This seasonal

430 variation opposes the previous distribution of atmospheric Hg observed in the background sites of  
431 southwestern China. This behavior seems to be dominated by the seasonal variation of monsoons and the  
432 influence of the long-range and transboundary transport of Hg from high anthropogenic Hg emissions and  
433 biomass burning. The high Hg regional sources from inland China were an important factor in the elevated  
434 TGM level. Meanwhile, with the economy developing rapidly, anthropogenic Hg emission in Southeast Asia is  
435 also increasing. This will elevate the TGM level in the area, including that of southwestern China. Additionally,  
436 Hg emitted from India can travel to southwestern China due to the ISM in the summer and a strong south  
437 tributary of westerlies during cold seasons. Biomass burning includes high-frequency fire events in Southeast  
438 Asia that could play an important role for high TGM levels during the non-ISM period. Thus, the TGM  
439 concentrations during different seasons in addition to the impacts of monsoonal climate may pose an important  
440 constraint on the global models of atmospheric Hg.

651 **Figure Captions**

652

653 **Table 1:** The statistics for mercury species and meteorological variables based on daily averages from May  
654 2010 through May 2011 at the ALS site.

655 **Fig. 1:** Map showing the location of ALS, anthropogenic mercury emissions ( $\text{g km}^{-2} \text{y}^{-1}$ ) and major cities in  
656 Asia (AMAP/UNEP, 2013).

657 **Fig. 2:** Total gaseous mercury (TGM) concentration in the ambient air at ALS. Source 1 represents the peaks  
658 of high TGM concentrations at ALS during the ISM period, which were caused by anthropogenic Hg  
659 emissions from inland China due to the strengthening of EASM. Source 2 represents the peaks of high TGM  
660 concentrations at ALS during the non-ISM period, which were caused by the biomass burning from Southeast  
661 Asia and anthropogenic Hg emissions from South Asia.

662 **Fig. 3:** Distribution frequency of TGM above and under the average ( $2.09 \text{ ng m}^{-3}$ ) based on wind direction  
663 during the ISM and the non-ISM period. The high and low Hg levels of the SW frequency was higher than  
664 both the high and low Hg levels of the NE and SE frequencies.

665 **Fig. 4:** Monthly TGM anomalies at ALS. The Hg concentration during the ISM period (May to September)  
666 was higher than that of the non-ISM period (October to April). The highest monthly concentration ( $2.46 \text{ ng m}^{-3}$ )  
667 was observed in May, and the lowest monthly mean concentration ( $1.45 \text{ ng m}^{-3}$ ) was observed in November.  
668 The air temperature was higher, and the wind speed was lower during the ISM period than that of the non-ISM  
669 period.

670 **Fig. 5:** TGM, GOM and PBM variation during the ISM and non-ISM period based on the four sampling  
671 campaigns. TGM, GOM and PBM concentrations showed a monsoonal variation with higher level during the  
672 ISM period than in the non-ISM period.

673 **Fig. 6:** Pollution roses of Hg species. Most of the TGM, GOM and PBM were from SW, and some higher  
674 TGM, GOM and PBM events were from NE during the ISM period. Almost all TGM, GOM and PBM were  
675 from SW during the non-ISM period.

676 **Fig. 7:** Air mass backward trajectory analysis for long range transport to ALS. Most of these backward  
677 trajectories consisted of air masses that originated from South and Southeast Asia and were accompanied by  
678 lower Hg levels. Air masses originating from inland China were less frequent and accompanied by higher Hg  
679 levels.

680 **Fig. 8:** The distribution of the Indian monsoon index (IMI), TGM and rainfall at ALS. IMI displays that the  
681 ISM period was from May to September. RF events mainly appeared during the ISM period. Some high Hg  
682 events were accompanied by NE and east wind events during the ISM period. High TGM events were  
683 accompanied by the appearance of SW during the non-ISM period.

684 **Fig. 9:** Backward trajectories of air masses and the variation of TGM concentrations because of the  
685 strengthening of and incursion of air flow from EASM on June 23-28, 2011 (a), and July 10-18, 2011 (b),  
686 during the ISM period (May to September). The TGM level ( $\text{C}$ ) were  $3.27 \text{ ng m}^{-3}$ (a) and  $3.65 \text{ ng m}^{-3}$ (b) with

687 the air masses from important industrial regions of inland China. The TGM level were down to 2.49 ng m<sup>-3</sup>(a)  
688 and 3.02 ng m<sup>-3</sup>(b) while the air flow shifted to southwest and swept Southeast Asia.

689 **Fig. 10:** Backward trajectories of air masses and the variation of TGM concentrations because of the  
690 strengthening and incursion of air flow from EASM and the cold Siberian current from September 28 to  
691 October 9, 2011, during the non-ISM period (October to April). The TGM level (C) were 2.25 ng m<sup>-3</sup>, 3.18 ng  
692 m<sup>-3</sup> and 2.53 ng m<sup>-3</sup> with the air masses from inland China. The TGM level was down to 1.89 ng m<sup>-3</sup> with the  
693 air masses from South China Sea, northern Vietnam and Laos.

694 **Fig. 11:** Backward trajectories of air masses and the sites of fire events from December 23-31, 2011, during the  
695 non-ISM period (October to April). The TGM level (C) was 3.13 ng m<sup>-3</sup> with air masses from important  
696 Southeast Asia industrial regions. The TGM level dropped to 2.78 ng m<sup>-3</sup> with air masses from the Bay of  
697 Bengal.

698 **Fig. 12:** Correlation of TGM and CO in December 23-31, 2011, during the non-ISM period.

699 **Fig. 13:** Backward trajectories of air masses and the sites of fire events in March 23-29, 2012, during the  
700 non-ISM period (October to April). The TGM level (C) were 4.53 ng m<sup>-3</sup> with the air masses from inland  
701 China. The TGM level was 3.11 ng m<sup>-3</sup> with the air masses from Myanmar and high-frequency fire events.

702 **Fig. 14:** Correlation of TGM and CO ( $R^2=0.53$ ), correlations between TFRP (total fire radiative power) and  
703 CO ( $R^2=0.98$ ) and TGM ( $R^2=0.45$ ) in March 23-29, 2012, during the non-ISM period (October to April).

704 **Fig. 15:** Potential source regions and pathways of atmospheric TGM at ALS as identified by the CWT during  
705 the ISM period (a, May to September) and the non-ISM period (b, October to April).

706

707 **Table 1:** The statistics for mercury species and meteorological variables based on daily averages from May  
 708 2010 through May 2011 at the ALS site.

710

711

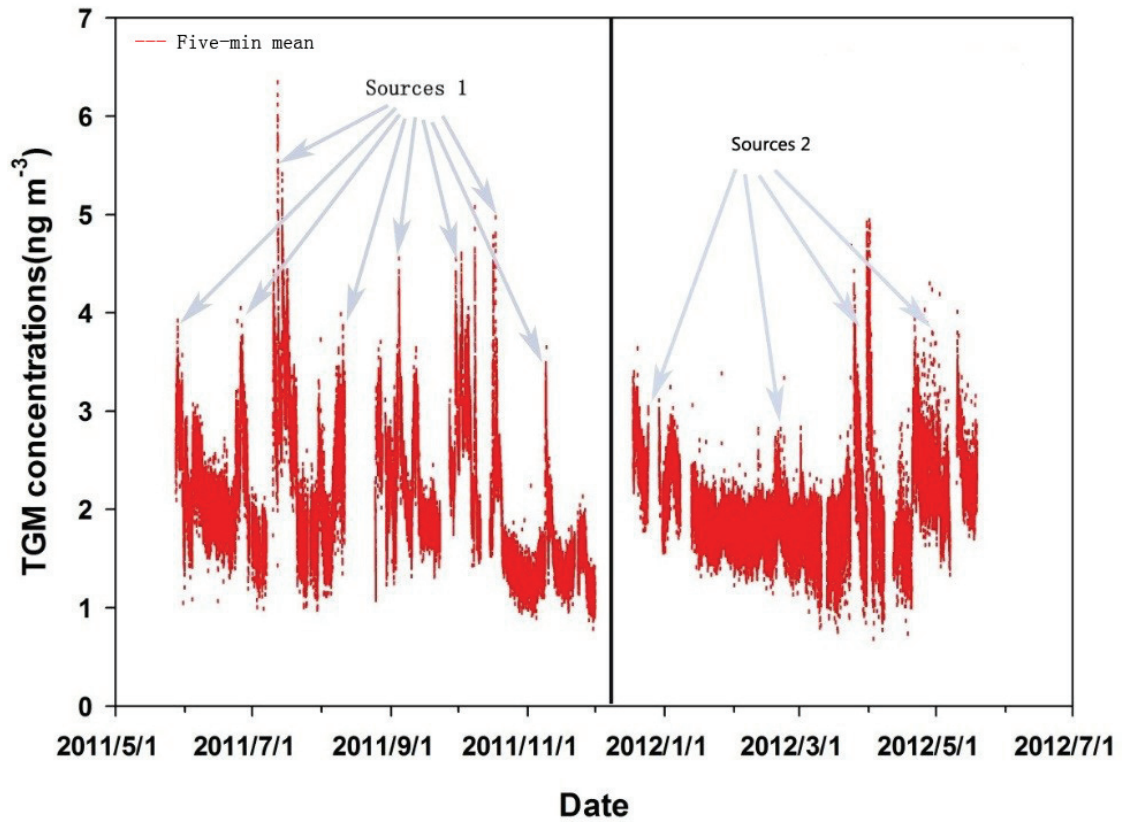

712 **Fig. 1:** Map showing the location of ALS, anthropogenic mercury emissions ( $\text{g km}^{-2} \text{y}^{-1}$ ) and major cities in  
 713 Asia (AMAP/UNEP, 2013).

714

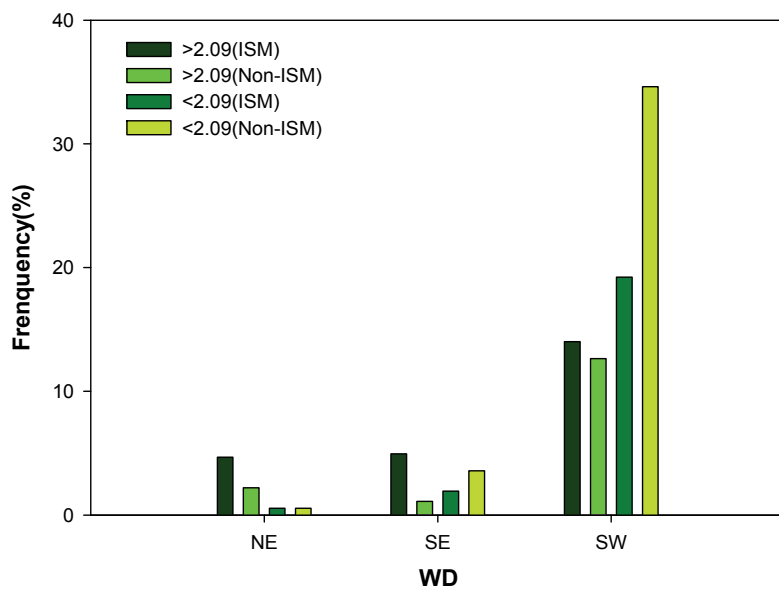

715

716 **Fig. 2:** Total gaseous mercury (TGM) concentration in the ambient air at ALS. Source 1 represents the peaks  
717 of high TGM concentrations at ALS during the ISM period (May to September), which were caused by  
718 anthropogenic Hg emissions from inland China due to the strengthening of EASM. Source 2 represents the  
719 peaks of high TGM concentrations at ALS during the non-ISM period (October to April), which were caused  
720 by the biomass burning from Southeast Asia and anthropogenic Hg emissions from South Asia.  
721

722  
723

724 **Fig. 3:** Distribution frequency of TGM above and under the average ( $2.09 \text{ ng m}^{-3}$ ) based on wind direction  
 725 during the ISM (May to September) and the non-ISM period (October to April). The high and low TGM levels  
 726 of the SW frequency was higher than both the high and low TGM levels of the NE and SE frequencies.  
 727

728

729

730

731

732

733

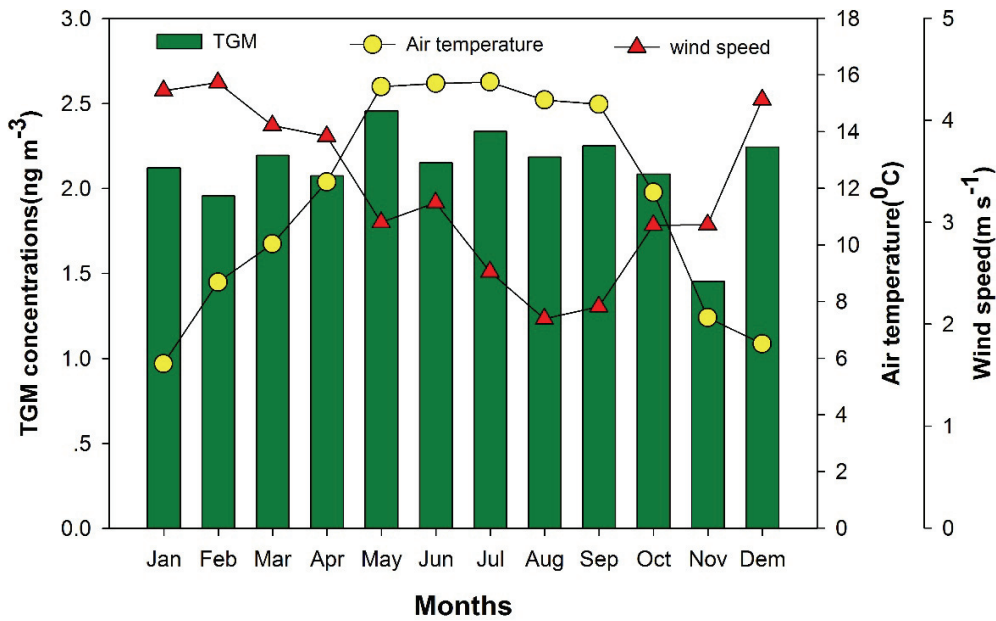

734

735

736

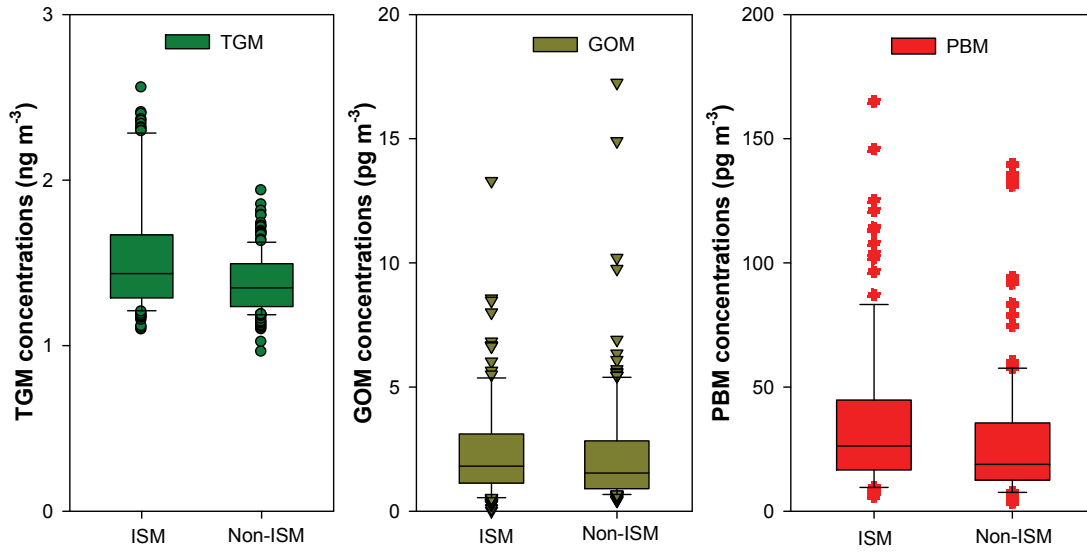

737

738 **Fig. 4:** Monthly TGM anomalies at ALS. The TGM concentration during the ISM period (May to September)  
 739 was higher than that of the non-ISM period (October to April). The highest monthly concentration ( $2.46 \text{ ng m}^{-3}$ )  
 740 was observed in May, and the lowest monthly mean concentration ( $1.45 \text{ ng m}^{-3}$ ) was observed in November.  
 741 The air temperature was higher, and the wind speed was lower during the ISM period than that of the non-ISM  
 742 period.  
 743

744  
 745

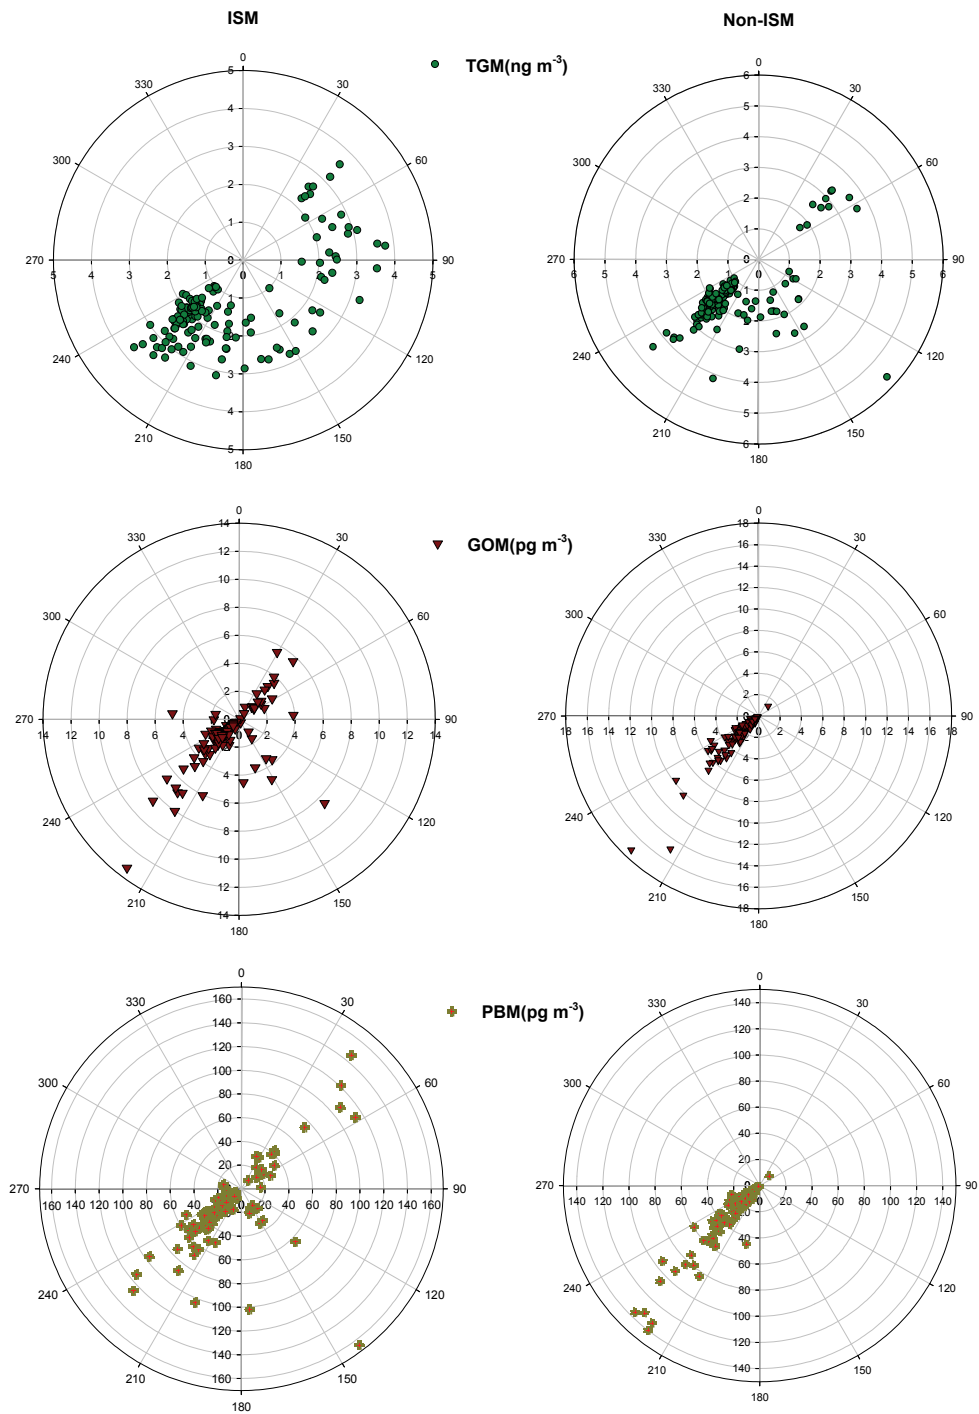

746 **Fig. 5:** TGM, GOM and PBM variation during the ISM (May to September) and non-ISM period (October to  
747 April) based on the four sampling campaigns. TGM, GOM and PBM concentrations showed a monsoonal  
748 variation with higher level during the ISM period than in the non-ISM period.

749

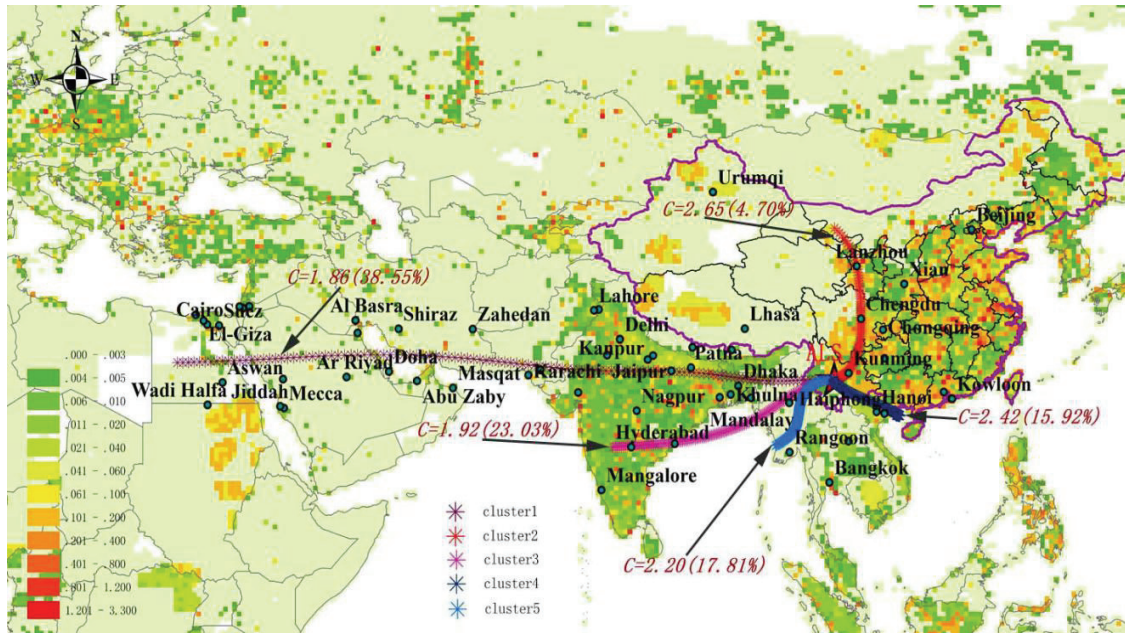

750 **Fig. 6:** Pollution roses of Hg species. Most of the TGM, GOM and PBM were from SW, and some higher  
 751 TGM, GOM and PBM events were from NE during the ISM period (May to September). Almost all TGM,  
 752 GOM and PBM were from SW during the non-ISM period (October to April).  
 753

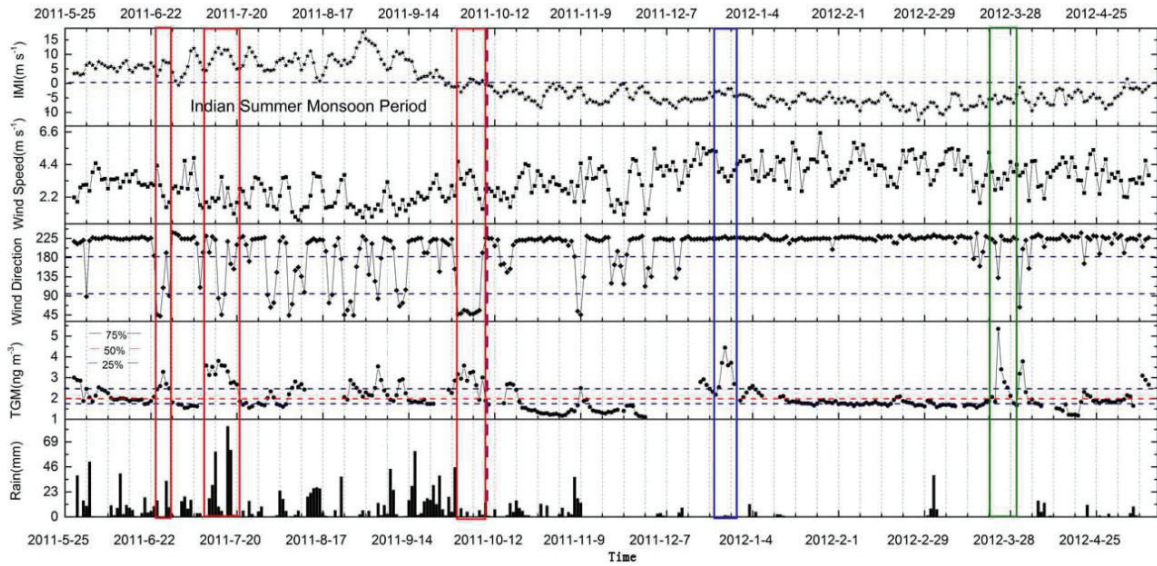

754

755 **Fig. 7:** Air mass backward trajectory analysis for long range transport to ALS. Most of these backward  
 756 trajectories consisted of air masses that originated from South and Southeast Asia and were accompanied by  
 757 lower TGM levels. Air masses originating from inland China were less frequent and accompanied by higher  
 758 TGM levels.  
 759

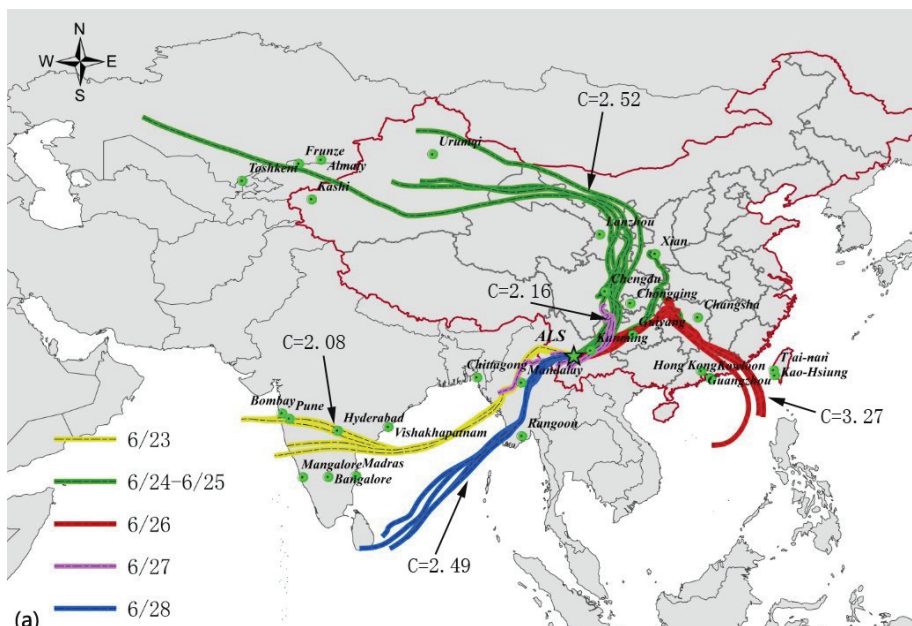

760  
 761

762 **Fig. 8:** The distribution of the Indian monsoon index (IMI), TGM and rainfall at ALS. IMI displays that the  
 763 ISM period was from May to September. RF events mainly appeared during the ISM period. Some high TGM  
 764 events were accompanied by NE and east wind events during the ISM period. High TGM events were  
 765 accompanied by the appearance of SW during the non-ISM period (October to April).  
 766

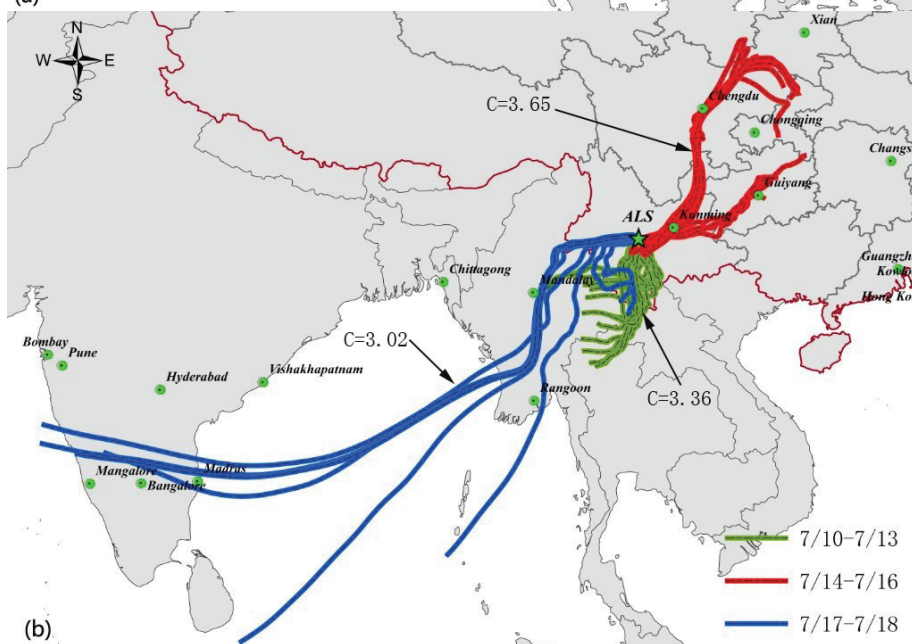

767  
 768

769 **Fig. 9:** Backward trajectories of air masses and the variation of TGM concentrations because of the  
 770 strengthening of and incursion of air flow from EASM on June 23-28, 2011 (a), and July 10-18, 2011 (b),  
 771 during the ISM period (May to September). The TGM level (C) were  $3.27 \text{ ng m}^{-3}$ (a) and  $3.65 \text{ ng m}^{-3}$ (b) with  
 772 the air masses from important industrial regions of inland China. The TGM level were down to  $2.49 \text{ ng m}^{-3}$ (a)  
 773 and  $3.02 \text{ ng m}^{-3}$ (b) while the air flow shifted to southwest and swept Southeast Asia.  
 774

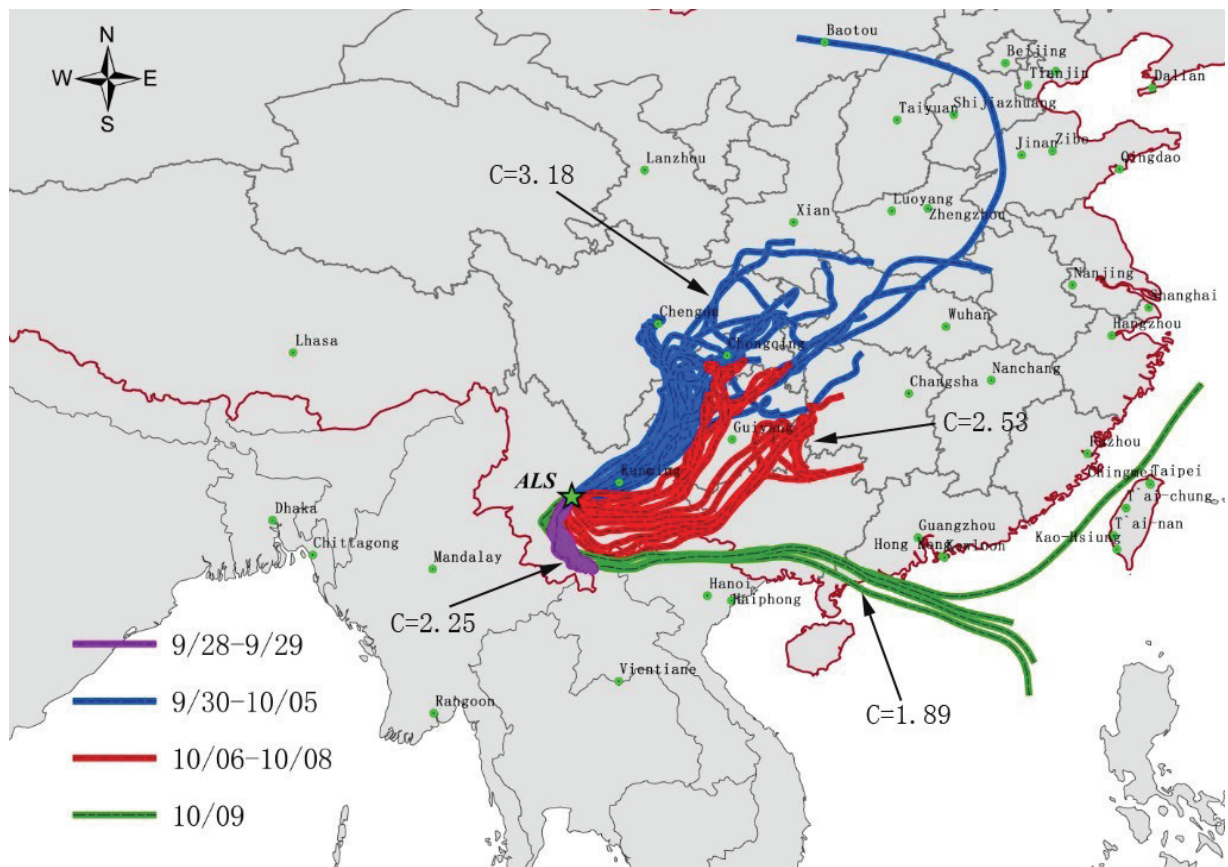

775

776  
777

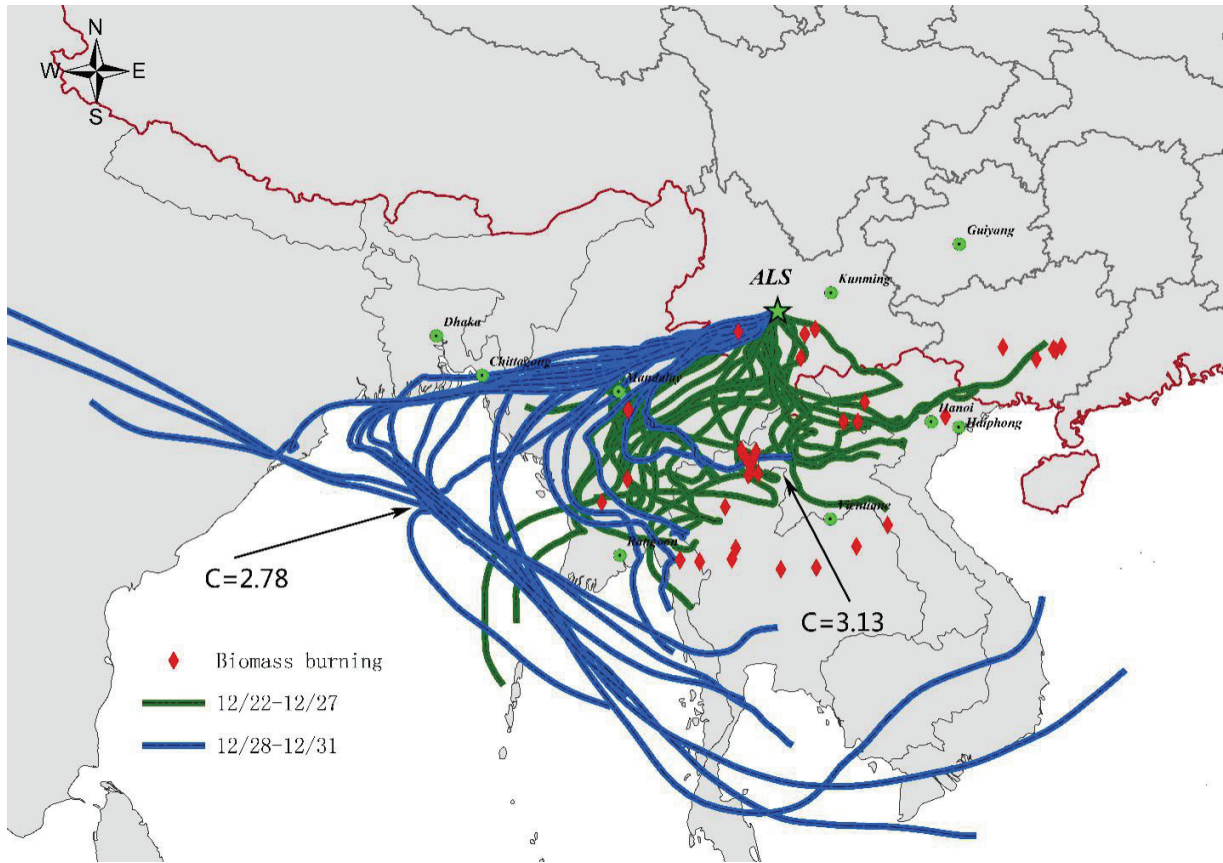

778 **Fig. 10:** Backward trajectories of air masses and the variation of TGM concentrations because of the  
 779 strengthening and incursion of air flow from EASM and the cold Siberian current from September 28 to  
 780 October 9, 2011, during the non-ISM period (October to April). The TGM level (C) were  $2.25 \text{ ng m}^{-3}$ ,  $3.18 \text{ ng}$   
 781  $\text{m}^{-3}$  and  $2.53 \text{ ng m}^{-3}$  with the air masses from inland China. The TGM level was down to  $1.89 \text{ ng m}^{-3}$  with the  
 782 air masses from South China Sea, northern Vietnam and Laos.  
 783

784  
 785

786 **Fig. 11:** Backward trajectories of air masses and the sites of fire events from December 23-31, 2011  
 787 (<https://firms.modaps.eosdis.nasa.gov/firemap/>), during the non-ISM period (October to April). The TGM  
 788 level (C) was  $3.13 \text{ ng m}^{-3}$  with air masses from important Southeast Asia industrial regions. The TGM level  
 789 dropped to  $2.78 \text{ ng m}^{-3}$  with air masses from the Bay of Bengal.  
 790

791  
 792  
 793

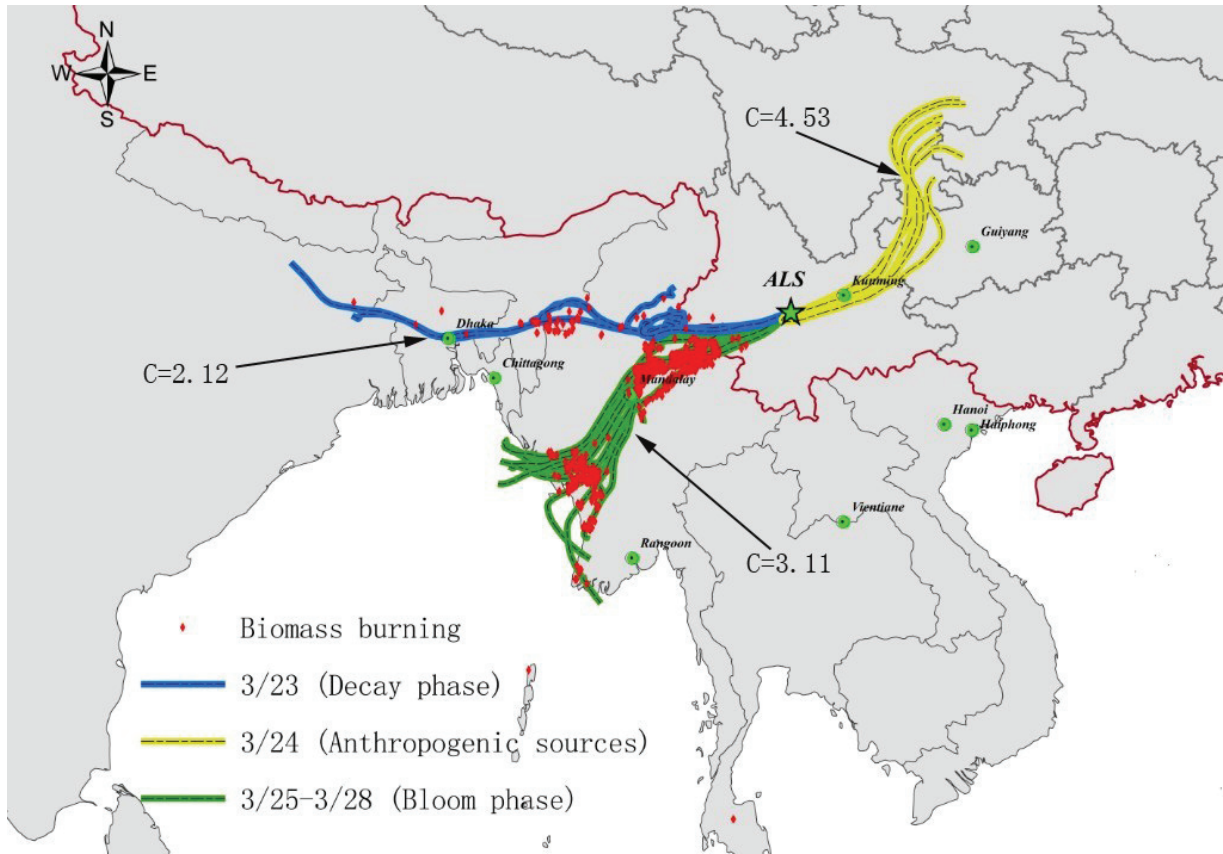

794 **Fig. 12:** Correlation of TGM and CO in December 23-31, 2011, during the non-ISM period (October to April).  
795

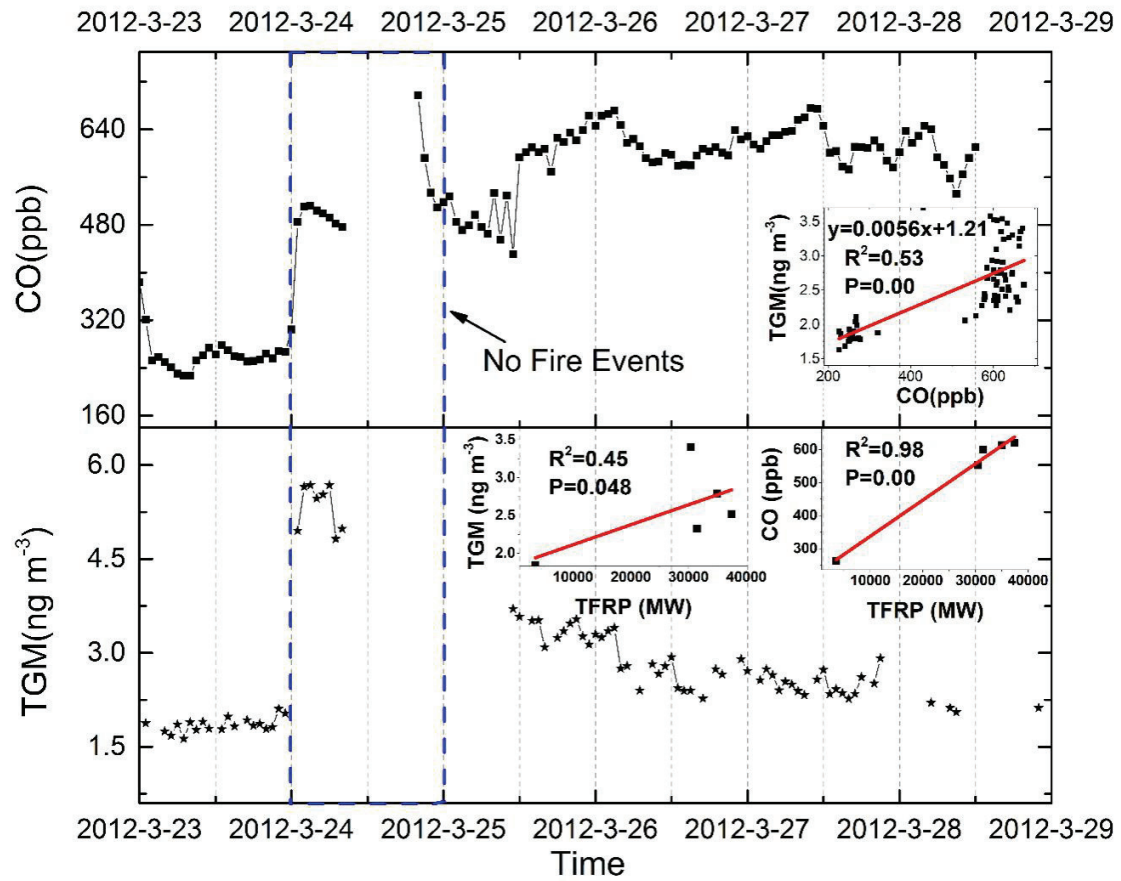

796  
797

798 **Fig. 13:** Backward trajectories of air masses and the sites of fire events in March 23-29, 2012  
799 (<https://firms.modaps.eosdis.nasa.gov/firemap/>), during the non-ISM period (October to April). The TGM  
800 level (C) were 4.53 ng m<sup>-3</sup> with the air masses from inland China. The TGM level was 3.11 ng m<sup>-3</sup> with the air  
801 masses from Myanmar and high-frequency fire events.  
802

803  
804

805 **Fig. 14:** Correlation of TGM and CO ( $R^2=0.53$ ), correlations between TFRP (total fire radiative power) and  
 806 CO ( $R^2=0.98$ ) and TGM ( $R^2=0.45$ ) in March 23-29, 2012, during the non-ISM period (October to April).  
 807

808  
 809

810 **Fig. 15:** Potential source regions of atmospheric TGM at ALS as identified by the CWT during the ISM period  
 811 (a, May to September) and the non-ISM period (b, October to April).
