10 **Abstract.** The summer of 2015 was an extreme forest fire year in the Pacific North West. Our  
sample site at Mt. Bachelor Observatory (MBO, 2.7 km a.s.l.) in central Oregon observed  
biomass burning events more than 50% of the time during August. In this paper we characterize  
the aerosol physical and optical properties of 19 aged biomass burning (BB) events during  
August 2015. Six of the nineteen events were influenced by Siberian fires originating near Lake  
15 Baikal. The remainder of the events resulted from wildfires in Northern California and  
Southwestern Oregon with transport times to MBO ranging from 4.5-35 hours. Fine particulate  
matter (PM<sub>1</sub>), carbon monoxide (CO), aerosol light scattering ( $\sigma_{scat}$ ) and absorption ( $\sigma_{abs}$ ), and  
aerosol number size distributions were measured throughout the campaign. We found that the  
Siberian events had significantly higher  $\Delta\sigma_{abs}/\Delta CO$  enhancement ratio, higher mass absorption  
20 efficiency (MAE;  $\Delta\sigma_{abs}/\Delta PM_1$ ), lower single scattering albedo ( $\omega$ ), and lower Absorption  
Ångström exponent (AAE) when compared with the regional events. We suspect the Siberian  
events observed represent a portion of the fire plume that has hotter flaming fire conditions that  
enabled strong pyro-convective lofting and long transport to MBO. These plumes would then  
have preferentially higher black carbon emissions and thus absorption enhancement. The lower  
25 AAE values in the Siberian events compared to regional events indicates a lack of brown carbon  
(BrC) production by the Siberian fires or a loss of BrC during transport. We found that mass  
scattering efficiencies (MSE) for the BB events to range from 2.50-4.76 m<sup>2</sup> g<sup>-1</sup>. We measured  
aerosol size distributions with a scanning mobility particle sizer (SMPS). Number size  
distributions ranged from unimodal to bimodal and had geometric mean diameters ranging from  
30 138-229 nm and geometric standard deviations ranging from 1.53-1.89. We found MSE's for BB  
events to be positively correlated with the geometric mean of the aerosol size distributions ( $R^2 =$

0.73), which agrees with Mie Theory. We did not find any dependence on event size distribution to transport time or fire source location.

## 1. Introduction

35 Biomass burning (BB) is a major source of aerosol in the atmosphere [Andreae and Merlet, 2001; Bond *et al.*, 2004]. BB particles are predominantly organic carbon (OC) and black carbon (BC), with some inorganic material [Reid *et al.*, 2005b; Vakkari *et al.*, 2014]. These particles can significantly impact the Earth's radiative balance and climate through direct and indirect aerosol effects. The direct effects on radiative forcing are due to the light scattering and  
40 absorption of the aerosol [Boucher *et al.*, 2013; Haywood and Boucher, 2000], and the indirect effects are caused by particles acting as cloud condensation nuclei (CCN) which affects cloud albedo [Pierce *et al.*, 2007; Spracklen *et al.*, 2011]. According to the IPCC 2013 report the largest uncertainty in determining global radiative forcing comes from quantifying the direct and indirect effects of aerosols [Boucher *et al.*, 2013]. Biomass burning is a major contributor to  
45 global aerosol burden and it has been predicted that these emissions are likely to increase due to climate change, particularly in the boreal forests of North America and Russia [Flannigan *et al.*, 2009; Stocks *et al.*, 1998] and the western U.S. [Y Liu *et al.*, 2014b; Westerling *et al.*, 2006]. This makes the proper characterization of aged BB emissions even more important.

Currently there are few field measurements of well-aged BB emissions. Our knowledge  
50 of BB aerosol primarily comes from laboratory experiments and near-field measurements taken within a few hours of a wildfire [May *et al.*, 2015; May *et al.*, 2014; Okoshi *et al.*, 2014; Vakkari *et al.*, 2014; Yokelson *et al.*, 2013b; Yokelson *et al.*, 2009]. Holder *et al.* [2016] showed that laboratory measurements of aerosol optical properties do not accurately reproduce field measurements. Freshly emitted BB particles are small in diameter (30-100 nm) [Hosseini *et al.*,  
55 2010; Levin *et al.*, 2010]. As the plume ages, the aerosol undergo rapid chemical and physical changes on the time scale of minutes to hours [Reid *et al.*, 2005a; Reid *et al.*, 2005b; Vakkari *et al.*, 2014]. The change in particle size is due to coagulation and the condensation of organic material onto the existing particles [Reid *et al.*, 2005b; Seinfeld and Pandis, 2006]. The coagulation rate can be very high in fresh BB plumes since this is equivalent to the square of  
60 particle number concentration. This process increases the size of the particles while decreasing

the number concentration. Condensation of secondary organic aerosol (SOA) onto particles in BB plumes can also increase particle size. The condensation of SOA is counterbalanced by the loss of primary organic aerosol (POA), which can evaporate during plume dilution [May *et al.*, 2015; May *et al.*, 2013]. The net condensation/evaporation effect is highly variable. Some studies  
65 have observed an increase in mass with plume age due to SOA production [Briggs *et al.*, In Press; Hobbs, 2003; Vakkari *et al.*, 2014; Yokelson *et al.*, 2009], while others have observed limited SOA formation [Akagi *et al.*, 2012; Jolleys *et al.*, 2015]. All of these uncertainties in the aging process of biomass burning underscores the importance of characterizing the physical and optical properties of well-aged biomass burning aerosol.

70 In this study we analyze the physical and optical aerosol properties of 19 aged BB events observed in the summer of 2015 at Mt. Bachelor in Oregon. The BB events consisted of Regional events (fires in Northern California and Southwestern Oregon; transported 3-30 hours) and Siberian fire events (fires around Lake Baikal; transported 4-10 days). We investigated the aerosol optical and physical properties of these events and explored their variation with source  
75 location and transport time. This study addresses the following questions:

- What are the differences in the optical properties of regional and Siberian BB events observed at MBO?
- What is the range of mass scattering efficiencies for BB events and what explains their variability?
- 80 - What is the range in aerosol size distributions of BB events at MBO and how does this vary with plume age?

## 2. Methods

### 2.1. Mt Bachelor Observatory

The Mt. Bachelor Observatory (MBO) is a mountaintop site that has been in operation since  
85 2004 [Jaffe *et al.*, 2005]. It is located at the summit of Mt. Bachelor in central Oregon, US (43.98° N, 121.69° W, 2,764 m a.s.l.). A suite of measurements (including carbon monoxide (CO), ozone (O<sub>3</sub>), aerosol scattering, and more) have been made continuously at the summit site since 2004. Previous studies have observed BB plumes in the free troposphere from regional and distant sources in the spring, summer, and fall [Baylon *et al.*, 2015; Briggs *et al.*, In Press;

90 *Collier et al.*, Submitted; *Timonen et al.*, 2014; *Weiss-Penzias et al.*, 2007; *Wigder et al.*, 2013],  
and long-range transport of Asian pollution in the spring [*Ambrose et al.*, 2011; *Fischer et al.*,  
2010a; *Fischer et al.*, 2010b; *Gratz et al.*, 2014; *Jaffe et al.*, 2005; *Reidmiller et al.*, 2010;  
*Timonen et al.*, 2014; *Timonen et al.*, 2013; *Weiss-Penzias et al.*, 2006]. During the summer of  
2015 an intensive field campaign was performed at MBO to measure aerosol physical and optical  
95 properties of wildfire emissions.

## 2.2. CO, CO<sub>2</sub>, and meteorological data

CO and CO<sub>2</sub> measurements were made using a Picarro G2302 Cavity Ring-Down Spectrometer.  
Calibrations were performed every 8 hours using three different NOAA calibration gas  
standards, which are referenced to the World Meteorological Organization's (WMO) mole  
100 fraction calibration scale [*Gratz et al.*, 2014]. Basic meteorology measurements, such as  
temperature, humidity and wind speed are also measured continuously [*Ambrose et al.*, 2011].

## 2.3. Aerosol Instruments

We measured dry (relative humidity (RH) less than 35%) aerosol scattering and absorption  
coefficients, aerosol number size distribution, and particle mass during the 2015 summer  
105 campaign in 5 minute averages. The aerosol instruments were located in a temperature-  
controlled room within the summit building, situated approximately 15 m below the inlet. A 1  
µm impactor was located inline prior to any The aerosol sample line was situated such that the  
last 2.5 m was located within a space that was temperature controlled at  $20 \pm 3^\circ\text{C}$ , typically  
10°C–20°C warmer than ambient. Relative humidity of the sampled air was less than 35%  
110 throughout the campaign. The temperature increase from outside into the heated building  
reduced the RH of the sample. RH was measured in the sample airstream by the nephelometer  
and SMPS. The average RH during the campaign measured by the nephelometer and SMPS was  
22.1% and 22.6%, respectively. Ninety- five percent of the 5 minute averaged samples had an  
RH less than 30%.

115 We measured multiwavelength aerosol light scattering ( $\sigma_{scat}$ ) using an integrating  
nephelometer (model 3563, TSI Inc., Shoreview, MN) at wavelengths 450, 550, and 700 nm.  
Anderson and Ogren (1998) corrections were applied to the  $\sigma_{scat}$  coefficients [*Fischer et al.*,  
2010a]. We measured aerosol light absorption ( $\sigma_{abs}$ ) with a  $3\lambda$  tricolor absorption photometer

(TAP, Brechtel Inc., Hayward, CA) at wavelengths 467, 528, and 660 nm. Throughout the paper  
120  $\sigma_{scat}$  and  $\sigma_{abs}$  values represent measurements taken at 550 nm and 528 nm, respectively. The TAP  
is a new instrument that uses the same operating principle as the Particle Soot Absorption  
Photometer (PSAP) and the same filters (47 mm PALL E70-2075W). Unlike the PSAP, the TAP  
rotates through 8 filter spots per individual filter along with two reference spots. During  
125 deployment at MBO, the TAP was set to rotate to the next filter spot when filter spot's  
transmission reached 50%. The absorption coefficients were corrected using the filter loading  
and aerosol scattering correction factors derived for the 3 $\lambda$  PSAP by *Virkkula* [2010].

Single scattering albedo ( $\omega$ ) for each event was calculated as the RMA regression of  
scattering and total extinction (scattering + absorption) coefficient at 528 nm. To adjust the  $\sigma_{scat}$   
value from 550 nm-528 nm, a power law relationship was assumed between scattering and  
130 wavelength. The 450-550 nm pair was used to adjust the 550 nm  $\sigma_{scat}$  measurement to 528 nm  
using the equation:  $\sigma_{scat}^{528} = \sigma_{scat}^{550} * \left(\frac{\lambda_{550}}{\lambda_{528}}\right)^{SAE_{450,550}}$ , where  $\lambda$  is wavelength and SAE is the  
scattering Ångström exponent calculated with the two wavelengths specified. Absorption  
Ångström exponent (AAE) values were calculated for the absorption coefficient pair of 467 and  
660 nm [*Fischer et al.*, 2010a].

135 We measured 5 minute averaged dry aerosol number size distribution with TSI 3938  
Scanning Mobility Particle Sizer (SMPS). The SMPS system consisted of a TSI 3082  
electrostatic classifier with TSI 3081 Differential Mobility Analyzer (DMA) and TSI 3787  
water-based condensation particle counter. A total of 107 bins were used to measure a diameter  
range from 14.1-637.8 nm. A sheath to aerosol flow ratio of 10:1 was used for the DMA. A  
140 multiple charge correction and diffusion loss correction were applied to the SMPS particle  
number concentration data using the TSI software. An additional diffusion correction for the  
inlet tube (15 m, 12 LPM) was applied assuming a laminar flow [*Hinds*, 1999]. Prior to  
deployment we confirmed the sizing accuracy of the SMPS using polystyrene latex spheres  
(PSL).

145 We measured dry particle mass under 1  $\mu$ m (PM1) with an Optical Particle Counter  
(OPC, model 1.109, Grimm Technologies, Douglasville, GA). This is a U.S. EPA equivalent  
method for measuring PM2.5 mass concentration. The OPC was factory calibrated prior to  
deployment.

All particle measurements ( $\sigma_{\text{scat}}$ ,  $\sigma_{\text{abs}}$ , PM1, number size distribution) were corrected to  
150 standard temperature and pressure (STP;  $T = 273.15$ ,  $P = 101.325$  kPa).

#### 2.4. Enhancement ratio calculations

Enhancement ratios ( $\Delta Y/\Delta X$ ) were calculated from the slope of the RMA regression of Y plotted  
against X. *Briggs et al.* [In Press] calculated enhancement ratios (ERs) of BB plumes using three  
different methods, one being the RMA slope of the linear correlation of two species, and two  
155 calculating absolute enhancement above local background using two different definitions of  
background. All three methods produced similar results for  $\Delta\sigma_{\text{scat}}/\Delta\text{CO}$ ,  $\Delta\text{NO}_y/\Delta\text{CO}$ , and  
PAN/ $\Delta\text{CO}$ , but differing results for  $\Delta\text{O}_3/\Delta\text{CO}$ . In our study we will use the RMA regression  
method for calculating ERs of  $\Delta\sigma_{\text{scat}}/\Delta\text{CO}$  and  $\Delta\sigma_{\text{abs}}/\Delta\text{CO}$ .

Mass scattering and mass absorption efficiencies (MSE and MAE) were calculated as the  
160 enhancement ratios of  $\Delta\sigma_{\text{scat}}/\Delta\text{PM1}$  and  $\Delta\sigma_{\text{abs}}/\Delta\text{PM1}$ , respectively, at 550 nm for  $\sigma_{\text{scat}}$  and 528  
nm for  $\sigma_{\text{abs}}$ . In all cases the enhancements ( $\Delta$ ) are large compared to background, thus avoiding  
the problems described by *Briggs et al.* [In Press] for small enhancements above background.

#### 2.5. Biomass burning event identification

We identified BB events as time periods during which 5-min ambient aerosol scattering  $\sigma_{\text{scat}} > 20$   
165  $\text{Mm}^{-1}$  for at least one hour, 5-min CO  $> 150$  ppbv for at least one hour, and a strong correlation  
( $R^2 > 0.80$ ) was found between  $\sigma_{\text{scat}}$  and CO. To determine fire locations we calculated back-  
trajectories using the National Oceanic and Atmospheric Administration Hybrid Single-Particle  
Lagrangian Integrated Trajectory (HYSPLIT) model, version 4 [Draxler, 1999; Draxler and  
*Hess*, 1997; 1998; *Stein et al.*, 2015]. We used the Global Data Assimilation System (GDAS)  $1^\circ$   
170  $\times 1^\circ$  gridded meteorological data from the National Oceanographic and Atmospheric  
Administration's Air Resources Laboratory (NOAA-ARL). Within GDAS, the grid containing  
MBO is located at  $\sim 1500$  m amgl (above model ground level) so back-trajectory starting heights  
of 1300, 1500, and 1700 m amgl were chosen [Ambrose *et al.*, 2011]. We identified fire locations  
using Moderate Resolution Imaging Spectroradiometer (MODIS) satellite-derived active fire  
175 counts [Justice *et al.*, 2002]. Similar criteria for identifying BB events has been used by *Baylon*  
*et al.* [2015] and *Wigder et al.* [2013] from data collected at MBO.

### 3. Results and Discussion

#### 3.1. Identified BB events and Fire Source Identification

The summer of 2015 was a very active fire season in the Pacific North West (Figure 1). During  
180 the month of August 2015, 51% of the 5 minute averages met the criteria for a BB event of  
having  $\sigma_{\text{scat}} > 20 \text{ Mm}^{-1}$  and  $\text{CO} > 150 \text{ ppbv}$ , including several multi-day periods. We split these  
multi-day events up if discernable plumes within the event could be identified. Altogether we  
identified 19 events, ranging from 1.5-45 hours in duration. We use the term event, not plume,  
because of the long duration of some of the events and the fact that most BB events observed in  
185 2015 were influenced by emissions from multiple fires.

We categorized most of the events into three main periods (Figure 2). Periods 1 (8/9/15-  
8/12/15: events 2-8) and 3 (8/23/15-8/29/15: events 16-19) are both multi-day periods that  
experienced regional BB smoke from fires in Northern California and Southwestern Oregon.  
Transport time from these regional fires to MBO, estimated from the back-trajectories, ranged  
190 from 3-30 hours. Period 3 (8/17/15-8/22/15: events 10-15) is characterized by influence from  
Siberian BB events. During August there were intense forest fires around Lake Baikal in Siberia,  
peaking on 8/8/2015 with a total fire area of  $681 \text{ km}^2$ , and an estimated CO and BC emissions of  
 $3.22 \times 10^8$  and  $1.33 \times 10^6 \text{ kg/day}$ , respectively (*Fire INventory from NCAR (FINN) data*)  
[Wiedinmyer et al., 2011]. Transport times from the Northeastern Asia to MBO during these  
195 events ranged from 4-10 days. NASA MODIS aqua and terra images show the eastward  
transport of smoke from the Lake Baikal fires during this time period  
[<https://worldview.earthdata.nasa.gov/>, 2016]. We used V3.30 aerosol classification products  
from the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) instrument on the Cloud-  
Aerosol Lidar Infrared Pathfinder Satellite Observation (CALIPSO) satellite to confirm the  
200 transport of plumes of smoke from the Siberian fires to North America [[http://www-  
calipso.larc.nasa.gov/](http://www-calipso.larc.nasa.gov/), 2016; Winker et al., 2010; Winker et al., 2009]. Aerosol plumes are  
identified as one of six types: dust, polluted continental, polluted dust, smoke (biomass burning),  
clean continental or clean marine aerosols [Omar et al., 2009].

#### 3.2. Overview of Summer 2015 BB Events from difference sources

205 Table 1 provides an overview of the 19 BB events from MBO during the summer of 2015. We  
calculated water vapor enhancement ( $\Delta WV$ ) to indicate the origin of the event air mass. Positive  
 $\Delta WV$  suggest the air mass ascended from the boundary layer (BL) to while near zero or  
negative values mean the air mass is relatively dry and likely descended or arrived from the free  
troposphere (FT) [Baylon *et al.*, 2015; Wigder *et al.*, 2013]. All of the regional BB events have  
210  $\Delta WV$  values  $\geq 1.00$ , while all of the Siberian influenced events have  $\Delta WV$  values near zero or  
negative.

We found the  $\Delta\sigma_{\text{scat}}/\Delta\text{CO}$  ( $\sigma_{\text{scat}}$  at STP) enhancement ratio to range from 0.48-1.29  $\text{Mm}^{-1}/\text{ppbv}$ ,  
with the majority of events being between 0.8 and 1.25  $\text{Mm}^{-1}/\text{ppbv}$ . We found  
 $\Delta\text{PM1}/\Delta\text{CO}$  (PM1 at STP) to range from 0.18-0.43  $\mu\text{g cm}^{-3}/\text{ppbv}$ . These values are in the same  
215 range as BB plumes seen previously at MBO [Baylon *et al.*, 2015; Wigder *et al.*, 2013].

### 3.3. Optical Properties of the BB Aerosol at MBO

We observed significant differences in the optical properties of regional and Siberian influenced  
BB events. The Siberian influenced events had enhanced absorption coefficients relative to other  
measurements made. This resulted in higher  $\Delta\sigma_{\text{abs}}/\Delta\text{CO}$ , higher MAE, and lower  $\omega$  ( $\sigma_{\text{scat}}/(\sigma_{\text{scat}} +$   
220  $\sigma_{\text{abs}})$ ) compared to regional BB events (Figure 3 and 4). We found no significant differences for  
 $\Delta\sigma_{\text{scat}}/\Delta\text{CO}$  or MSE between regional and Siberian events. Event 9 was anomalous in that it has  
very low absorption enhancement, a high  $\omega$ , and is not part of the designated Periods defined in  
section 3.1. Back-trajectories show that event 9 came from the boundary layer under stagnant  
conditions, indicating an aged and mixed source. Back-trajectories for the Siberian events  
225 (events 10-15) indicate that the plumes were lofted to altitudes of 4-10 km (Figure S1). The  
Siberian events at MBO were observed over the course of a week (8/17/2015-8/23/2015),  
therefor the back-trajectories in Fig. S1 represent a sustained meteorological pattern that  
consistently transported Siberian smoke to North America throughout the week. Aerosol vertical  
profiles measured by CALIOP corroborate the transport of BB plumes from the Siberian fires  
230 across the Pacific at altitudes of 4-10 km. Large BB plumes were identified over Northeast Asian  
and the North Pacific consisting primarily of BB smoke and some polluted dust over the  
Northern Pacific from 8/8/2015-8/17/2015. Figures S2-S5 show selected CALIPSO transects  
from 8/13/2015-8/16/2015 over the Pacific. The location and altitude of these plumes match the

back-trajectories calculated from MBO for the Siberian events (Figure S1), verifying that events  
235 10-15 are heavily influenced by the Siberian fires.

We theorize the Siberian BB events observed at MBO represent hotter, more flaming  
fires which have higher BC emissions and thus higher absorption enhancements compared to the  
regional BB events. During the ARCTAS-A flight campaign in Alaska, Siberian fire plumes  
were found to have a much larger BC/CO ratio ( $8.5 \pm 5.4 \text{ ng m}^{-3}/\text{ppbv}$ ) than North American  
240 fire plumes ( $2.3 \pm 2.2 \text{ ng m}^{-3}/\text{ppbv}$ ) [Kondo *et al.*, 2011]. This difference was attributed to the  
Siberian fires having a higher modified combustion efficiency (MCE). In addition, for the  
Siberian BB plumes they found MCE to increase with altitude. Jolleys *et al.* [2015]  
correspondingly found higher  $\Delta\text{BC}/\Delta\text{OA}$  ratios to increase with altitude in Eastern Canadian BB  
plumes. Intense, flaming fire plumes have higher injection heights into the atmosphere due to  
245 enhanced pyro-convection, whereas smoldering fires have low thermal convective energy and  
are mostly contained within the boundary layer. BB aerosol lofted to the free troposphere via  
pyro-convection is less likely to be removed and can have a longer atmospheric lifetime of up to  
40 days [Bond *et al.*, 2013]. The back-trajectories for the Siberian events corroborate this idea.  
They were all relatively dry (water vapor mixing ratio  $< 5 \text{ g kg}^{-1}$ ) with little precipitation during  
250 transport, suggesting the aerosol in the Siberian events was subjected to very limited wet  
deposition, which is the main removal mechanism from the atmosphere. Flaming conditions  
produce more black carbon (BC) and less organic aerosol (OA) generally, which leads to  
amplified absorption [Vakkari *et al.*, 2014; Yokelson *et al.*, 2009]. Flaming conditions are  
associated with high modified combustion efficiency (MCE) values [Reid *et al.*, 2005a].  
255 Unfortunately we were not able to calculate MCE values for the Siberian events at MBO due to  
extensive dilution and boundary layer mixing during transport [Yokelson *et al.*, 2013a].

We found AAE values for the Siberian events to be significantly lower than regional BB  
events (Figures 3 and 4). High AAE values are indicative of the presence of brown carbon (BrC).  
Brown carbon is a fraction of organic aerosol (OA) that selectively absorbs short wavelengths  
260 [Andreae and Gelencser, 2006; Chen and Bond, 2010; Kirchstetter *et al.*, 2004]. There are two  
possible explanations for the difference in AAE values. The first is that the flaming conditions  
that produced the Siberian events seen at MBO had higher BC and lower OA emissions, which  
inherently have lower AAE as total absorption is dominated by BC and there is less BrC in the  
aerosol. Laboratory and field studies have corroborated this and observed an inverse relationship

265 between MCE and AAE [Holder *et al.*, 2016; S Liu *et al.*, 2014a; McMeeking *et al.*, 2014]. The  
other explanation is that BrC is lost during transport through photobleaching, volatilization, and  
aerosol-phase reactions. Forrister *et al.* [2015] determined that BrC decreased with transport  
with a half-life of 9 hours and that AAE decreases from ~4.0 to ~2.5 24 hours after emission. All  
of the regional BB events (Periods 1 and 3) were influenced by multiple fires that had transport  
270 times varying from 3- 30 hours. With each event being influenced by at least one fire with a  
transport time  $\leq 6$  hours, this short transport time is consistent with the higher AAE values we  
observed.

### 3.4. Mass Scattering Efficiency

Mass scattering efficiencies (MSE) are important for calculating the radiative forcing effects of  
275 aerosols in global climate and chemical transport models. Estimates of MSE are used to convert  
aerosol mass measurements to aerosol optical properties [Briggs *et al.*, In Press; Hand and  
Malm, 2007; Pitchford *et al.*, 2007]. MSE is dependent on particle composition, which  
determines the particle's refractive index and hygroscopy, and aerosol size distribution [Hand  
and Malm, 2007]. We calculated MSE's as the slope of the RMA regression of  $\sigma_{\text{scat}}$  and PM1  
280 ( $\Delta\sigma_{\text{scat}}/\Delta\text{PM1}$ ).  $R^2$  values were  $>0.94$  for all events. We found MSE values to range from 2.50-  
4.76  $\text{m}^2 \text{g}^{-1}$ , which are consistent with previously measured values.

During 2013 at MBO, MSE values estimated using AMS organic matter (OM) data and  
the  $\sigma_{\text{scat}}$  for four wildfire plumes ranged from 2.8-4.8  $\text{m}^2 \text{g}^{-1}$  (mean: 3.7  $\text{m}^2 \text{g}^{-1}$ ) [Briggs *et al.*, In  
Press]. Levin *et al.* [2010] calculated MSE values for fresh BB smoke from a variety of fuels to  
285 range from 1.5–5.7  $\text{m}^2 \text{g}^{-1}$ , with most of the values falling between 2.0 and 4.5  $\text{m}^2 \text{g}^{-1}$ . Reid *et al.*  
[2005a] reviewed MSE values from BB events and found a range between 3.2 and 4.2  $\text{m}^2 \text{g}^{-1}$   
(mean: 3.8  $\text{m}^2 \text{g}^{-1}$ ) for temperate and boreal fresh smoke, and larger values for aged smoke (3.5-  
4.6  $\text{m}^2 \text{g}^{-1}$ ; mean: 4.3  $\text{m}^2 \text{g}^{-1}$ ). MSE values upwards of  $\sim 6 \text{m}^2 \text{g}^{-1}$  have been observed for aged BB  
[Hand and Malm, 2007; McMeeking *et al.*, 2005]. Due to the large variation in MSE values for  
290 BB events, assigning an average MSE value to convert aerosol mass measurements to aerosol  
optical properties or vice versa introduces significant uncertainties.

We investigated the cause for variation in the MSE values we observed (Figure 5). We  
found MSE's for BB events to be positively correlated with  $D_{\text{pm}}$  ( $R^2 = 0.73$ ) (Figure 5a). If two  
 $D_{\text{pm}}$  values associated with bimodal size distributions are removed the correlation increases

295 substantially ( $R^2 = 0.88$ ). A positive correlation between MSE and mean particle diameter has previously been observed in ambient data [Lowenthal and Kumar, 2004] and laboratory studies [McMeeking *et al.*, 2005]. Theoretically according to Mei theory, MSE will increase as the average particle diameter grows, through coagulation and condensation, toward the measurement wavelength (550 nm) [Seinfeld and Pandis, 2006].

300 MSE was also well correlated with event integrated  $\sigma_{\text{scat}}$  and PM1 mass, and slightly correlated with CO (Figure 5b,c,d). The dependence of MSE on mass concentration [Malm and Hand, 2007] and  $\sigma_{\text{scat}}$  [Lowenthal and Kumar, 2004] has previously been observed, although it is mainly thought to be a function of particle size.

### 3.5. BB Size Distributions

305 Figure 6 shows the BB aerosol number size distributions for the events we observed at MBO in  $\text{dN}/\text{dlogDp}$  (Figure 6). We found  $D_{\text{pm}}$  and  $\sigma_g$  of the number distributions to range from 138-229 nm and 1.53-1.89, respectively. The size distributions observed at MBO are similar to Janhäll *et al.* [2010], who compiled aged biomass burning size distributions. They found the accumulation mode mean diameter to range from 175- 300 nm with geometric standard deviations of 1.3–1.7.

310 During the ARCTAS-B flight campaign, aged BB plumes of Western Canadian and Asian origins were found to have similar size distributions (Canadian:  $D_{\text{pm}} = 224 \pm 14$  nm,  $\sigma_g = 1.31 \pm 0.05$ ; Asian:  $D_{\text{pm}} = 238 \pm 11$  nm,  $\sigma_g = 1.31 \pm 0.03$ ) [Kondo *et al.*, 2011]. The BORTAS-B flight campaign in Eastern Canada observed aged BB plumes with median diameters of 180-240 nm [Sakamoto *et al.*, 2015].

315 We observed clear bimodal distributions with an accumulation mode (100-500 nm) and Aitken mode (20-100 nm) for five events (2, 3, 11, 14 and 15). The Aitken mode in these size distributions most likely represents a secondary source from within the boundary layer. A prominent “tail” consisting of higher than expected number concentrations of small-diameter particles (30-90 nm) was observed for most of the unimodal events at MBO. It would be expected that particles in this size range would grow to larger particles through coagulation relatively quickly. Sakamoto *et al.* [2015] observed a similar elevation in the number concentration of small particles during the BORTAS-B campaign. They attempted to account for the existence of the tail with a Lagrangian box model of coagulation and dilution but were unable to do so. Coagulation should cause a significant decrease in Aitken mode particles in a matter of

320

325 hours; and nucleation and condensation growth rates would have to be unreasonably high to maintain these small particles.

We observed no clear distinction between the size distributions from regional and Siberian events. These results are consistent with previous studies that have not observed a dependence from plume age, transport time, or source location on the BB size distribution.

330 *Kondo et al.* [2011] found little difference between the  $D_{\text{pm}}$  of Siberian and Canadian BB plumes despite different chemical composition and optical properties, and transport times. Similarly, *Sakamoto et al.* [2015] found no trend in size distribution with plume transport distance. We found event integrated  $D_{\text{pm}}$  to be correlated with event integrated  $\sigma_{\text{scat}}$  ( $R^2 = 0.65$ ) and PM1 mass ( $R^2 = 0.72$ ), and moderately correlated with CO ( $R^2 = 0.40$ ).  $D_{\text{pm}}$  was not found to be  
335 correlated with any normalized enhancement ratio ( $\Delta\sigma_{\text{scat}}/\Delta\text{CO}$ ,  $\Delta\text{PM1}/\Delta\text{CO}$ ). Therefore, the more concentrated the BB plume, the larger the size distribution.

In a related study, *Sakamoto et al.* [In Press], we selected subsets of the MBO BB regional events presented here and tested them against parameterizations of the aged size distribution. The parameterizations calculate  $D_{\text{pm}}$  and  $\sigma_{\text{g}}$  from inputs that can be derived from  
340 emissions-inventory and meteorological parameters. The seven inputs are: emission median dry diameter, emission distribution modal width, mass emissions flux, fire area, mean boundary-layer wind speed, plume mixing depth, and time/distance since emission. We identified eleven plumes from regional events that had consistent transport to known regional fires. The simple fits captured over half of the variability in observed  $D_{\text{pm}}$  and modal width, even though the freshly  
345 emitted  $D_{\text{pm}}$  and modal widths were unknown. The results demonstrate that the parameterizations presented in *Sakamoto et al.* [In Press] section 3.4 can be successfully used to estimate aged BB size distributions in regional BB plumes with transport times up to 35 hours. Using these parameterizations to estimate BB plume size distribution in global and regional aerosol models is a significant improvement to assuming fixed values for size-distribution parameters.

#### 350 4. Conclusions

We characterized the physical and optical properties of 19 aged biomass burning events observed at the Mt. Bachelor Observatory in the summer of 2015. Regional (Northern California and Southwestern Oregon) and Siberian events were observed. Our main conclusions were:

- 355 -  $\Delta\sigma_{\text{scat}}/\Delta\text{CO}$  ( $\sigma_{\text{scat}}$  at STP) enhancement ratio to range from 0.48-1.29  $\text{Mm}^{-1}/\text{ppbv}$ , with the majority of events being between 0.8 and 1.25  $\text{Mm}^{-1}/\text{ppbv}$ .
- Siberian influenced events had significantly higher  $\Delta\sigma_{\text{abs}}/\Delta\text{CO}$  and MAE, and lower  $\omega$  compared to regional events. We propose this is due to MBO sampling the portion on Siberian smoke that has been lofted to higher elevation through pyro-convection., thereby preferentially sampling emissions of strong flaming combustion conditions. In general
- 360 flaming conditions produce more BC, which would explain the amplified absorption in the Siberian events.
- Absorption Ångström exponent values were significantly lower for the Siberian events than regional events, which indicates lack of BrC produced by the Siberian fires or loss of BrC during transport through photobleaching, volatilization, and aerosol-phase reactions.
- 365 - Mass scattering efficiencies ranged from 2.50-4.76  $\text{m}^2 \text{g}^{-1}$ . MSE was positively correlated with  $D_{\text{pm}}$  ( $R^2 = 0.73$ ), which agrees with Mie theory.
- Aerosol number size distribution  $D_{\text{pm}}$  and  $\sigma_{\text{g}}$  ranged from 138-229 nm and 1.53-1.89, respectively. Five of the nineteen events had bimodal distributions, the rest being unimodal. The unimodal distributions had a prominent “tail” of small-diameter particles
- 370 (30-90 nm). No distinction could be made between regional and Siberian size distributions.

## 5. Author Contribution

J.R. Laing preformed the data analysis and prepared the manuscript with assistance from all co-authors.

## 375 6. Acknowledgments

Funding for research at MBO was supported by the National Science Foundation (grant number: 1447832). The MBO is also supported by a grant from the NOAA Earth System Research Laboratory. The views, opinions and findings contained in this report are those of the author(s) and should not be construed as an official National Oceanic and Atmospheric

380 Administration or U.S. Government position, policy or decision. The authors gratefully acknowledge the NOAA Air Resources Laboratory (ARL) for the provision of the HYSPLIT

|

transport model used in this publication. The CALIPSO satellite products was supplied from the  
| NASA Langley Research Center.

$\Delta WV$  is water vapor enhancement, calculated for each event by subtracting the average WV for the summer sampling period from the WV value at the time when maximum CO was observed.

Aerosol scattering  $\sigma_{scat}$  (550 nm) and absorption  $\sigma_{abs}$  (528 nm) measurements were converted to STP.

MSE and MAE calculated as the  $\Delta\sigma_{scat}/\Delta PMI$  and  $\Delta\sigma_{abs}/\Delta PMI$  enhancement ratios, respectively.

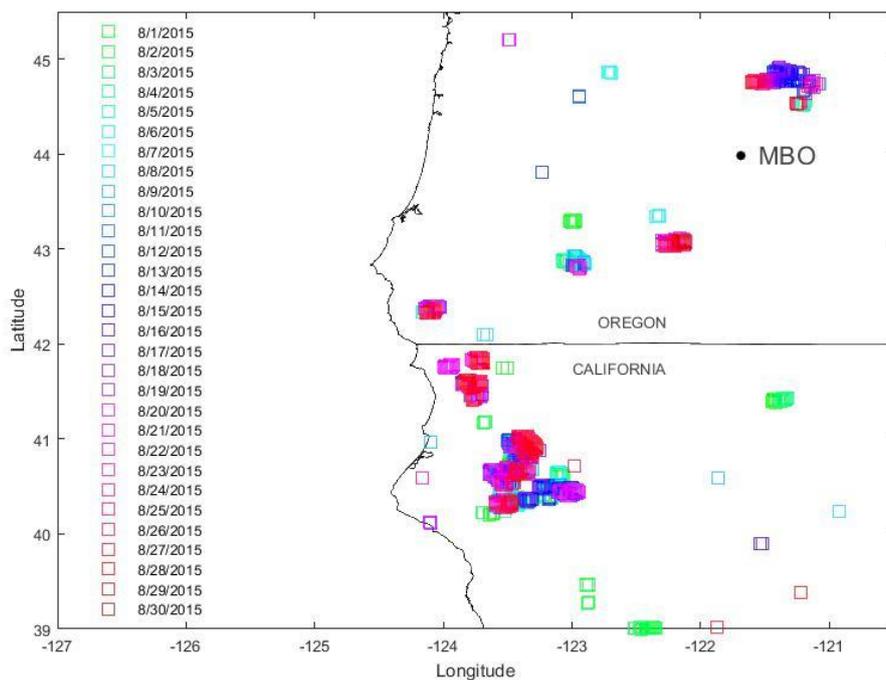

$D_{pm}$  is the geometric mean diameter and  $\sigma_g$  is the geometric standard deviation of the SMPS aerosol size distribution.

WC indicates a weak correlation in the MAE column ( $R^2 < 0.60$ ).

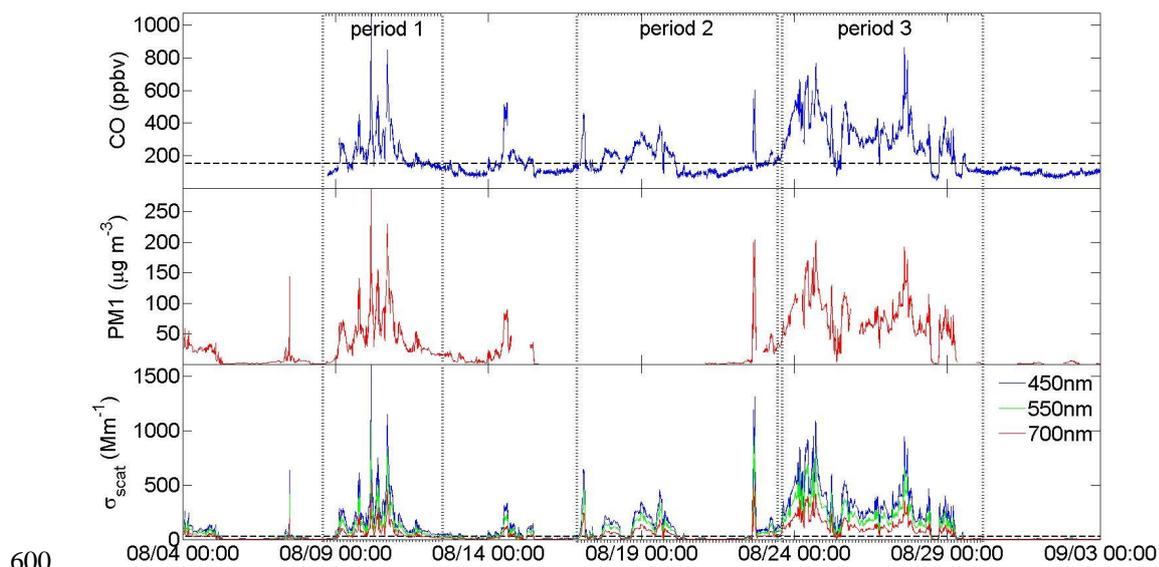

ND indicates missing data. PM data was not available for events 1 and 10-13; absorption data was not available for events 19 and 20.

**Figures:**

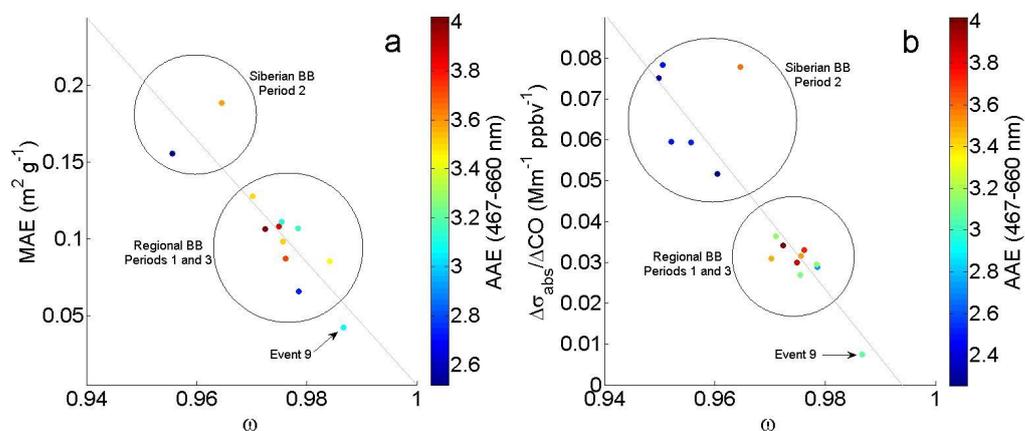

**Figure 1.** MBO and MODIS firespots colored by date for the month of August.

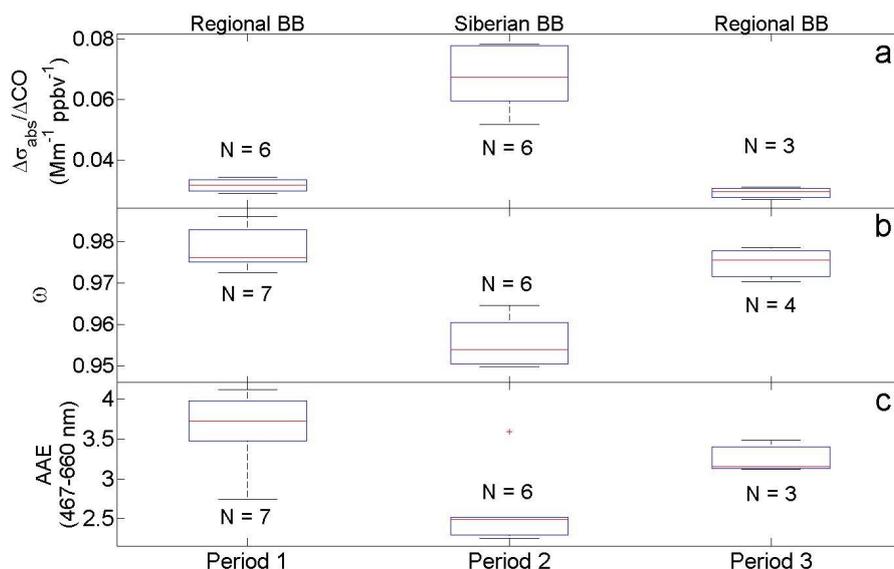

600

**Figure 2.** Time series of (i) CO, (ii) PM1, and aerosol scattering ( $\sigma_{\text{scat}}$ ) (iii) at MBO during August. Threshold values (dashed black lines) used for BB event criteria are displayed for CO (150 ppbv) and scattering ( $20 \text{ Mm}^{-1}$ ). Three period are identified by dotted boxes. Periods 1 and 3 are regionally influenced and encompass events 2-8 and 16-19, respectively. Period 2 is influenced by Siberian BB and encompasses events 10-15.

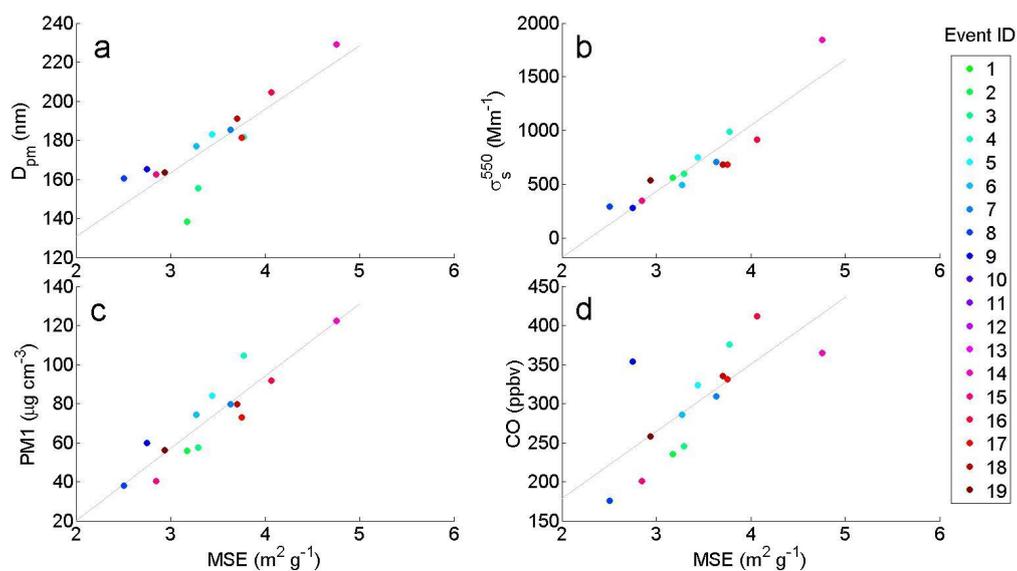

605

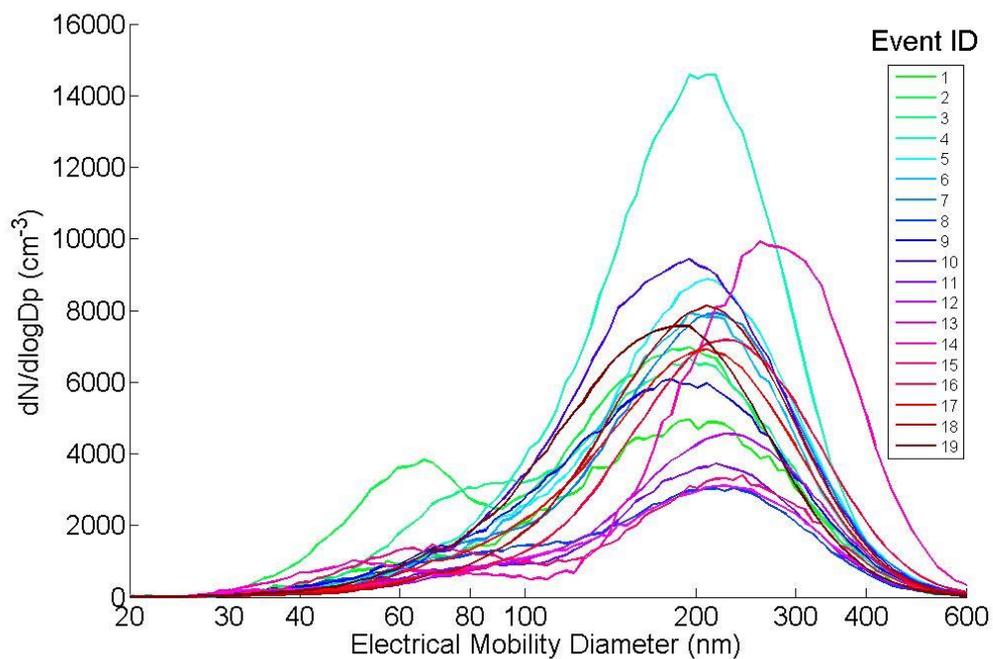

**Figure 3.** Scatter plots of (a) mass absorption efficiency (MAE) (b) absorption enhancement ratio  $\Delta\sigma_{\text{abs}}/\Delta\text{CO}$  versus single scattering albedo ( $\omega$ ). MAE values were not calculated for four of the six Siberian influenced events due to missing PM1 data.

**Figure 4.** Boxplots of (a)  $\Delta\sigma_{\text{abs}}/\Delta\text{CO}$ , (b) single scattering albedo ( $\omega$ ) measured at 528 nm, and  
 615 (c) absorption Ångström exponent (AAE) for absorption measurements at 467 and 660 nm for  
 the three periods shown in Figure 2. Periods 1 and 3 represent regional BB events, and period 2  
 consists of Siberian influenced events. N indicates the number of events for each box. Lower and  
 upper whiskers represent the minimum and maximum values, respectively. Lower and upper  
 620 lines of the box represent the 25th and 75th percentiles, respectively. The red line at the middle  
 of the box represents the median, and the red plus mark represents outliers.

625 **Figure 5.** Scatter plots of (a)  $D_{\text{pm}}$  ( $R^2 = 0.73$ ), (b)  $\sigma_{\text{scat}}^{550}$  ( $R^2 = 0.90$ ), (c) PM1 ( $R^2 = 0.85$ ), and (d) CO ( $R^2 = 0.53$ ) versus mass scattering efficiency (MSE) for the BB events at MBO in the summer of 2015.
