18
19 **Abstract.** Ground-based measurements of black carbon (BC) were performed near an
20 industrial source region in the early summer of 2014 and at a remote island in Japan in
21 the spring of 2015. Here, we report the temporal variations in the transport, size
22 distributions, and mixing states of the BC-containing particles. These particles were
23 characterized using a continuous soot monitoring system, a single particle soot

24 photometer, and an aerosol chemical speciation monitor. The effects of aging on the
25 growth of BC-containing particles were examined by comparing the ground-based
26 observations between the near-source and remote island sites. Secondary formation of
27 sulfate aerosols through gas- and cloud-phase reactions strongly affected the increases in
28 BC coating (i.e., enhancement of cloud condensation nuclei activity) with air mass aging
29 from the source to the outflow regions. The effects of wet removal on BC microphysics
30 were elucidated by classifying the continental outflow air masses depending on the
31 enhancement ratios of BC to CO ($\Delta\text{BC}/\Delta\text{CO}$) ratios, which was used as an indicator of
32 the transport efficiency of BC. It was found that $\Delta\text{BC}/\Delta\text{CO}$ ratios were controlled
33 mainly by the rainout process during transport in the planetary boundary layer (PBL) on
34 the timescale of 1-2 days. The meteorological conditions and backward trajectory
35 analyses suggested that air masses strongly affected by rainout originated mainly from a
36 region in South China (20°-35°N) in the spring of 2015. Selective removal of large and
37 thickly-coated BC-containing particles was detected in the air masses that were
38 substantially affected by the rainout in the PBL, as predicted by Köhler theory. The size
39 and water-solubility of BC-containing particles in the PBL can be altered by the rainout
40 process as well as the condensation of non-BC materials.

41

42 **1. Introduction**

43 Black carbon (BC)-containing particles in atmosphere can significantly affect the
44 radiative budget of the Earth through two effects; direct (light absorption and scattering)
45 and indirect (aerosol-cloud interactions) effects (Bond et al., 2013; references therein).
46 The difficulty in the estimation of these effects in the atmosphere results from both the
47 short lifetime relative to other greenhouse gases and the variable physicochemical
48 properties of BC-containing particles. The BC itself is water-insoluble immediately

49 after emission, but it subsequently exhibits on hygroscopicity (McMeeking et al., 2011)
50 and cloud condensation nuclei (CCN) activity (Kuwata et al., 2007) through atmospheric
51 transport and aging. Only small amounts of water-soluble materials on BC particles are
52 needed to cause their activation to form cloud droplets under moderate supersaturation
53 conditions (Kuwata et al., 2007; 2009). It is considered that BC-containing particles are
54 removed from the atmosphere mainly by wet deposition (Seinfeld and Pandis, 2006).

55 The horizontal and vertical distributions of aerosols can be substantially altered by their
56 atmospheric lifetimes (e.g., Lawrence et al., 2007). Moreover, their studies suggested
57 that the removal processes of BC such as dry deposition, below-cloud (i.e., washout), and
58 in-cloud (i.e., rainout) can greatly change the atmospheric lifetimes. The in-cloud
59 processes include nucleation scavenging and scavenging by the preexisting cloud droplets.
60 Precipitation followed by in-cloud processes leads to the irreversible removal of BC-
61 containing particles. Samset et al. (2014), using multiple global model data sets
62 constrained by aircraft observations, suggested that the atmospheric lifetime of BC
63 largely affects its distribution, especially in the northern hemisphere, and this results in
64 significant variations in global direct radiative forcing values. The removal of BC has
65 been considered as an important issue for the geochemical carbon cycle as well as for
66 climate science. The BC-containing particles deposited onto the ocean surface can
67 affect ocean surface particles, dissolved organic carbon (DOC), and microbial processes,
68 by absorbing DOC, stimulating particle aggregation, and changing the size distribution
69 of suspended particles (Mari et al., 2014).

70 Previous modeling studies have dealt with BC aging processes (condensational growth
71 and coagulation) in box and regional-scale models, and parameterized timescales for the
72 conversion of BC-containing particles from water-insoluble to -soluble in global models

73 (Oshima et al., 2009; Liu et al., 2011; Oshima and Koike, 2013). However, quantitative
74 knowledge of the variability of microphysical parameters of BC-containing particles and
75 the timescale of their aging processes is still limited, and thus more investigation are
76 needed for near-source and remote regions (Samset et al., 2014). Moteki et al. (2012)
77 reported the first observational evidence of the size-dependent activation of BC during
78 the cloud droplets formation, in air masses uplifting from the planetary boundary layer
79 (PBL) to the free troposphere (FT) in East Asia in the spring of 2009, as the part of the
80 Aerosol Radiative Forcing in East Asia (A-FORCE) aircraft campaigns (Oshima et al.,
81 2012). A similar altitude dependence of the BC size distribution and similarity in the
82 BC mixing state were observed in other aircraft measurements conducted in East Asia in
83 winter (Kondo et al., 2016). Selective removal of larger BC-containing particles though
84 the cloud process, which is predicted by Köhler theory, was qualitatively observed in the
85 atmosphere. This observational evidence indicates that the size distributions and mixing
86 states of BC-containing particles control the global- and regional-scale spatial
87 distributions of BC through their upward transport from the PBL to the FT associated
88 with rainout processes. Despite the importance of the size distributions and mixing
89 states of BC-containing particles in the PBL, the measurements of their microphysical
90 properties are still limited around the source regions in East Asia.

91 Kanaya et al. (2016) have conducted long-term measurements of BC for 6 years (2009-
92 2015) at Fukue Island, and they synthetically reported the emission and removal of BC
93 in East Asia using these data sets. It was found in their study that wet removal through
94 transport in the PBL substantially reduced the transport efficiency of BC aerosols. Here
95 we examine the effects of aging and wet removal during transport on the changes in BC
96 size distributions and mixing state, as well as concentrations, based on ground-based

97 measurements conducted at the same site in the spring of 2015 using a single particle soot
98 photometer (SP2) and an Aerosol Chemical Speciation Monitor (ACSM). We first
99 describe the meteorological characteristics of the East Asian region in the spring of 2015.
100 Then, we discuss the relative importance of the washout and rainout processes for the
101 removal of BC as well as the transport patterns of the East Asian outflow air masses in
102 spring. The loss of BC-containing particles for that period is investigated using a similar
103 approach to that used by Kanaya et al. (2016), and this is performed in connection with
104 the associated changes in BC microphysics and their relevance to the transport pathways.

105

106 **2. Experimental and data analysis**

107 **2.1. Atmospheric observations**

108 Continuous measurements of PM_{2.5} and BC aerosols have been conducted at a remote
109 island, Fukue Island, since February 2009 (Kanaya et al., 2013; Ikeda et al., 2014). The
110 observation site is located at the Fukue Island Atmospheric Environment Monitoring
111 Station (32.75°N, 128.68°E, **Fig. 1**). The site is located in the northwest portion of
112 Fukue Island, approximately 20 km from the main residential area in the southeast. The
113 fine mode aerosols sampled at the site are mostly transported from areas beyond the island.
114 The enhanced concentrations of BC aerosols in Fukue Island can be mainly attributed to
115 long-range transport from the Asian continent, according to a previous study (Shiraiwa et
116 al., 2008) and an emission inventory work (**Fig. 1**, REAS ver. 2.1, Kurokawa et al., 2013).

117 We deployed an SP2 (Droplet Measurement Technologies, Inc., USA) for the analysis
118 of microphysical parameters of refractory BC (rBC, Petzold et al., 2013) from March 26,
119 2015 to April 14, 2015. The SP2 was calibrated before starting the ambient
120 measurements. The calibration protocol for our SP2 is described in Miyakawa et al.
121 (2016). Fullerene soot (FS, stock 40971, lot L20W054, Alfa Aesar, USA) particles were

122 used as a calibration standard for the SP2. A differential mobility analyzer (Model 3081,
123 TSI Inc., USA) was used for preparing the monodisperse FS particles. The analysis of
124 the calibration results suggests that the full width of half maxima (FWHM) was typically
125 30% of the modal incandescence signal intensity (S_{LII}) for the diameter range studied.
126 Note that the FWHM can be regarded as an upper limit to describe the resolving power
127 of rBC mass per particle using our SP2, because the combination of polydisperse size
128 distribution of FS particles and the transfer function of the DMA can broaden the
129 distributions of S_{LII} for the prepared FS particles. The variations in the laser power were
130 within $\pm 3\%$ during the observation period, thus indicating that the fluctuations of laser
131 power did not largely affect the lower limit of the detectable rBC size using the SP2.
132 Mass equivalent diameter (MED) was derived from the rBC mass per particle (m_{pp}) with
133 an assumed particle density for BC (1800 kg m^{-3} , Bond and Bergstrom, 2006). A large
134 diameter Nafion dryer (MD-700, Perma Pure, Inc., USA) was placed in front of the SP2
135 for drying the sample air without significant loss of the aerosol particles greater than 50
136 nm. The dry air for MD-700 was generated by a heatless dryer (HD-2000, Perma Pure,
137 Inc., USA) and a compressor (2AH-23-M222X, MFG Corp., USA). The relative
138 humidity of the sample air was less than 20% during the observation period. The hourly
139 number/mass size distributions and hourly median values of shell (D_S) to rBC diameter
140 (D_{core}) ratios (D_S/D_{core}) for the selected D_{core} ranges were calculated. The retrievals of
141 D_S from the light scattering signals measured by an avalanche photodiode and a position
142 sensitive detector (Gao et al., 2007) were performed using a time-resolved scattering cross
143 section method given by Laborde et al. (2012). In this study, we quantified the D_S/D_{core}
144 ratios with a D_{core} range between 0.15 and 0.35 μm . The maximum value of D_S/D_{core}
145 ratios analyzed is 4 in this study. Retrieved results suggest that almost all rBC particles

146 were not so thickly coated (for example, D_S/D_{core} ratios of ~ 2.5 at highest at D_{core} of 0.2
147 μm). We also analyzed the microphysical parameters of rBC particles measured using
148 the SP2 in the early summer of 2014 at Yokosuka (35.32°N, 139.65°E, **Fig. 1**), located
149 near industrial sources along Tokyo Bay (Miyakawa et al., 2016). These data sets were
150 used as a reference for the BC-containing particles in air masses strongly affected by
151 combustion sources.

152 Equivalent BC (EBC, Petzold et al., 2013) mass concentrations are continuously
153 measured at Fukue Island using two instruments; a continuous soot-monitoring system
154 (COSMOS; model 3130, Kanomax, Japan), and a multi-angle absorption photometer
155 (MAAP; MAAP5012, Thermo Scientific, Inc., USA). The details of the air sampling
156 and intercomparisons for EBC measurements at Fukue Island have been described
157 elsewhere (Kanaya et al., 2013; 2016). In this study, mass concentrations of EBC
158 measured using the COSMOS were evaluated by comparison with those of SP2-derived
159 rBC. The intercomparison between SP2 and COSMOS will be briefly discussed below.

160 **Figure 2** depicts the correlation between COSMOS-EBC and SP2-rBC hourly mass
161 concentrations. The unmeasured fraction of the rBC mass was corrected by
162 extrapolation of the lognormal fit for the measured mass size distributions, to the outsides
163 of the measurable D_{core} range (0.08-0.5 μm). Note that the uncertainty with respect to
164 the unmeasured fraction of rBC mass was minor (<5%) in this study. The linear
165 regression slope of the correlation between EBC and rBC was 0.88 (± 0.03). Uncertainty
166 with respect to the calibration was examined in an industrial region and found to be within
167 around 3% (Miyakawa et al., 2016). The average discrepancy between EBC and rBC
168 was beyond the uncertainty of the calibration and was comparable to the uncertainty of
169 COSMOS (10%) as evaluated by Kondo et al. (2009). While the validity of the

170 calibration standard, FS particles, has been evaluated only near source regions (Moteki
171 and Kondo, 2011; Miyakawa et al., 2016), the discrepancy can be partly attributed to the
172 differences in physicochemical properties between ambient BC in remote air and FS
173 particles. Onsite calibration of the SP2 using ambient BC particles prepared by a
174 thermal denuder and particle mass classifier, such as an aerosol particle mass analyzer
175 (APM), is desirable for better quantification of the rBC mass based on the laser-induced
176 incandescence technique in remote areas. Although we need to make further attempts
177 to evaluate SP2 in remote areas, this study indicated that SP2-rBC mass concentrations
178 agreed well with COSMOS-EBC within the uncertainty of COSMOS. Therefore we
179 simply use “BC”, instead of the EBC and rBC defined depending upon the measurement
180 techniques. We analyzed the COSMOS data for the BC mass concentrations, and the
181 SP2 data for the BC microphysics.

182 The chemical composition of non-refractory submicron aerosols was measured using
183 an Aerodyne Aerosol Chemical Speciation Monitor (ACSM, Aerodyne, Inc., USA.)
184 placed in an observatory container at Fukue Island during the observation period. The
185 details of the ACSM at Fukue Island have been described in Irei et al. (2014). The
186 collection efficiency (CE) of the ACSM was assumed to be 0.5 for this period (Yoshino
187 et al., 2016). We considered sulfate (SO_4^{2-}) ions as a major non-BC material and one of
188 the most important secondary aerosols in East Asia (Takami et al., 2007) for the data
189 interpretation. The fact that SO_4^{2-} is produced in the cloud phase as well as in the gas
190 phase is beneficial for interpreting temporal changes in SO_4^{2-} concentration associated
191 with the wet removal processes. We also analyzed other non-refractory components
192 such as nitrate (NO_3^-), ammonium (NH_4^+), and organic matter (OM). During the period
193 April 1 -7, 2015, the critical orifice of the inlet assembly of the ACSM became clogged.

194 ACSM-derived SO_4^{2-} , NO_3^- , NH_4^+ , and OM (ACSM- SO_4^{2-} , $-\text{NO}_3^-$, $-\text{NH}_4^+$, and -OM) for
195 this period was not used in the analysis.

196 Two high volume air samplers (HV500F, Sibata Scientific Technology, Ltd., Japan)
197 were deployed on the rooftop of the observatory container. The sampling flow rate for
198 both samplers was 500 liters per minute (lpm). Air sampling was carried out for 21 h
199 (from 10:00 AM to 7:00 AM) on a 110-mm pre-combusted (900°C for 3 h) quartz filter
200 (QR-100, Advantec Toyo Kaisha Ltd., Japan). Both have a $\text{PM}_{2.5}$ impactor for
201 classifying the particle size. One impaction plate was coated with vacuum grease
202 (HIVAC-G, Shin-Etsu Chemical Co., Ltd., Japan) to minimize the impact of coarse mode
203 particles on the chemical analysis of fine mode particles such as radiocarbon analysis,
204 and a pre-combusted quartz fiber filter with slits was set on another impaction plate to
205 collect the coarse particles. Water soluble ions were analyzed using ion chromatography
206 (IC, Dionex ICS1000, Thermo Fisher Scientific K.K., Japan). The results from the
207 chemical analysis of filter samples are not discussed in this study in detail. We only
208 used the mass concentration of SO_4^{2-} (IC- SO_4^{2-}) in this study to evaluate the uncertainty
209 in relation to CE of the ACSM, and to analyze the temporal variations during the period
210 when the ACSM- SO_4^{2-} data were not available (April 1-7, 2015).

211 The carbon monoxide (CO) mixing ratio was also continuously measured using a
212 nondispersive infrared (NDIR) CO monitor (model 48C, Thermo Scientific, Inc., USA).
213 Details of the CO measurements including the long-term variations in sensitivity and zero
214 level are discussed elsewhere (Kanaya et al., 2016).

215

216 **2.2. Enhancement ratio of BC and SO_4^{2-} to CO as an indicator of the transport and**

217 **transformation of aerosol particles**

218 In order to quantify the extent of the removal of BC, we calculated the hourly
219 enhancement ratio of BC mass concentrations to CO mixing ratios ($\Delta BC/\Delta CO$) against
220 the East Asian background air concentrations as follows:

221

$$222 \quad \frac{\Delta BC}{\Delta CO} = \frac{[BC] - [BC]_{bg}}{[CO] - [CO]_{bg}}, \quad (1)$$

223

224 where [BC] and [CO] are measured hourly concentrations of the BC and CO respectively,
225 and [BC]_{bg} and [CO]_{bg} are their estimated background concentrations. Here we assumed
226 that [BC]_{bg} is zero (Oshima et al., 2012). The background concentration of CO during
227 the analysis period (March 11 – April 14, 2015) was calculated by averaging the
228 concentrations lower than the 5th percentile (120 ppb). The validity of this value is
229 discussed in the supporting information (S.I.).

230 Relative changes in SO₄²⁻ to CO were also analyzed using the linear regression slopes
231 of their correlation in this study. We did not calculate their hourly values, because it was
232 difficult to determine the background concentration of SO₄²⁻. The use of CO as a tracer
233 of sulfur compounds in East Asia was validated by Koike et al. (2003). Although sulfur
234 dioxide (SO₂), which is a major precursor of anthropogenic SO₄²⁻, does not always share
235 the emission sources with CO, the special distributions of SO₂ emissions is similar to
236 those of CO emissions in East Asia (Koike et al., 2003; Kurokawa et al., 2013).
237 Analyzing the increase or decrease in the slopes of the SO₄²⁻-CO correlation is beneficial
238 to the investigation of the formation and removal processes for SO₄²⁻. Especially, the
239 aqueous-phase reaction of SO₄²⁻ in clouds is discussed using this parameter.

240

241 **2.3. Meteorological field analysis**

242 We used the 6-hourly meteorological data, with a resolution of 1° in terms of the
243 latitude and longitude, from the National Centers for Environmental Prediction (NCEP)
244 Final (FNL) operational global analysis; and daily precipitation data, with a resolution of
245 1° in terms of the latitude and longitude, from the Global Precipitation Climatology
246 Project (GPCP) data set (Huffman et al., 2001). We analyzed these data sets to
247 investigate the general features of the meteorological field in East Asia during the
248 observation period.

249

250 **2.4. Backward trajectory analysis**

251 We calculated backward trajectories from the observation site to elucidate the impact
252 of the Asian outflow. Three-day backward trajectories from the observation site (the
253 starting altitude was 0.5 km) were calculated every hour using the National Oceanic and
254 Atmospheric Administration (NOAA) Hybrid Single-Particle Lagrangian Integrated
255 Trajectory model (Draxler and Rolph, 2012; Rolph, 2012) with the meteorological data
256 sets (NCEP's Global Data Assimilation system, GDAS). In this study, the residence
257 time over specific source regions was used as an indicator of their impacts on the observed
258 air masses. We defined five domains for assessing the impact over the Asian continent;
259 Northeast China (NE), Korea (KR), Central North China (CN), Central South China (CS),
260 and Japan (JP) (**Fig. 1**). The period when air masses passed over the domains NE, KR,
261 CN, and CS at least for one hour is defined as that of "continental outflow". The impacts
262 of precipitation on the observed air masses were assessed by a parameter referred to as
263 the "Accumulated Precipitation along Trajectory" (APT, Oshima et al., 2012). In this

264 study, we calculated the APT values by integrating the amount of hourly precipitation in
265 the Lagrangian sense along each 3-day back trajectory of the sampled air masses. The
266 hourly variations of APT were merged into the observed gas and aerosol data sets.

267

268 **3. Results and discussion**

269 **3.1. The meteorological field in the spring of 2015**

270 The mean meteorological field during the observation period (March 11–April 14,
271 2015) is discussed for the purpose of characterizing the general features of the wind flow
272 and precipitation in this region. The migrating anticyclone and cyclone were observed
273 during this period, which is typically dominant in spring over East Asia (Asai et al., 1988).
274 We here only briefly describe the meteorological fields (wind flow and precipitation) in
275 the following. **Figure 3a** shows the mean sea level pressure (SLP) and mean horizontal
276 winds at the 850 hPa level in East Asia during the observation period. The mean
277 equivalent potential temperature (θ_e) and the meridional moisture transport at the 850 hPa
278 level during the same period are also shown in **Figure 3b**. The mid-latitude region (35-
279 50°N, 120-140°E) was under the influence of a modest monsoonal northwesterly flow,
280 which advected cold, dry air from the continent to the observation area. The subtropical
281 region (20°-30°N, 110°-130°E) was under the influence of a persistent southwesterly flow,
282 part of which was converging into the observation area (30°-35°N), and this flow was
283 confluent with the northwesterlies from the continent. The low-level southerly flow
284 advected warm, moist air into the observation area to sustain a large amount of
285 precipitation (**Fig. 4a**).

286 **Figure 3c** shows the temporal variations in surface pressure and precipitable water at
287 the observation site. The surface pressure is well anti-correlated with the precipitable
288 water. During the observation period, migratory cyclones and anticyclones occurred

289 occasionally (3 times each). The occurrence of migratory cyclones advected moist air,
290 which could have contributed to the wet removal of BC during transport in the PBL. In
291 contrast, the occurrence of anticyclones advected dry air, which could have contributed
292 to the efficient transport of BC from the source regions.

293 **Figure 4a** depicts the mean precipitation over East Asia during the observation period.
294 Mean precipitation showed a latitudinal gradient over eastern China and the Yellow Sea
295 and East China Sea region (i.e., increasing precipitation from south to north), and these
296 results suggest that transport pathways can greatly affect the wet removal of aerosols.
297 The APT was compared with the averaged latitude of each trajectory for 48 h backwardly
298 from the time of -24 h (L_{ORIG}) (**Fig. 4b**), which can be interpreted as an indicator of the
299 latitudinal origin of the air masses arriving at Fukue Island. The high APT values
300 corresponded to the air masses that originated from the southern regions (20° - 40° N).
301 The data points are colored according to the maximum RH values along each backward
302 trajectory (RH_{max}). The lower relative humidity (RH_{max}) were observed in the air masses
303 with low APT values that originated from northern regions (30° - 50° N). These air mass
304 characteristics were consistent with the mean precipitation field (**Fig. 4a**). Some of the
305 data points showed high values of RH_{max} ($\sim 100\%$) when their APT was almost zero.
306 These data probably correspond to the air masses that experienced cloud processes not
307 associated with precipitation. Possible effects of cloud processes without precipitation
308 on the removal of aerosol particles during transport will be discussed using these data
309 points in the following section.

310

311 **3.2. Removal processes of fine aerosol particles**

312 In this study, the removal processes including dry deposition and washout were

313 considered to be minor. The dry deposition in this region has already been evaluated by
314 Kanaya et al. (2016). The washout is dependent on the precipitation intensity and rain
315 drop size as well as the particle size range. We quantitatively investigated the relative
316 importance of rainout to washout in this study. The removal rates of submicron
317 accumulation mode particles through the washout (Λ_{accum}) was estimated to be $\sim 1 \times 10^{-3}$
318 h^{-1} ($0.5\text{-}2 \times 10^{-3} \text{h}^{-1}$) using a parametrization given by Wang et al. (2014) and the average
319 precipitation intensity along the trajectories ($0.78 \pm 0.6 \text{ mm h}^{-1}$) as an input to the
320 parameterization. The possible uncertainties in this estimation are derived from the
321 discrepancies in Λ_{accum} the removal rates between the parameterization and some
322 experimental results (Wang et al., 2014). The values of Λ_{accum} can be underestimated by
323 an order of magnitude by using the parameterization, which is however overly pessimistic.
324 The temporal duration in rain along trajectories for air masses with the APT greater than
325 0 mm was 10 (± 8) hours on average. These values can be used for the estimation of the
326 removed fraction of submicron aerosols through the washout process. The average
327 fraction of submicron aerosols removed was 1% ($+2.59\%/-0.9\%$). Even though we took
328 into account the uncertainties for estimating Λ_{accum} , it was found that the washout process
329 did not play a major role in the removal of BC in East Asian outflow.

330

331 **3.3. Temporal variations in aerosols and CO**

332 Temporal variations in the concentrations of BC (measured using COSMOS and SP2),
333 SO_4^{2-} (measured using ACSM and IC), NO_3^- , OM, and CO are shown in **Figure 5**.
334 ACSM- SO_4^{2-} generally agreed well with IC- SO_4 , thus indicating that the assumed CE
335 (0.5) was valid for the observation period. As NO_3^- and SO_4^{2-} were almost fully
336 neutralized by NH_4^+ , we assumed their chemical forms were ammonium salts. In

337 general, BC, SO_4^{2-} , and OM were positively correlated with CO at Fukue Island, and these
338 results illustrate the impact of continental outflow affected by incomplete combustion
339 sources on aerosol mass concentrations. The mean chemical composition of fine
340 aerosols during the observation period was listed in **Table 1**. Ammonium sulfate and
341 OM were abundant components. **Figure 5** also includes the temporal variations in the
342 fractional residence time over the selected region defined in section 2.4 (top panel). The
343 CO concentrations were typically enhanced for the period with the higher contributions
344 of CN and CS. A previous study suggested that the majority of SO_4^{2-} aerosols were
345 formed in less than around 1.5 days after the air masses left the Chinese continent (Sahu
346 et al., 2009). Kanaya et al. (2016) showed that the typical transport time of continental
347 outflow air masses at Fukue Island was around 1-2 days in spring. The positive
348 correlation of SO_4^{2-} and CO suggests that the secondary formation of SO_4^{2-} through
349 transport was significant during the observation period. The structure and composition
350 of fine aerosols in East Asian outflow were analyzed by using a secondary ion mass
351 spectrometer in a previous study (Takami et al., 2013). They suggest that SO_4^{2-} and OM
352 are constituents in the coating of almost all BC-containing particles. Hence we
353 concluded that ammonium sulfate and OM contributed to the growth of BC-containing
354 particles. The period with the APT > 3 mm is highlighted by light blue in **Figure 5** to
355 show the impact of wet removal on the transport of BC and SO_4^{2-} aerosols. The
356 maximum concentrations of aerosols and CO were observed on the morning of March 22
357 (Ep.1) under the influence of the anticyclone (corresponding to the trajectories colored
358 red in **Fig. 4a**) when the APT values were almost zero. In contrast, aerosol
359 concentrations did not increase with CO in the period from the evening of April 5 to the
360 morning of April 6 (Ep.2) under the influence of the migratory cyclone (corresponding to

361 the trajectories colored black in **Fig. 4a**), when the APT was greater than 10 mm.

362

363 **3.4. Correlation of BC, SO₄²⁻, and CO**

364 **Figures 6a** and **6b** show scatter plots of CO with BC and SO₄²⁻, respectively. Positive
365 correlation of BC and SO₄²⁻ with CO was clearly found in air masses with low APT values.
366 The linear regression was performed to the data points with the APT higher than 15 mm
367 for BC-CO and SO₄²⁻-CO. Note that the linear regression slope for BC-CO was
368 determined by forcing through the background concentrations of BC (0 μg m⁻³) and CO
369 (120 ppb). The slopes of the fitted lines were 1.4 and 9.8 ng m⁻³ ppb⁻¹ for BC-CO and
370 SO₄²⁻-CO, respectively, were close to the lower envelopes of the correlations. It is
371 evident from these scatter plots that the relative enhancements of BC and SO₄²⁻ to CO
372 were mainly affected by the APT. Kanaya et al. (2016) found that the estimated
373 emission ratios of BC to CO over the East Asian continent ranged from 5.3 (±2.1) to 6.9
374 (±1.2) ng m⁻³ ppb⁻¹, slightly depending on the origin of the air masses (this range is
375 overlaid on **Fig. 6a**). ΔBC/ΔCO observed in the PBL over the Yellow Sea during the
376 same season was 6.2 ng m⁻³ ppb⁻¹ (Kondo et al., 2016). The data points with ΔBC/ΔCO
377 in these ranges show low APT values (less than or ~1 mm). Wet removal (rainout) was
378 one of the most important controlling factors on the transport efficiency of BC in this
379 region during the observation period. The use of the ΔBC/ΔCO ratios is feasible for
380 examining the wet removal of BC during the observation period.

381 The cloud processes of aerosol particles not associated with precipitation can also
382 reduce the slope of their correlation. However, no decreasing tendency of BC/CO and
383 SO₄²⁻/CO slopes against RH_{max} when APT was zero was found during the observation
384 period (data not shown). The SO₄²⁻/CO slopes with the APT values of zero were

385 analyzed as a function RH_{\max} (**Figure 6b**), and these varied from 30.7 to 44.1 $\text{ng m}^{-3} \text{ppb}^{-1}$
386 ¹ under the conditions without ($RH_{\max} < 50\%$) and with ($RH_{\max} > 80\%$) cloud impacts,
387 respectively. The $\text{SO}_4^{2-}/\text{CO}$ slope increased with RH_{\max} when the APT was zero, thus
388 suggesting that aqueous phase formation and subsequent droplet evaporation partly
389 contributed to the mass concentrations of SO_4^{2-} observed at Fukue Island. Therefore,
390 the changes in the $\text{SO}_4^{2-}/\text{CO}$ correlation were controlled largely by the rainout process
391 and weakly by aqueous-phase formation during transport.

392

393 **3.5. Changes in fine aerosol compositions**

394 Chemical compositions of fine aerosols were investigated in terms of the APT and
395 RH_{\max} . Four cases are selected here, namely (1) APT of zero (no precipitation), (2) APT
396 of zero with $RH_{\max} < 50\%$ (no precipitation without cloud impacts), (3) APT of zero with
397 $RH_{\max} > 80\%$ (no precipitation with cloud impacts), and (4) APT > 15 mm (heavily
398 affected by wet removal). The results are summarized in **Table 1**. Ammonium sulfate
399 and OM were dominant in all cases. The relative changes in chemical compositions of
400 fine aerosol particles were within around 10%. The relative contributions of ammonium
401 sulfate in the cases (3) and (4) increased from the average, indicating that cloud processes
402 affected the relative abundance of ammonium sulfate. The contributions of OM in the
403 case (2) increased from the average. The formation of secondary OM can be significant
404 under dry conditions during transport. Detailed mass spectral analyses of OM and
405 cloud-phase formation of OM in East Asia are beyond the scope of this study, and they
406 are not discussed in this study. The former issue has been investigated by previous
407 studies (e.g., Irei et al., 2014; Yoshino et al., 2016).

408

409 **3.6. Changes in microphysical parameters of BC-containing particles associated**

410 **with wet removal**

411 Number and mass size distributions of BC classified by the values of $\Delta BC/\Delta CO$ are
412 shown in **Figures 7a** and **7b**, respectively. When $\Delta BC/\Delta CO$ values in continental
413 outflow air masses were greater than $3 \text{ ng m}^{-3} \text{ ppb}^{-1}$ (within the range of the BC/CO
414 emission ratios given by Kanaya et al. 2016), these air masses are defined as “outflow
415 without BC loss”. These air masses originated mainly from CN via KR and NE. When
416 $\Delta BC/\Delta CO$ values of continental outflow air masses are less than $1 \text{ ng m}^{-3} \text{ ppb}^{-1}$, the air
417 masses were defined as “outflow with BC loss”. Considering the typical emission ratios
418 of BC to CO ($6\text{-}7 \text{ ng m}^{-3} \text{ ppb}^{-1}$; Kanaya et al., 2016), transport efficiency for the “outflow
419 with BC loss” air masses can be estimated to be less than $\sim 17\%$. These air masses
420 originated mainly in CS. The low and high APT values for “outflow without BC loss”
421 and “outflow with BC loss” air masses, respectively, gave us confidence in the validity
422 of our classification as discussed in the previous section. As a reference for emission
423 sources (“source”), the average size distributions of BC in a Japanese industrial area (see
424 section 2.1, Miyakawa et al., 2016) are shown in **Figure 7**. The statistics of the size
425 distributions are summarized in **Table 2**. Observed differences in the size distributions
426 between source and outflow were generally consistent with previous studies (Schwarz et
427 al., 2010). Air mass aging leads to the growth of BC-containing particles. Number-
428 size distributions of BC largely varied in the size range less than $0.1 \mu\text{m}$ (**Fig. 7a**). In
429 outflow air masses, such small BC-containing particles were scavenged by larger particles
430 in the coagulation process during transport. The washout process can also affect the
431 BC-containing particles in the smaller size range ($<0.1 \mu\text{m}$). The peak diameter of mass
432 (number) size distributions of BC became larger, from 0.16 (0.06) μm to $0.18\text{-}0.2$ (0.09-
433 0.1) μm , between source and outflow. The BC-containing particles have systematically

434 different size distributions in outflow air masses with and without BC loss, indicating that
435 the BC loss process also affected the size distributions. The peak diameter of BC
436 number and mass size distributions in outflow air masses with BC loss was slightly lower
437 than that for air masses without BC loss. The changes in the peak diameter as a function
438 of $\Delta BC/\Delta CO$ ratios are shown in **Figure 7c**. The observed changes in the diameter or
439 mass per particle were clear and were beyond the uncertainties (see section 2.1).

440 **Figure 8** depicts the probability density of the D_S/D_{core} ratio for the BC size of 0.2
441 (± 0.02) μm for source and outflow air masses. The modal values of the D_S/D_{core} ratio
442 were systematically changed with air mass aging and BC loss (wet removal). The
443 condensation of inorganic and organic vapors on BC-containing particles during transport
444 can account for the increase in the D_S/D_{core} ratio, as discussed in previous studies (e.g.,
445 Shiraiwa et al., 2008; Subramanian et al. 2010). As discussed earlier, the results of this
446 study suggested that SO_4^{2-} and OM substantially contributed to the increase in the D_S/D_{core}
447 ratio. In outflow air masses with BC loss, modal values of the D_S/D_{core} ratio were clearly
448 lower than those in outflow without BC loss. Furthermore, it is indicated that the wet
449 removal process also affected the coating thickness distributions for the BC sizes in the
450 range 0.15-0.35 μm (**Table 2**). It should be noted that the coating of BC-containing
451 particles is not always thick in remote regions, and that the D_S/D_{core} ratio distributions, as
452 well as size distributions, can be affected by the wet removal process during transport in
453 the PBL.

454

455 **3.7. Discussion**

456 Not only in-cloud scavenging of BC-containing particles but also subsequent
457 precipitation (i.e., the rainout process) can account for the changes in the microphysical

458 parameters of BC detected in this study. Our results show a decrease of both the peak
459 diameter of the BC mass size distribution, and the modal value of the D_S/D_{core} ratios in
460 relation to the rainout. The observed evidence implies that there can be the selective
461 removal of large and water-soluble BC-containing particles during transport in the PBL.
462 The Köhler theory suggests that a lower super saturation is needed for the large and highly
463 water-soluble particles, and this can qualitatively account for the observed changes in the
464 BC microphysics.

465 Note that the magnitude of the change in the BC size distributions in the PBL (~ 0.02
466 μm ($\sim 2\text{-}2.5$ fg)) shown in **Figure 7c** is smaller than that observed in air masses uplifted
467 from the PBL to the FT, in association with wet removal (~ 0.04 μm (~ 3 fg), Fig 2 of
468 Moteki et al., 2012) at a similar level of transport efficiency ($< \sim 20\%$). Although the
469 shape of mass size distributions soon after the rainout processes can be distorted by the
470 droplet activation of larger aerosol particles, the observed mass size distributions were
471 well fitted by a log-normal function (**Fig. 7b**). **Figure 8** showed the existence of BC-
472 containing particles with the D_S/D_{core} ratios higher than 1.2 even in outflow air masses
473 with BC loss that are expected to readily act as CCN. Air masses sampled at the ground
474 level would be affected by turbulent mixing of those near the clouds around the top of the
475 PBL and those in cloud-free conditions at below-cloud levels. On the other hand, most
476 air masses sampled by aircraft measurements in the FT would experience the cloud
477 processes during upward transport from the PBL. Mixing of air masses in the PBL
478 suggests that they partially experience the in-cloud scavenging processes. The aging
479 (e.g., coagulation) of aerosols particles through the transport (i.e., around ~ 1 day) after
480 the wet removal events can also lead to the further modification of the particle size and
481 mixing state distributions which have been affected by cloud processes. The

482 suppression of changes in the microphysical properties of BC-containing particles during
483 transport in the PBL can be related to these factors. More quantitative assessments of
484 the impacts of these factors on the observed features should be performed using a model
485 which has a function to resolve the mixing state of aerosol particles (e.g., Matsui et al.,
486 2013).

487 The transport pathways of the continental outflow air masses are horizontally and
488 vertically variable in spring in East Asia because of the frequent alternate
489 cyclone/anticyclone activities in spring (Asai et al., 1988). Oshima et al. (2013)
490 examined the three-dimensional transport pathways of BC over East Asia in spring and
491 showed that the PBL outflow through which BC originating from China was advected by
492 the low-level westerlies without uplifting out of the PBL was one of the major pathways
493 for BC export from continental East Asia to the Pacific, thus supporting the general
494 features of microphysical properties of BC in continental outflow obtained by this study.
495 Mori et al. (2014) measured the seasonal variations in BC wet deposition fluxes at another
496 remote island in Japan (Okinawa, ~500 km south of Fukue Island), and revealed their
497 maxima in spring, which were consistent with the seasonal variations in the cyclone
498 frequencies. It has been suggested that BC-containing particles were efficiently
499 activated to form cloud droplets in the continental outflow air masses, especially from the
500 CS region, and can affect the cloud physicochemical properties in spring in East Asia, as
501 indicated by Koike et al. (2012). As the results from this study are based on the
502 observations during a limited length of time, it would be worthwhile to further investigate
503 the possible connections of the variabilities in BC microphysical properties with
504 meteorological conditions to provide useful constraints on more accurate evaluations
505 climatic impacts of BC-containing particles in this region (Matsui, 2016).

506

507 **4. Conclusions**

508 Ground-based measurements of BC were performed near an industrial source region
509 and at a remote island in Japan. We have reported the temporal variations in the
510 transport and the microphysics of the BC-containing particles, measured using COSMOS,
511 SP2, and ACSM. The impacts of air mass aging upon the growth of BC-containing
512 particles were examined by comparing the ground-based observations between the near-
513 source and remote island sites. $\Delta BC/\Delta CO$ was used as an indicator of the transport
514 efficiency of BC, because it was controlled mainly by rainout during transport in the PBL.
515 The BC size and coating increased during transport from the near-source to the outflow
516 regions on the timescale of 1-2 days when the rainout during transport was negligible.
517 SO_4^{2-} aerosol was secondarily formed both in the gas- and cloud-phase during transport,
518 and it contributed to the significant increase in the coating materials of BC (i.e., it
519 enhanced the whole size and water-solubility of BC-containing particles). Decreases in
520 the peak diameter of mass size distributions ($\sim 0.01 \mu m$) and modal D_s/D_{core} ratios (~ 0.4
521 for BC of $0.2 \mu m$) of BC-containing particles were observed in air masses substantially
522 affected by rainout. The observed evidences for the selective removal of large and
523 water-soluble BC-containing particles was qualitatively consistent with the Köhler
524 theory; however the values were not as large as those found in air masses uplifted from
525 the PBL to the FT in East Asia associated with precipitation. The mixing of below-cloud
526 and in-cloud air masses in the PBL would result in suppression of the degree of changes
527 in BC microphysical parameters by cloud processes. This study indicates (1) that the
528 changes (sign and degree) in BC microphysics can be affected by how the air masses are
529 transported and (2) that the observed selective removal of large and water-soluble BC-

530 containing particles in East Asia can be expected to be significant in the PBL as well as
531 in the FT in East Asia.

699

700

701 **Figure 1.** Map of the investigated region with two observation sites (Yokosuka, open
 702 triangle; Fukue Island, closed circle) and five defined areas (1 Northeast China; 2 Korea;
 703 3 Central North China; 4 Central South China; 5 Japan). The bimonthly mean BC
 704 emission rate (March-April) in 2008 is overlaid on the map (REAS ver. 2.1, Kurokawa et
 705 al., 2013).

706

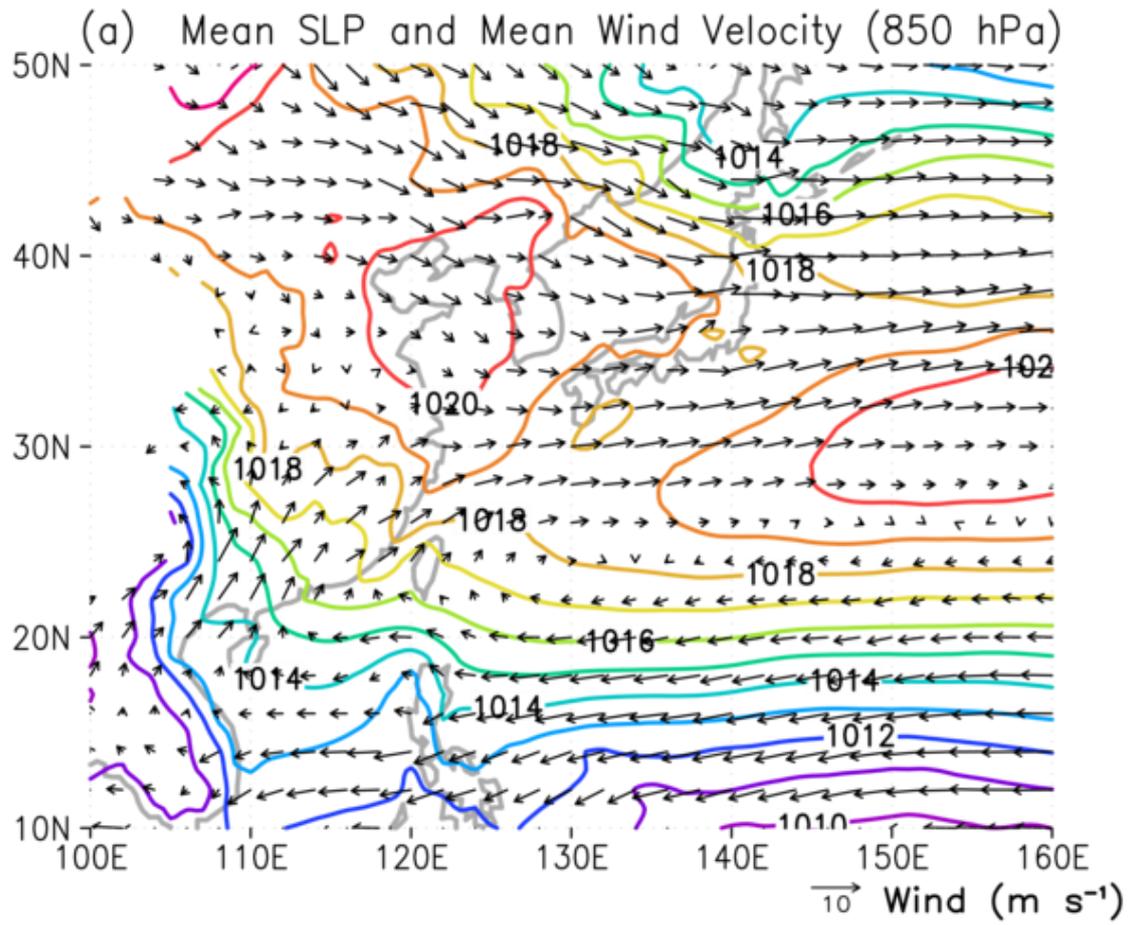

707

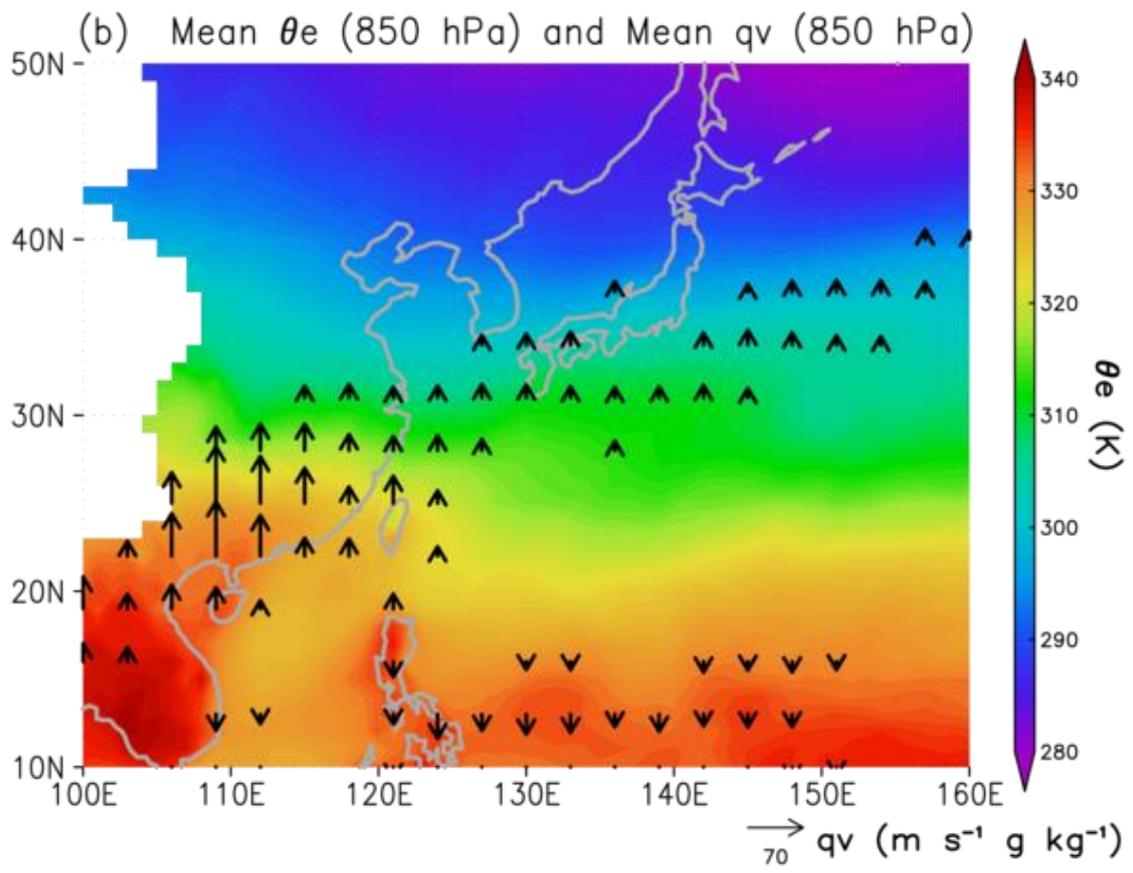

708

709 **Figure 2.** Correlation plot of SP2-rBC and COSMOS-EBC mass concentrations (at
710 standard temperature and pressure). The shaded region corresponds to within $\pm 20\%$.

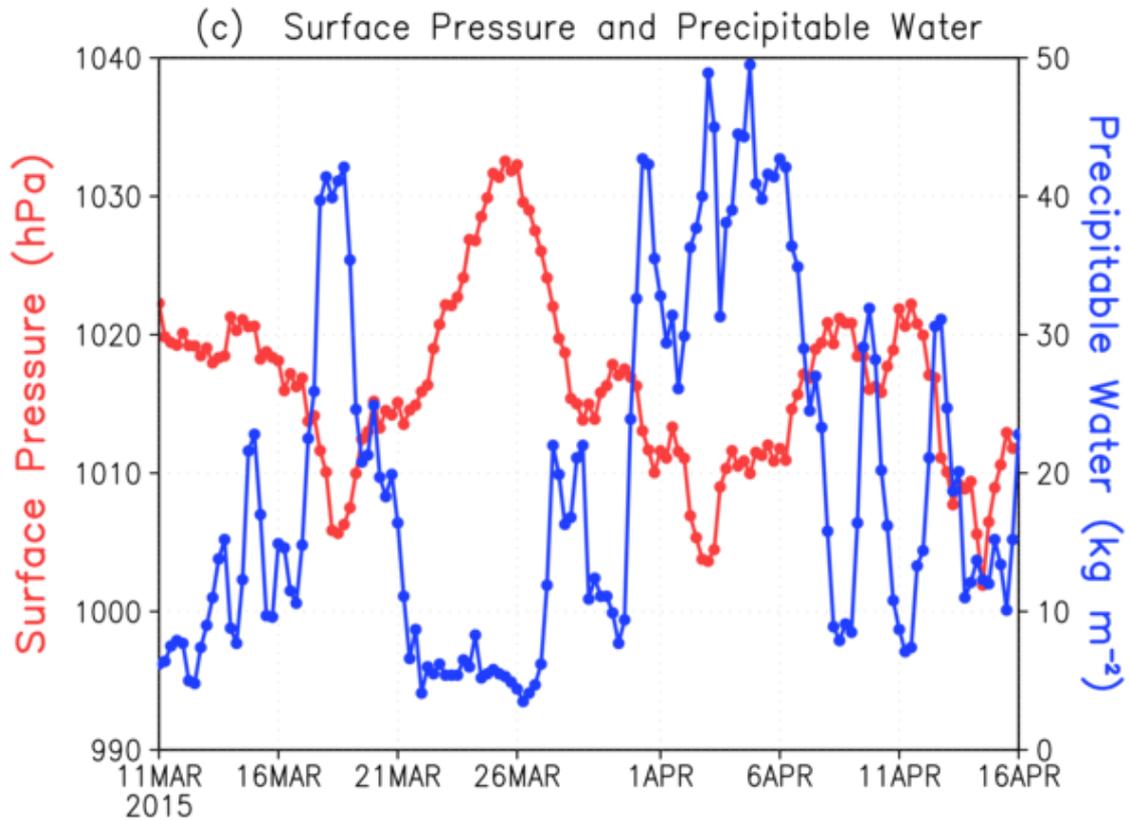

711

712

713

714

715

716 **Figure 3.** Meteorological fields in East Asia during the observation period (March 11-

717 April 14, 2015) based on NCEP FNL data. (a) Mean SLP (hPa, contours) and mean

718 horizontal wind velocity at the 850-hPa level (m s^{-1}). Regions without data correspond

719 to those of high-altitude mountains. (b) Mean θ_e (K) and total meridional moisture

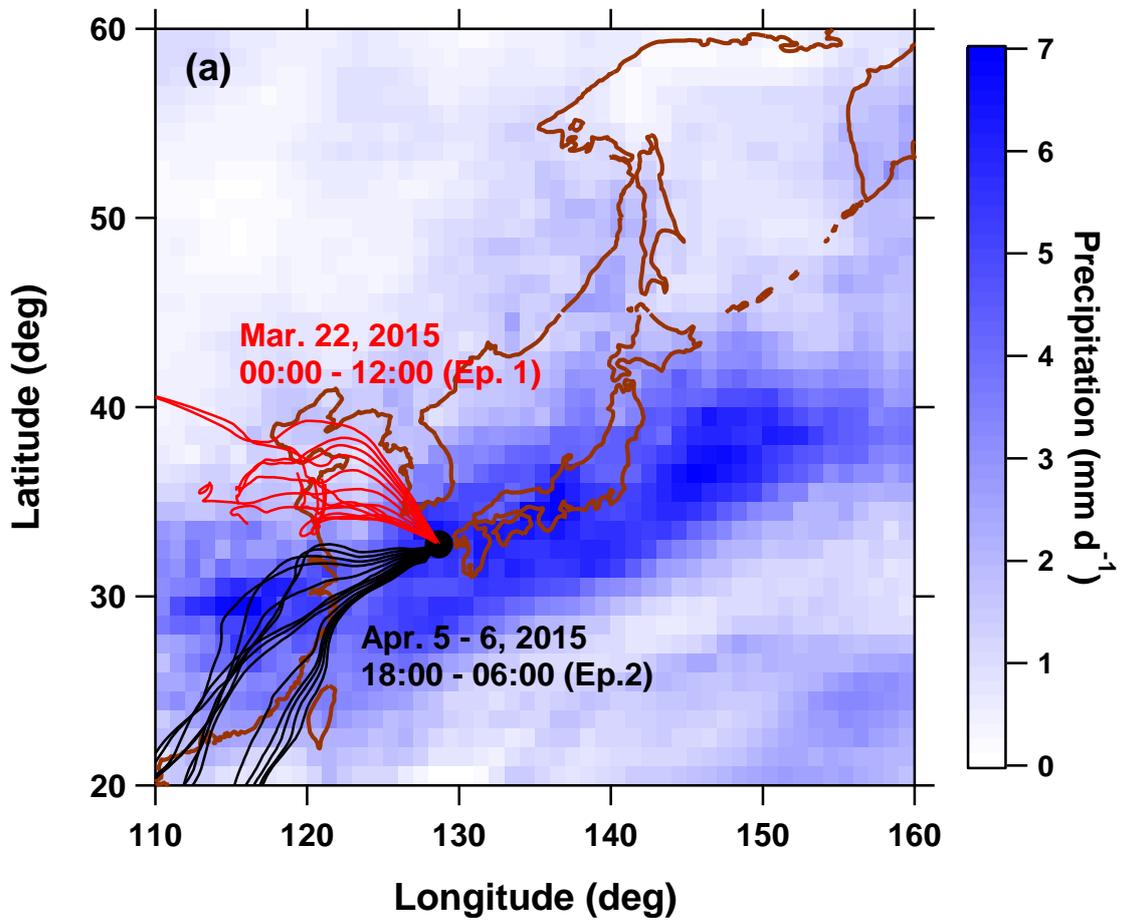

720 transport (qv values) at the 850-hPa level ($\text{m s}^{-1} \text{g kg}^{-1}$). Only qv vectors with

721 magnitudes greater than $10 \text{ m s}^{-1} \text{g kg}^{-1}$ were plotted. (c) Temporal variations in the

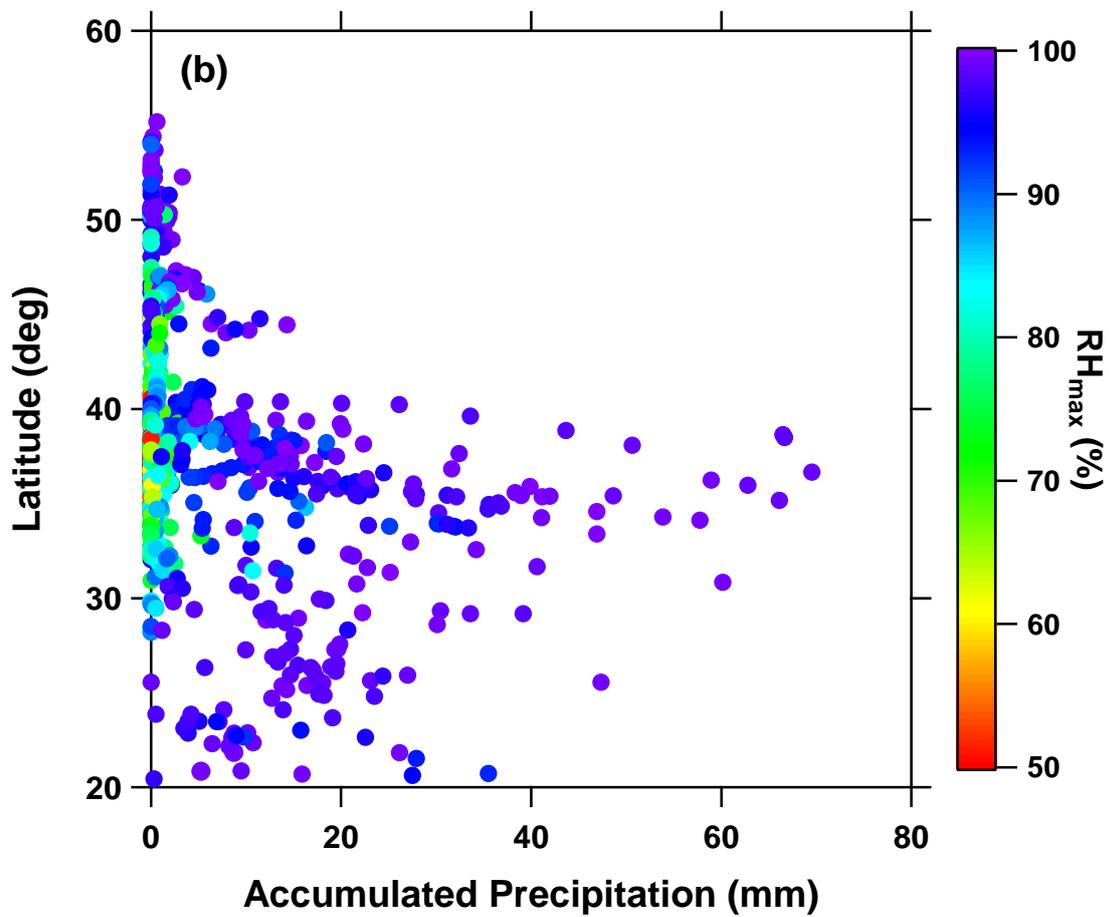

722 surface pressure (hPa, red line and markers with left axis) and precipitable water (kg m^{-2} ,

723 blue line and markers with right axis) at the Fukue observation site (32.75°N , 128.68°E).

724

725

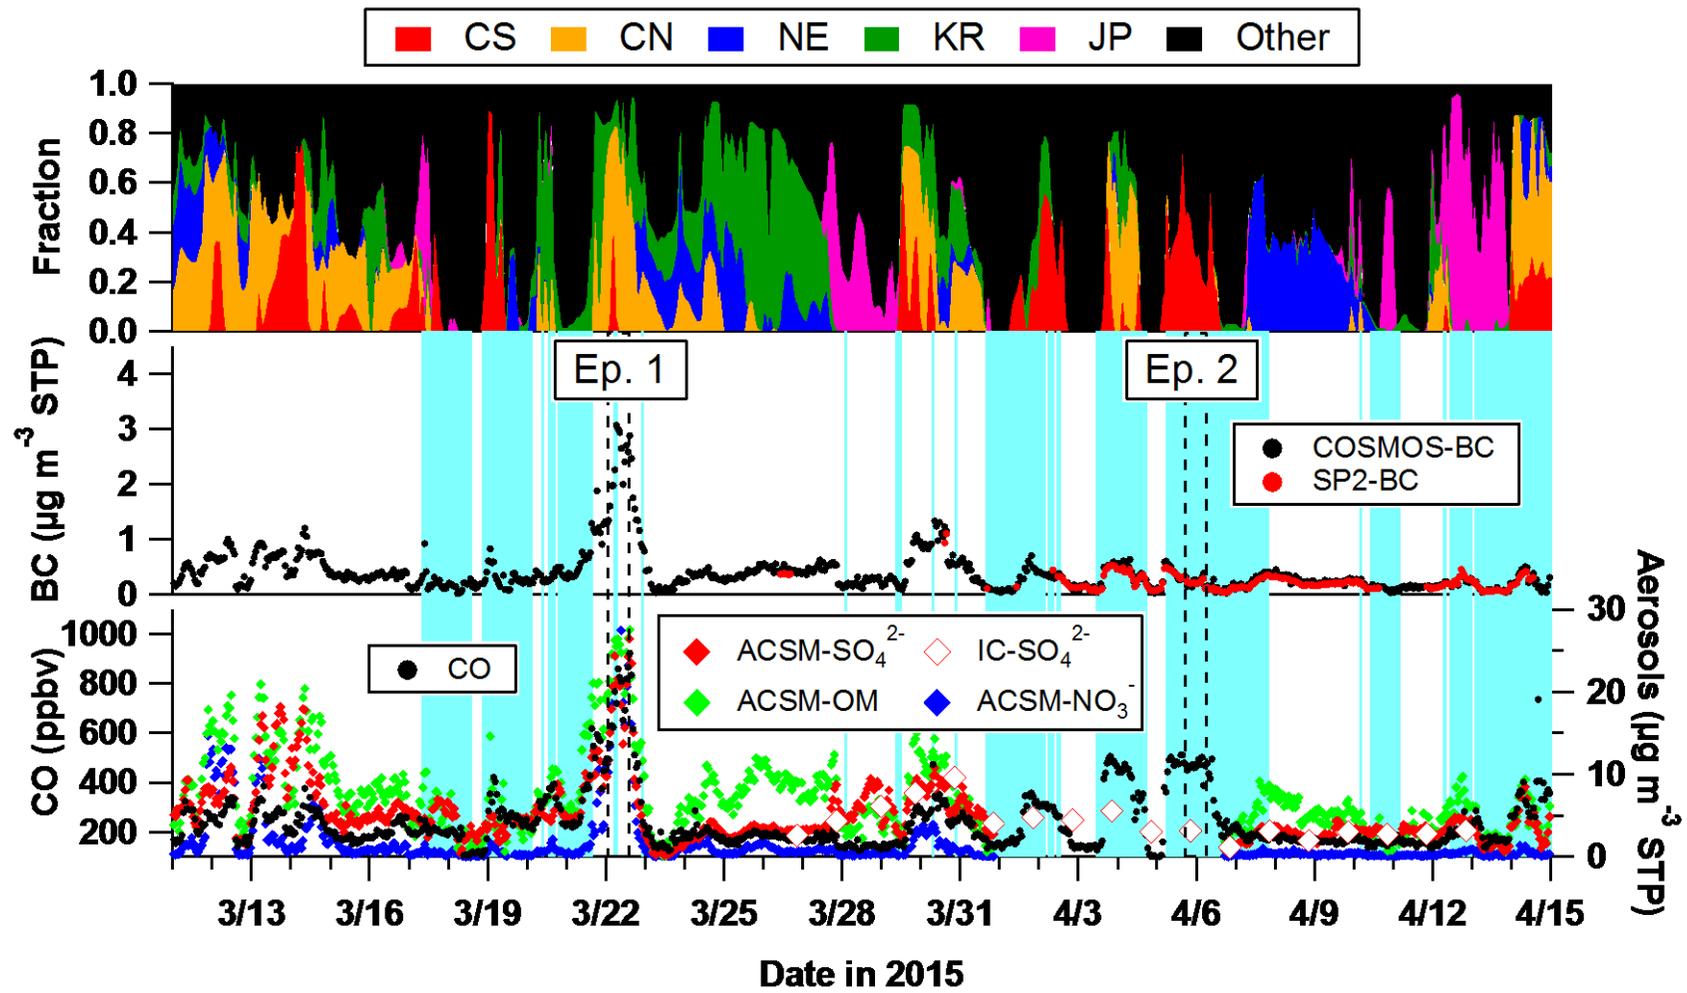

726

727

728 **Figure 4.** (a) Mean precipitation derived from GPCP during the observation period
 729 (March 11-April 14, 2015). Three-day backward trajectories for selected periods are
 730 overlaid (red lines, 00:00-12:00LT March 22, 2015 (Ep.1); black lines, 08:00LT April 5-
 731 06:00LT April 6, 2015 (Ep.2)). (b) The relationship between APT and L_{ORIG} (see text
 732 for details) colored by the maximum RH along the backward trajectories.

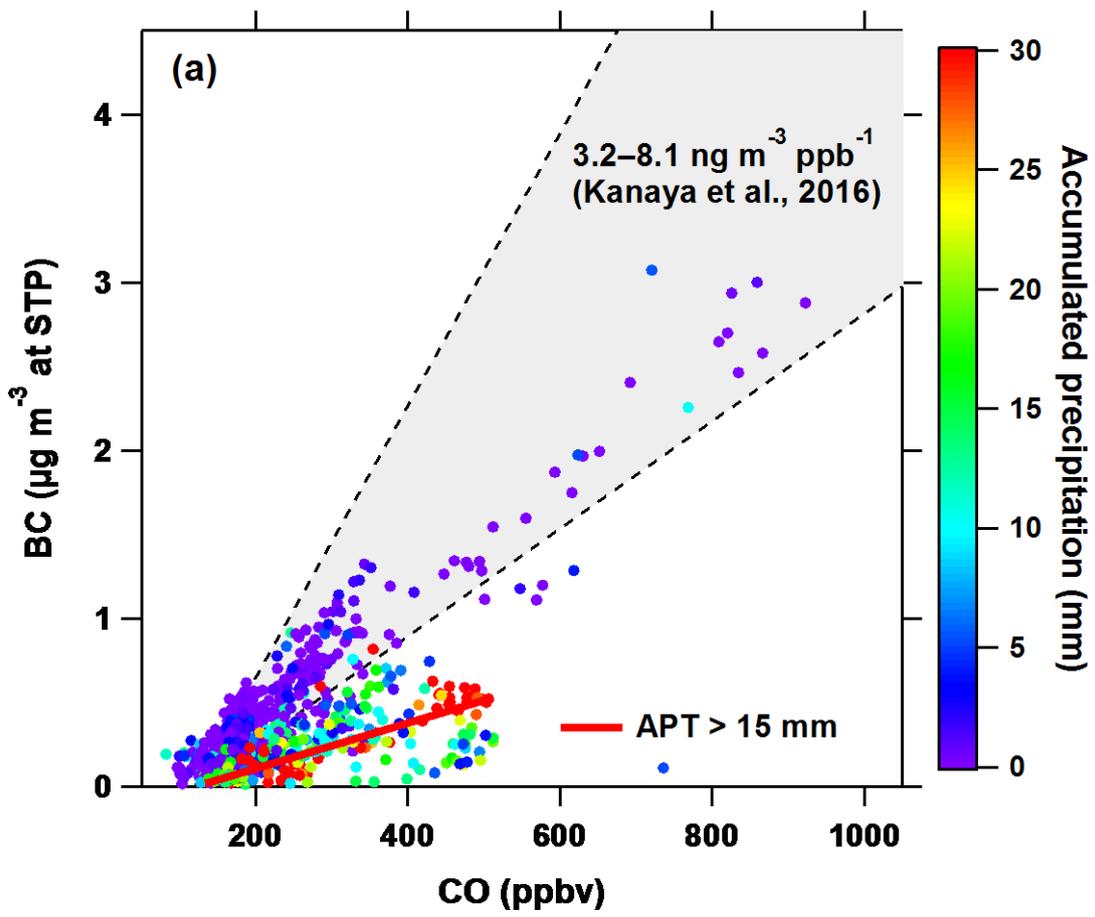

733

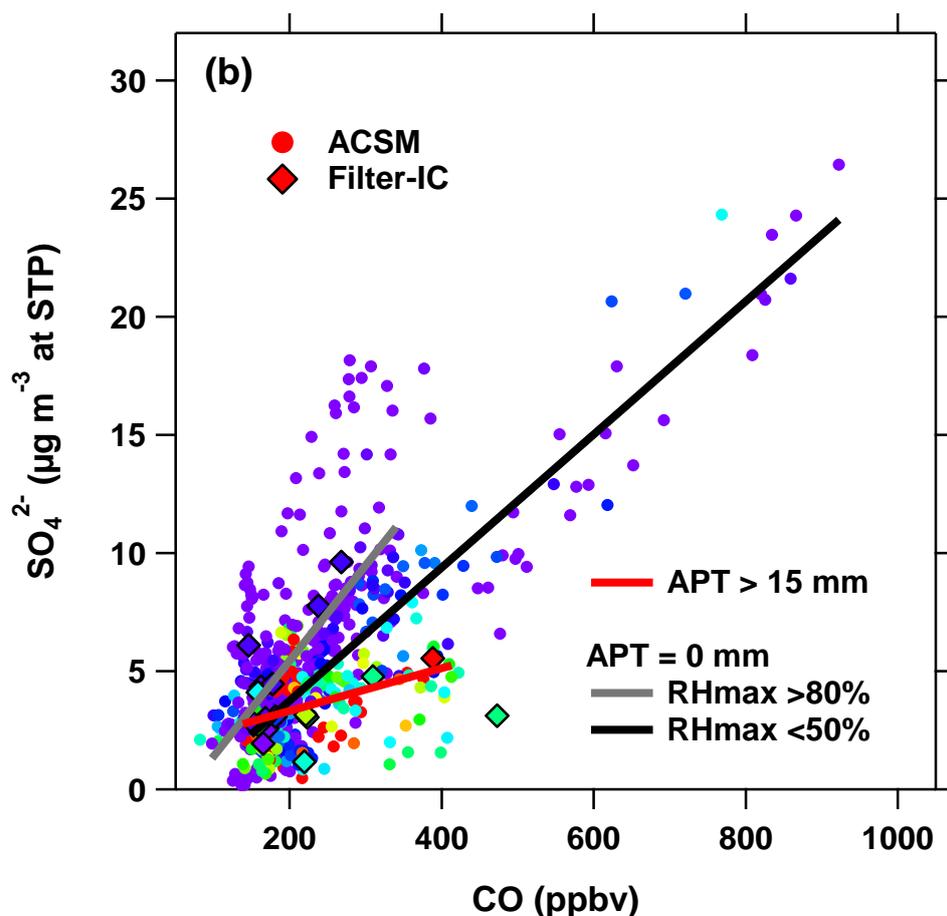

734

735

736 **Figure 5.** Temporal variations in air mass origin and concentration of trace species. (Top panel) Fractional residence time of air masses
737 passed over selected area (Red, Central South China; Orange, Central North China; Blue, Northeast China; Green, Korea; Pink, Japan;
738 Black, other regions such as Ocean). (Middle panel) mass concentrations of BC measured using the COSMOS (black markers) and SP2
739 (red markers). (Bottom panel) concentrations of CO (black markers), SO_4^{2-} (red closed and open markers for ACSM and IC, respectively),
740 ACSM- NO_3^- (blue markers), and ACSM-OM (light green markers). The periods with the APT > 3 mm are highlighted in light blue in the
741 middle and bottom panels. The periods denoted as Ep.1 and Ep.2 (see the text for details) were enclosed by dashed lines.

742

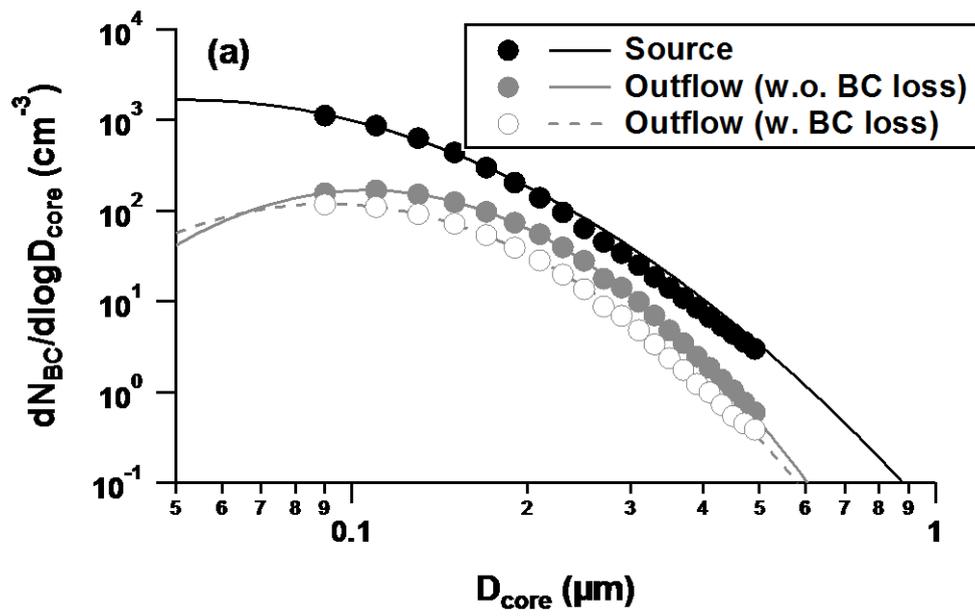

743

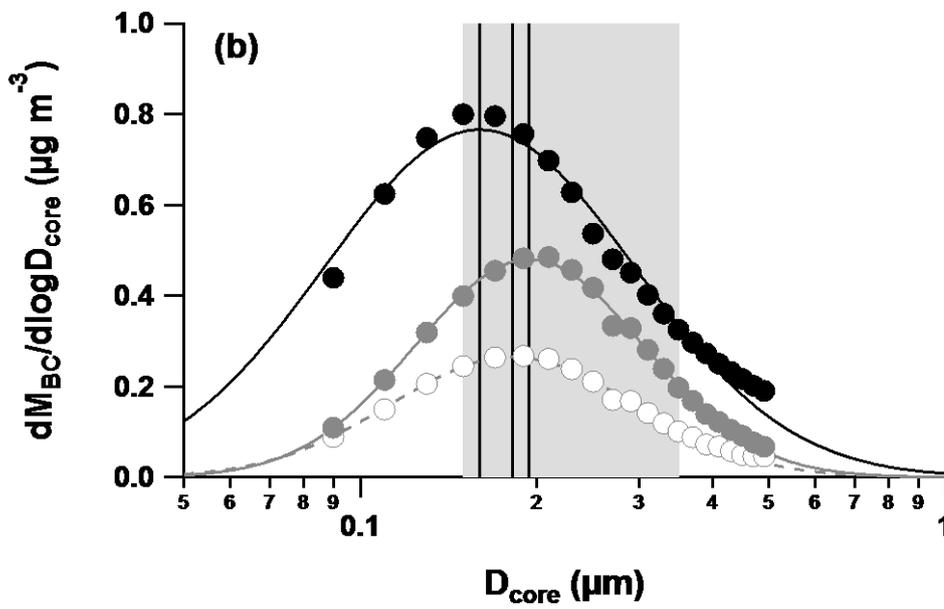

744

745 **Figure 6.** Correlation between aerosol mass concentrations and CO mixing ratio colored
 746 according to the APT. (a) BC measured by COSMOS and (b) SO₄²⁻ measured by ACSM
 747 and IC (circles and diamond markers, respectively). The bold lines are the linear fitting
 748 to the BC/CO and ACSM-SO₄²⁻/CO correlations for the selected data points, i.e., those
 749 with the APT >15 mm for BC and SO₄²⁻ (red lines), those with the APT of zero and the
 750 RH_{max} <50% for SO₄²⁻ (black line), and those with the APT of zero and the RH_{max} >80%
 751 (shaded line).

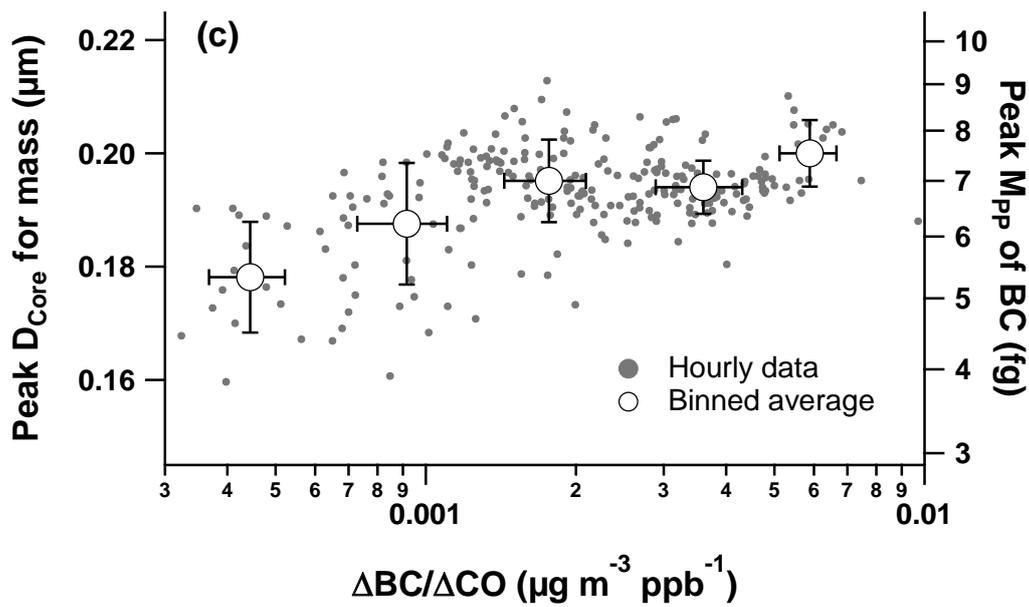

752

753

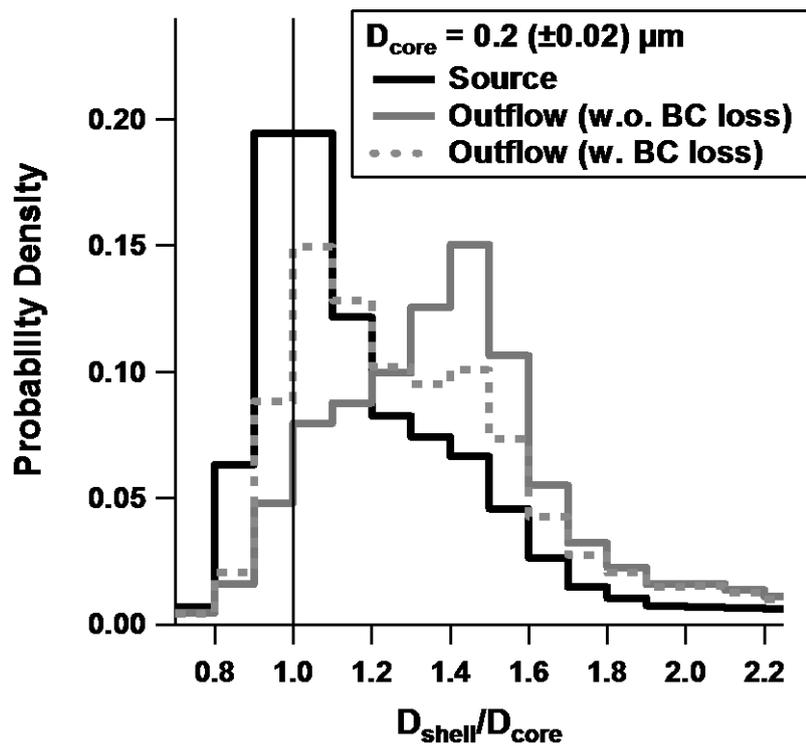

754

755

756

757 **Figure 7.** The (a) number and (b) mass size distributions of BC measured at Yokosuka
 758 (black markers) and at Fukue Island (gray markers). (c) The evolution of the peak D_{core}
 759 as a function of the degree of removal of BC. The size distributions at Fukue Island
 760 include the data for the outflow air masses with (open markers) and without (closed
 761 markers) BC loss. Lines are the lognormal fitting results. The shaded band in 7(b)
 762 corresponds to the size range analyzed to estimate D_s/D_{core} ratios. Vertical lines in 7(b)
 763 represent the peak diameter of the lognormal fit for each of three mass size distributions.
 764 Note that the peak diameter of log-normal fit for the BC number size distributions at
 765 Yokosuka was estimated from the peak diameter of its mass size distribution (**Table 2**).

766

767

768 **Figure 8.** Probability density function of the estimated D_s/D_{core} ratios for BC-containing
 769 particles with the size $0.2 (\pm 0.02) \mu m$ at Yokosuka (black line) and in the air masses of
 770 continental outflow with (gray dashed line) and without (gray solid line) BC loss.

771

772 **Tables**773 **Table 1. Mean chemical composition of fine aerosols during the observation period**

Components	Period average	APT			
		0 mm	0 mm RH _{max} <50%	0 mm RH _{max} >80%	>15 mm
Ammonium sulfate	44.9%	41.8%	34.0%	48.9%	50.4%
Ammonium nitrate	11.7%	15.7%	10.7%	8.0%	5.0%
OM	40.9%	40.1%	52.0%	40.4%	42.0%
BC	2.5%	2.4%	3.2%	2.6%	2.5%

774

775

776 **Table 2. Summaries of BC microphysical parameters measured at Yokosuka and Fukue Island**

777

Site	Air mass type	Averaging time* (hrs)	$\Delta BC/\Delta CO$ (ng m ⁻³ ppb ⁻¹)	APT (mm)	Log Normal Fit Parameters Avg. (1 σ)		1-hr Median D _S /D _{core} for selected D _{core} Avg. (1 σ)			
					MMD (μ m)	σ_g	0.15 - 0.2	0.2 - 0.25	0.25 - 0.3	0.3 - 0.35 (μ m)
Yokosuka	Source	184	-	-	0.160 (0.019)	1.84 (0.08)	1.18 (0.07)	1.15 (0.06)	1.10 (0.04)	1.07 (0.04)
