11

12 **Abstract:** Severe high ozone (O₃) episodes usually have close relations to synoptic systems. A
13 regional continuous O₃ pollution episode was detected over the Yangtze River Delta (YRD) region
14 in China during August 7-12 2013, in which the O₃ concentrations in more than half of the cities
15 exceeded the national air quality standard. The maximum hourly concentration of O₃ reached
16 167.1 ppb. By means of the observational analysis and the numerical simulation, the
17 characteristics and the essential impact factors of the typical regional O₃ pollution are integratedly
18 investigated. The observational analysis shows that the atmospheric subsidence dominated by
19 Western Pacific subtropical high plays a crucial role in the formation of high-level O₃. The
20 favorable weather conditions, such as extremely high temperature, low relative humidity and weak
21 wind speed, caused by the abnormally strong subtropical high are responsible for the trapping and
22 the chemical production of O₃ in the boundary layer. In addition, when the YRD cities at the front
23 of Typhoon Utor, the periphery circulation of typhoon system can enhance the downward airflows
24 and cause worse air quality. But when the typhoon system weakens the subtropical high, the
25 prevailing southeasterly surface wind leads to the mitigation of the O₃ pollution. The Integrated
26 Process Rate (IPR) analysis incorporated in the Community Multi-scale Air Quality (CMAQ)
27 Model is applied to further illustrate the combined influence of subtropical high and typhoon
28 system in this O₃ episode. The results show that the vertical diffusion (VDIF) and the gas-phase
29 chemistry (CHEM) are two major contributors to O₃ formation. During the episode, the

30 contributions of VDIF and CHEM to O₃ maintain the high values over the YRD region. On August
31 10-12, the cities close to the sea are apparently affected by the typhoon system, with the
32 contribution of VDIF increasing to 28.45 ppb/h in Shanghai and 19.76 ppb/h in Hangzhou. In
33 contrast, the cities far away from the sea can hardly be affected by the periphery circulation of
34 typhoon system. When the typhoon system significantly weakens the subtropical high, the
35 contribution values of all individual processes decrease to a low level in all YRD cities. These
36 results provide an insight for the O₃ pollution synthetically impacted by the Western Pacific
37 subtropical high and the tropical cyclone system.

39

40 **1. Introduction**

41 Ground-level ozone (O₃) is a secondary air pollutant generated by a series of complicated
42 photochemical reactions involving nitrogen oxides (NO_x) and hydrocarbons (HC) (Crutzen, 1973;
43 Sillman, 1999; Jenkin et al., 2000; Wang et al., 2006b; Xie et al., 2014; 2016b). Severe O₃
44 pollution events usually occur in the presence of sunlight and under favorable meteorological
45 conditions, with the abundance of O₃ precursors (NO_x and HC) (Wang et al., 2006b). These O₃
46 pollutions in troposphere can deteriorate the air quality, and thereby cause adverse effects on
47 human health and vegetation (Feng et al., 2003; Fann and Risley, 2013; Landry et al., 2013).
48 Consequently, the formation mechanism and the integrated prevention of O₃ pollution are of great
49 concern in many megacities all over the world (Xie et al., 2016b).

50 Over the past decades, along with the rapid industrial and economic development, many areas
51 in China have been suffering from high levels of O₃ pollution. Especially in the most economically
52 vibrant and densely populated areas, such as the Yangtze River Delta (YRD) region, the Pearl
53 River Delta (PRD) region, and the Beijing-Tianjin-Hebei (BTH) area, the severe O₃ pollution
54 episode has frequently occurred (Lam et al., 2005; Wang et al., 2006b; An et al., 2007; Chan and
55 Yao, 2008; Duan et al., 2008; Jiang et al., 2008; Zhang et al., 2008; Guo et al., 2009; Shao et al.,
56 2009; Ma et al., 2012) , and the background air pollutant concentrations have steadily increased
57 (Chan and Yao, 2008; Zhang et al., 2008; Tang et al., 2009; Wang et al., 2009a; Ma et al., 2012;
58 Liu et al., 2013). Many studies on the O₃ pollution, including satellite data analyses, field
59 experiments, and model simulations, have been carried out over China in order to investigate the

60 temporal and spatial characteristics of surface photochemical pollutions (Lu and Wang, 2006;
61 Wang et al., 2006a; Tu et al., 2007; Zhang et al., 2007; 2008; Geng et al., 2008; Tang et al., 2008;
62 2009; Chen et al., 2009; Han et al., 2011; Ding et al., 2013; Xie et al., 2016b), nonlinear
63 photochemistry of O₃ and its precursors (Lam et al., 2005; Ran et al., 2009; Liu et al., 2010; Li et
64 al., 2011; Xie et al., 2014), interactions between O₃ and aerosols (Lou et al., 2014; Shi et al., 2015),
65 the effects of urbanization on O₃ formation (Wang et al., 2007; 2009b; Liao et al., 2015; Li et al.,
66 2016; Xie et al., 2016a; Zhu et al., 2016), and other essential impact factors (Jiang et al., 2012; Li
67 et al., 2012; Wei et al., 2012; Liu et al., 2013; Gao et al., 2016).

68 The Yangtze River Delta (YRD) region is a highly developed area of urbanization and
69 industrialization. With the accelerated economic development and remarkable increase in energy
70 consumption, the photochemical smog with high level of O₃ concentration is becoming more and
71 more prominent and frequent, tending to present the characteristics of regional pollution (Chan
72 and Yao, 2008; Ma et al., 2012; Li et al., 2012). Being located on the southeastern coast of China,
73 YRD features a typical subtropical monsoon climate and is strongly affected by the Western
74 Pacific subtropical high in summer. So, high O₃ concentrations are usually observed in late spring
75 and summer by in-situ monitoring (Ding et al., 2013; Xie et al., 2016b). Severe high O₃ episodes
76 usually have close relations to synoptic systems (Huang et al., 2005; 2006; Wang et al., 2006b;
77 Jiang et al., 2008; Cheng et al., 2014; Hung and Lo, 2015). Horizontal and vertical transport
78 processes from upwind O₃-rich air masses as well as poor atmospheric diffusion conditions can
79 lead to the accumulation of surface O₃ concentrations and aggravating the photochemical pollution
80 (Wang et al., 2006b). In previous studies on high O₃ pollution in the YRD region, some
81 researchers have discussed this issue. For example, Jiang et al. (2012) investigated the spring O₃
82 formation over East China, and suggested that O₃ concentrations over the YRD region were
83 transported and diffused from surrounding areas. Li et al. (2012) presented quantitative analysis on
84 atmospheric processes affecting O₃ concentrations in the typical YRD cities during a summertime
85 regional high O₃ episode, and found that the maximum concentration of photochemical pollutants
86 was usually related with the process of transportation. Gao et al. (2016) evaluated the O₃
87 concentration during a frequent shifting wind period, and revealed that vertical mixing played an
88 important positive role in the formation of surface O₃. However, these investigations only focused
89 on the O₃ formation mechanism for one megacity (such as Shanghai, Nanjing and Hangzhou, etc.)

90 or just a single station. Up to now, studies on the process analysis of high ozone episodes over the
91 YRD are quite limited (Li et al., 2012). So, more studies should pay attention to the typical
92 weather systems and the exact formation mechanism of the regional O₃ pollution in this region.

93 During August 7-12 2013, there was a typical regional O₃ pollution episode in the YRD
94 region, which might be synthetically influenced by the Western Pacific subtropical high and
95 Typhoon Utor. To better understand the important factors impacting O₃ formation from the
96 regional scale, we investigated the exact roles of these two typical weather systems in this
97 pollution episode by using observational analysis and numerical simulations. The observational
98 analysis was performed to identify the temporal and spatial characteristics of the episode. The
99 WRF/CMAQ model system, which consists of the Weather Research and Forecasting model
100 (WRF) and the Community Multi-scale Air Quality Model (CMAQ), were used to reveal the exact
101 formation mechanism. With the aid the Integrated Process Rate (IPR) analysis coupled in CMAQ,
102 the qualitative and the quantitative analysis on the contributions of individual atmospheric
103 processes were conducted as well. In this paper, the brief description of observational data and
104 model configurations are shown in Section 2. The detailed observational analysis of air quality and
105 meteorological conditions are given in Section 3. The evaluation of model performance and the
106 formation mechanism of O₃ explored by IPR technique are presented in Section 4. In the end, a
107 summary of main findings is given in Section 5.

108

109 **2. Methodology**

110 **2.1 Observed meteorological and chemical data**

111 The air quality observational data are used to identify the regional characteristics of the O₃
112 episode in August 2013. Fifteen cities are selected as the representative research objects to better
113 reflect the status of O₃ pollution over the YRD region. The locations of these cities are shown in
114 Fig. 1b, which contains Shanghai, 8 cities in Jiangsu province (Changzhou, Nanjing, Nantong,
115 Suzhou, Taizhou, Wuxi, Yangzhou, and Zhenjiang), and 6 cities in Zhejiang province (Hangzhou,
116 Huzhou, Jiaxing, Ningbo, Shaoxing, and Zhoushan). The in-situ monitoring data for the hourly
117 concentrations of O₃, CO, NO₂, SO₂, PM_{2.5} and PM₁₀ can be acquired from National
118 Environmental Monitoring Center (NEMC) (<http://106.37.208.233:20035>). The assurance/quality
119 control (QA/QC) procedures for monitoring strictly follow the national standards (State

120 Environmental Protection Administration of China, 2006). The hourly pollutant concentration for
121 a city is calculated as the average of the pollutant concentrations from several national monitoring
122 sites in that city, which can better characterize the pollution level of the city. In order to identify
123 invalid or lacking data, a checking procedure for these data is performed following the work of
124 Chiqueto and Silva (2010). Finally, only less than 0.2% of the primary data are ignored in the
125 calculation. Moreover, the observed data of total VOCs (TVOC) during August 4-10 at an urban
126 site in Shanghai (SAES, 31.17°N, 121.43°E) is also used. They are provided by Shanghai
127 Academy of Environmental Sciences. The sampling height is about 15 m, and individual VOC
128 species are continuously measured every 30 min by two on-line high performance gas
129 chromatograph with flame ionization detector (GC-FID) systems (Chromato-sud airmoVOC
130 C2-C6 #5250308 and airmoVOC C6-C12 #2260308, France). The details for measurement and
131 QA/QC can refer to Wang et al. (2013).

132 The weather charts and the observed surface meteorological records are used to analyze the
133 synoptic systems during the episode. The weather charts for East Asia are accessible from Korea
134 Meteorological Administration (<http://www.kma.go.kr/chn/weather/images/analysischart.jsp>). The
135 hourly meteorological data at the observation sites of SH (31.40°N, 121.46°E) located in Shanghai,
136 HZ (30.23°N, 120.16°E) in Hangzhou, and NJ (32.00°N, 118.80°E) in Nanjing can be obtained
137 from the University of Wyoming (<http://weather.uwyo.edu/wyoming/>), where 2-m air temperature,
138 2-m relative humidity, 10-m wind speed and 10-m wind direction are available.

139 Meteorological and air quality observation data are also used to validate the reliability of
140 simulations in this study. Comparisons of the modeling results with the observation data are
141 performed in Shanghai, Nanjing, and Hangzhou. Shanghai is the most populous city in China, and
142 also a global financial and transportation center. Locating to the northwest of Shanghai, Nanjing is
143 the capital of Jiangsu Province and the second largest commercial center in East China. Hangzhou
144 is the capital of Zhejiang Province and located to the southwest of Shanghai. These cities are the
145 provincial capitals and the typical metropolis in the YRD region. They are highly urbanized and
146 industrialized, and all suffer from severe O₃ pollution.

147

148 **2.2 Model description and configurations**

149 In this study, WRF/CMAQ, which consists of WRF model version 3.4.1 and CMAQ Model

150 version 4.7.1, is applied to simulate the high O₃ episode over the YRD region in August 2013.
151 Developed at the National Center for Atmospheric Research (NCAR), WRF is a new generation of
152 meso-scale weather forecast model and assimilation system. Numerous applications have proven
153 that it shows a good performance in all kinds of weather forecasts and has broad application
154 prospects in China (Jiang et al., 2008; 2012; Wang et al., 2009b; Liu et al., 2013; Xie et al., 2014;
155 2016a; Liao et al., 2014; 2015; Li et al., 2016; Zhu et al., 2016). WRF provides off-line
156 meteorological fields as the input for the chemical transport model CMAQ. CMAQ is a third
157 generation of regional air quality model developed by the Environmental Protection Agency of
158 USA (USEPA). A set of up-to-date compatible modules and control equations for the atmosphere
159 is incorporated in the model, which can fully consider atmospheric complicated physical processes,
160 chemical processes and the relative contribution of different species (Byun and Schere, 2006;
161 Foley et al., 2010). CMAQ has been widely applied in China and proven to be a reliable tool in
162 simulating air quality from city scale to meso scale (Li et al., 2012; Wei et al., 2012; Liu et al.,
163 2013; Zhu et al., 2016).

164 The simulation run is conducted from 08:00 (local standard time, LST) on August 2 to 08:00
165 (LST) on August 16 2013, in which the first 48 h is taken as the spin-up time. Three one-way
166 nested domains are used in WRF with a Lambert Conformal map projection. The domain setting is
167 shown in Fig. 1. The outermost domain (domain 1, d01) covers the most areas of East Asia and
168 South Asia, with the horizontal grids of 88×75 and the grid spacing of 81km. The nested domain
169 d02 covers the southeastern part of China, with the horizontal grids of 85×70 and the grid spacing
170 of 27km. The finest domain (domain 3, d03) covers the core areas of the YRD region, with the
171 grid system of 70×64 and the resolution of 9km. For all domains, there are 23 vertical sigma
172 layers from the surface to the top pressure of 100hPa, with about 10 layers in the planetary
173 boundary layer. The detailed configuration options for the dynamic parameterization in WRF are
174 summarized in Table 1. Additionally, the SLAB scheme that does not consider urban canopy
175 parameters is adopted to model the urban effect. In order to reflect the rapid urban expansion in
176 the YRD region, the default United States Geological Survey (USGS) land-use archives are
177 updated by adding the present urban land-use conditions from 500-m Moderate Resolution
178 Imaging Spectroradiometer (MODIS) data, based on the work of Liao et al. (2014; 2015). The
179 initial meteorological fields and boundary conditions are from 1° resolution global reanalysis data

180 provided by National Center for Environmental Prediction (NCEP). The boundary conditions are
 181 forced every 6 h.
 182

183
 184 **Fig. 1. Domain settings, include (a) the three nested modeling domains and (b) the nested domain 3 (d03)**
 185 **with the terrain elevations and the locations of 15 main cities in the YRD region.**

186

187 **Table 1. The grid settings and the physical options for WRF in this study.**

Items	Options
Dimensions (x, y)	(88, 75), (85, 70), (70, 64)
Grid spacing (km)	81, 27, 9
Microphysics	WRF Single-Moment 5-class scheme (Hong et al., 2004)
Longwave Radiation	RRTM scheme (Mlawer et al., 1997)
Shortwave Radiation	Goddard scheme (Kim and Wang, 2011)
Surface layer	Moni-Obukhov scheme (Monin and Obukhov, 1954)
Land-surface layer	Noah Land Surface Model (Chen and Dudhia, 2001)
Planetary Boundary layer	YSU scheme (Hong et al., 2006)
Cumulus Parameterization	Grell-Devenyi ensemble scheme (Grell and Devenyi, 2002)

188

189 With respect to the air quality model, CMAQ uses the same vertical levels and the similar
 190 three nested domains as those adopted in the meteorological simulation, whereas the CMAQ
 191 domains are one grid smaller than the WRF domains. The Meteorology Chemistry Interface
 192 Processor (MCIP) is used to convert WRF outputs to the input meteorological files needed by
 193 CMAQ. The Carbon Bond 05 chemical mechanism (CB05) (Yarwood et al., 2005) is chosen for
 194 gas-phase chemistry, and the 4rd generation CMAQ aerosol module (Byun and Schere, 2006) is
 195 adopted for aerosol chemistry. The initial and outmost boundary conditions are obtained from the

196 Model for Ozone and Related Chemical Tracers version 4 (MOZART-4) (Emmons et al., 2010),
197 while those for the two nested inner domains are extracted from the immediate concentration files
198 of their parent domains. The anthropogenic emissions are mainly from the 2012 Multi-resolution
199 Emission Inventory for China (MEIC) with $0.25^{\circ} \times 0.25^{\circ}$ resolution, which is re-projected for the
200 grids of China in both domains. For the grids outside of China, the inventory developed for the
201 Intercontinental Chemical Transport Experiment-Phase B (INTEX-B) by Zhang et al. (2009) is
202 used. The natural O_3 precursor emissions are calculated by the natural emission model developed
203 by Xie et al. (2007; 2009; 2014), including NO from soil, VOCs from vegetations, and CH_4 from
204 rice paddies and terrestrial plants. The biomass burning emissions are acquired from the work of
205 Xie et al. (2014; 2016a).

206 **2.3 Integrated Process Rate (IPR) analysis method**

207 The CMAQ modeling system contains process analysis module (PROCAN), which consists
208 of the Integrated Process Rate (IPR) analysis and the Integrated Reaction Rate (IRR) analysis
209 (Byun and Schere, 2006). IPR has the capability of calculating the hourly contributions of
210 individual physical processes and the net effect of chemical reaction compared to the overall
211 concentrations, and thereby can determine the quantitative contribution of each process in a
212 specific grid cell. The atmospheric processes considered in IPR include the horizontal advection
213 (HADV), the vertical advection (ZADV), the horizontal diffusion (HDIF), the vertical diffusion
214 (VDIF), the emissions (EMIS), the dry deposition (DDEP), the cloud processes with the aqueous
215 chemistry (CLDS), the aerosol processes (AERO) and the gas-phase chemistry (CHEM). IPR has
216 been widely applied to investigate the regional photochemical pollutions, and proven to be an
217 effective tool to show the relative importance of every process and provide a fundamental
218 interpretation (Goncalves et al., 2009; Li et al., 2012; Liu et al., 2013; Zhu et al., 2016). In this
219 paper, the period from August 4 to 15 is selected for the IPR analysis. With the aid of IPR, we
220 assess the roles of the individual physical and chemical processes involved in O_3 formation over
221 the YRD region, and further present those in the typical cities (Shanghai, Nanjing and Hangzhou).

222 **2.4 Evaluation method**

223 Comparisons of the modeling results in the finest domain (d03) with the hourly observation
224 data are performed for meteorological factors and air pollutants in Shanghai, Hangzhou, and
225 Nanjing. The correlation coefficient (R), the normalized mean bias (NMB) and the

226 root-mean-square error (RMSE) are used to evaluate the model performance. These statistic values
 227 are calculated as follows:

$$228 \quad R = \frac{\sum_{i=1}^N (S_i - \bar{S})(O_i - \bar{O})}{\sqrt{\sum_{i=1}^N (S_i - \bar{S})^2} \sqrt{\sum_{i=1}^N (O_i - \bar{O})^2}} \quad (1)$$

$$229 \quad NMB = \frac{\sum_{i=1}^N (S_i - O_i)}{\sum_{i=1}^N O_i} \times 100\% \quad (2)$$

$$230 \quad RMSE = \left[\frac{1}{N} \sum_{i=1}^N (S_i - O_i)^2 \right]^{\frac{1}{2}} \quad (3)$$

231 where S_i and O_i represent the simulated and the observed value, respectively. N means the total
 232 number of valid data. Generally, the model performance is acceptable if the values of NMB and
 233 RMSE are close to 0 and that of R is close to 1.

234

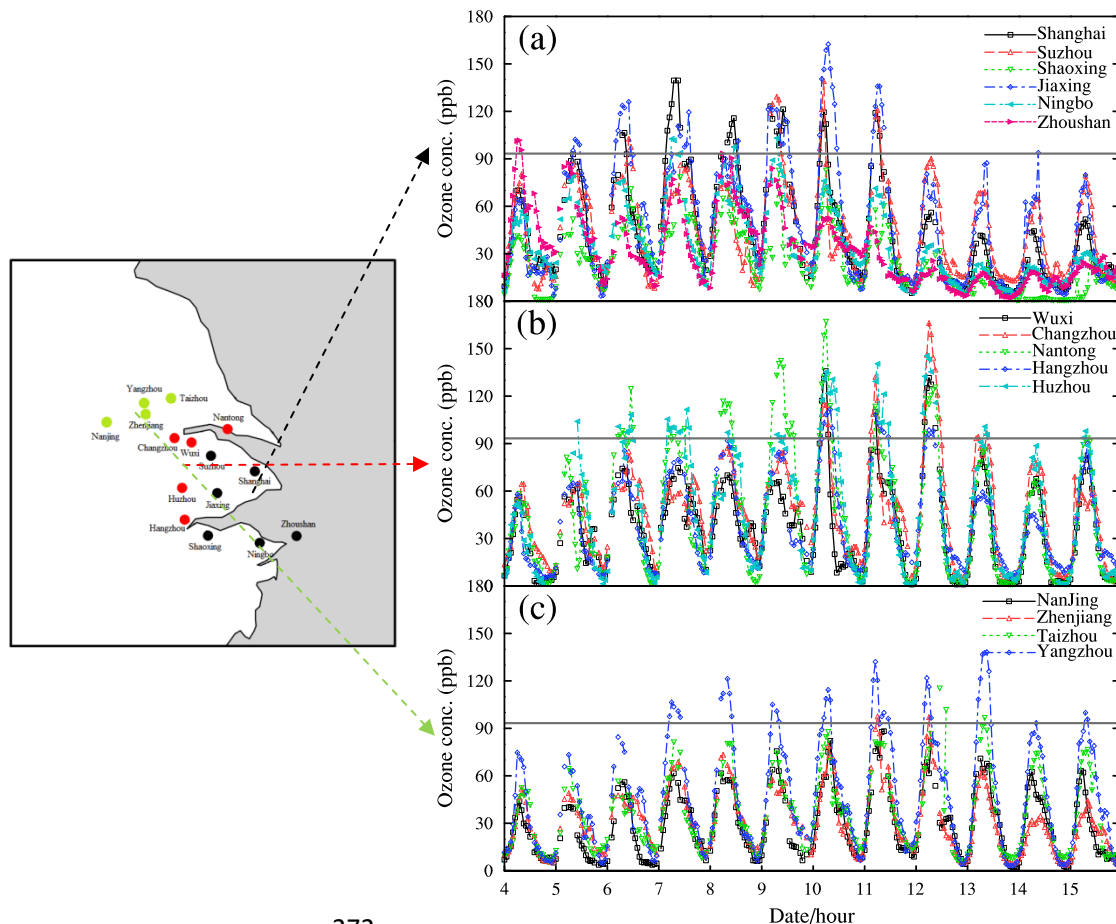

235 3. Characteristics of the continuous ozone episode

236 3.1 Basic characteristic of the regional ozone episode in August 2013

237 Fig. 2 shows the temporal variation of the hourly O_3 concentrations observed in 15 typical
 238 cities over the YRD region from 00:00 (Universal Time Coordinated, UTC) August 4 to 23:00
 239 (UTC) August 15 in 2013. Obviously, from August 7 to 12, high O_3 concentrations over 93.5 ppb
 240 (approximately equal to the hourly national air quality standard of $200 \mu\text{g}/\text{m}^3$) have been
 241 frequently recorded in 13 cities, which means O_3 concentrations in most cities over the YRD
 242 region exceed the national air quality standard. So, this high O_3 pollution episode is a typical
 243 regional O_3 pollution episode that can affect the people and the ecosystem in a large area. In
 244 general, for each city, there is a remarkable continuous growth in O_3 concentrations before the O_3
 245 episode, followed by the lasting heavy O_3 pollution period. Though the O_3 concentrations in
 246 Shaoxing and Nanjing meet the national O_3 standard, their time series still show the similar
 247 tendency for the other cities in the same region. The excessive level of O_3 occurring in Huzhou,
 248 Jiaxing, Nantong, Yangzhou and Shanghai lasts for more than six consecutive days, reflecting the
 249 regional continuous characteristics of this O_3 pollution episode.

250 According to the temporal variation characteristics of O_3 illustrated in Fig. 2, the
 251 abovementioned 15 typical YRD cities can be classified into three categories: (1) the cities in the

252 Southeast Coastal Region (SCR), including Shanghai, Suzhou, Jiaxing, Ningbo, Shaoxing, and
253 Zhoushan; (2) the cities in the Central Inland Region (CIR), including Hangzhou, Huzhou, Wuxi,
254 Changzhou, and Nantong; and (3) the cities in the Northwestern Inland Region (NIR), including
255 Nanjing, Yangzhou, Zhenjiang, and Taizhou. The classification is primarily on basis of the
256 observational facts that the maximum O₃ concentrations occur on August 10-11, 12, and 13, and
257 begin to synchronously decrease on August 12, 13 and 14 in SCR, CIR and NIR, respectively. As
258 shown in Fig. 2, in the Southeast Coastal Region (SCR), Zhoushan firstly exceeds the national O₃
259 standard on August 4, followed by Jiaxing, Shanghai, Suzhou and Ningbo. The peak hourly O₃
260 concentration of SCR occurs in Jiaxing on August 10, with the value up to 162.4 ppb. In the
261 Central Inland Region (CIR), Huzhou is the first city exceeding the national O₃ standard, followed
262 by the order of Nantong, Changzhou, Wuxi, and Hangzhou. The high-level O₃ pollution in
263 Huzhou lasts during August 5-13. In Nantong and Changzhou, the maximum hourly O₃
264 concentration reaches 167.1 ppb on August 10 and 166.1 ppb on August 12, respectively. As for
265 the Northwest Inland Region (NIR), Yangzhou, Zhenjiang, and Taizhou successively exceed the
266 national O₃ standard. It is also noteworthy that the date when O₃ concentration exceeds the
267 national air quality standard in coastal region is ahead of that in inland regions, so is the date of O₃
268 decrease. The different start time of O₃ decreasing in different regions might be related to the
269 strong southeast wind in accordance with the movement of Typhoon Utor, which is discussed in
270 Sect. 3.2 in detail.
271

272

273 **Fig. 2. The time series of the observed O_3 concentrations in 15 typical cities from August 4 to 15 2013 over**
 274 **the YRD region, which can be divided into three areas: (a) the Southeast Coast Region (SCR), including**
 275 **Shanghai, Suzhou, Shaoxing, Jiaxing, Ningbo, and Zhoushan; (b) the Central Inland Region (CIR),**
 276 **including Wuxi, Changzhou, Nantong, Hangzhou, and Huzhou; (c) the Northwest Inland Region (NIR),**
 277 **including Nanjing, Zhenjiang, Taizhou and Yangzhou. The gray solid lines in (a), (b), and (c) represent the**
 278 **national standard for the hourly O_3 concentration, which is $200 \mu\text{g}/\text{m}^3$.**
 279

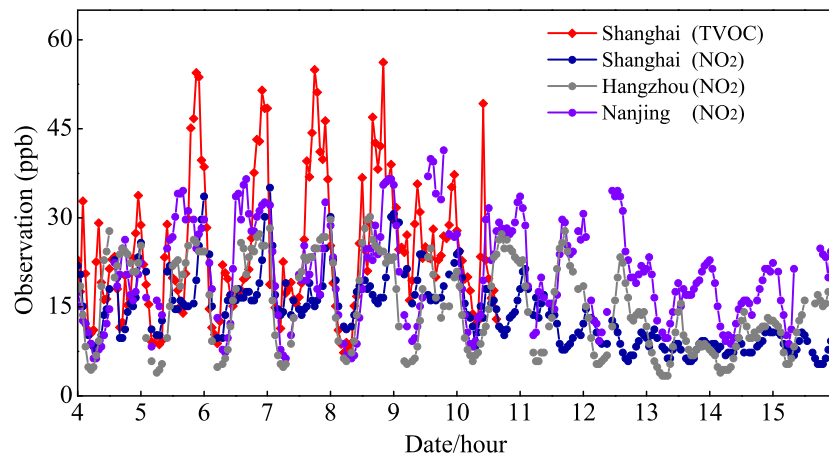

280 Table 2 presents the maximum and the average concentrations of O_3 and NO_2 in 15 YRD
 281 cities during August 7-12 2013. It illustrates that the mean concentrations of NO_2 in different YRD
 282 cities range from 7.7 to 24.5 ppb during the O_3 episode, indicating the heterogeneity of the spatial
 283 distribution of O_3 precursor emissions. For O_3 , the highest hourly concentration (167.1 ppb)
 284 occurs in Nantong, followed by 166.1 ppb in Changzhou and 162.4 ppb in Jiaxing. These values
 285 are all nearly 2 times of the national air quality standard. It seems that O_3 concentrations are
 286 higher in the cities around Shanghai, where the concentrations of O_3 precursors are more adequate
 287 as well. High concentrations of O_3 and its precursors imply that there may be stronger
 288 photochemical reactions.
 289

290 **Table 2. The maximum and average concentrations of O₃ and NO₂ observed in 15 cities during August 7-12**
 291 **2013 (ppb).**

Sites	O ₃		NO ₂	
	Max	Mean	Max	Mean
Shanghai	139.5	55.1	35.1	15.6
Southeast	139.1	50.9	50.6	19.7
Coast	162.4	61.1	52.1	17.1

292

293 Fig. 3 demonstrates the hourly variations of the observed NO₂ concentrations in Shanghai,
 294 Nanjing and Hangzhou from August 4 to 15 2013, and the time series of TVOC observed at SAES
 295 in Shanghai from August 4 to 10 2013. Obviously, there are two peaks in the diurnal cycles of
 296 NO₂ and VOC at all sites, which should be related with the rush hours in cities. The photolysis of
 297 NO₂ dominates O₃-VOC-NO_x chemistry after 8:00, and thereby makes the concentrations of
 298 precursors (NO₂ and VOC) begin to decrease. Thus, the related reactions form O₃ and increase its
 299 concentration until about 14:00. These diurnal variations of O₃ and its precursors follow the
 300 typical patterns in the polluted areas and reflect the close relationships between O₃, VOC and NO_x
 301 (Wang et al., 2013; Xie et al., 2016b). Moreover, the daily variations of NO₂ and VOC show good
 302 agreement with those of O₃. For VOC, the concentration in Shanghai largely increases since
 303 August 6, which corresponds well with the over-standard O₃ concentrations since then (Fig. 2).
 304 For NO₂, the higher values occur from August 6 to 11 in all cities, but the concentrations start to
 305 decrease on August 12, 13 and 14 in Shanghai, Hangzhou and Nanjing, respectively. It seems that
 306 the changes of O₃ precursors (NO₂ and VOC) are also affected by the movement of Typhoon Utor.

308
 309 Fig. 3. Temporal variations of the observed NO₂ concentrations at Shanghai, Nanjing and Hangzhou
 310 stations from August 4 to 15 2013 and the observed TVOC concentration at SAES (31.17°N, 121.43°E) in
 311 Shanghai from August 4 to 10 2013.

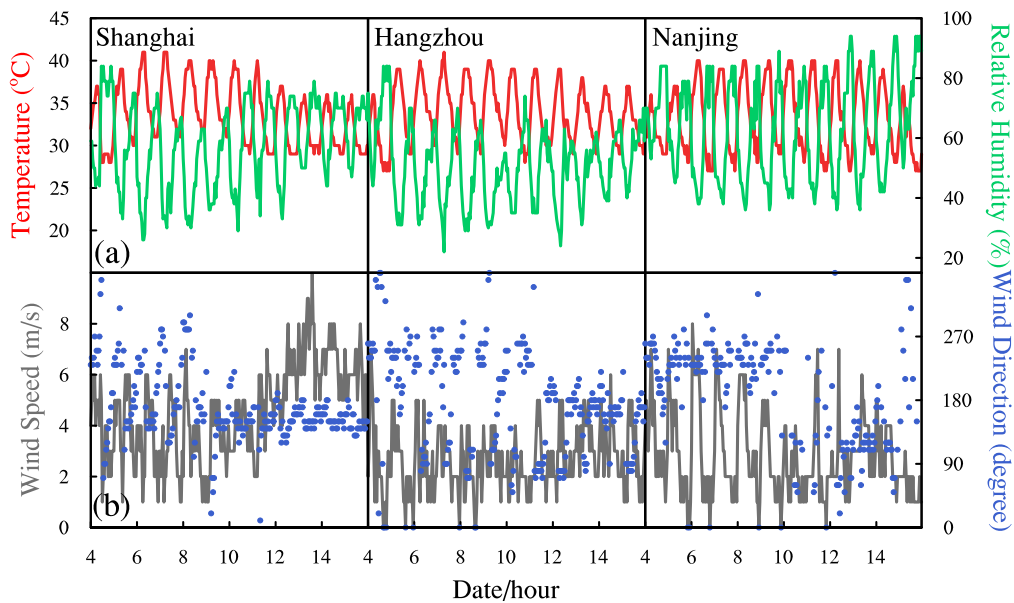

312

313 3.2 Meteorological condition and its effect

314 Favorable weather conditions have large impacts on the formation of severe O₃ pollution
 315 (Huang et al., 2005; 2006; Wang et al, 2006b; Jiang et al., 2008; Cheng et al., 2014; Hung and Lo,
 316 2015). High-level O₃ episodes often take place in hot seasons, when the meteorological conditions
 317 with high temperature and strong solar radiation are beneficial to the photochemical reactions of
 318 O₃ (Lam et al., 2005). Fig. 4 shows the variations of the surface meteorological parameters that are
 319 related to this photochemical pollution episode during August 4-15, including 2-m air temperature,
 320 2-m relative humidity, 10-m wind speed and 10-m wind direction at the meteorological sites in
 321 Shanghai (SH) of SCR, Hangzhou (HZ) of CIR, and Nanjing (NJ) of NIR .

322 As shown in Fig. 4a, the hot weather at SH, HZ and NJ exists for nearly a week from August
 323 7 to 12, with the hourly maximum temperature reaching the value over 40 °C. Meanwhile, the
 324 variations of 2-m relative humidity show the negative correlation with those of 2-m air
 325 temperature. The minimum 2-m relative humidity at SH and HZ occur on August 9 and August 10
 326 respectively, with the value below 75%. These minimum values are also lower than the values
 327 before and after the O₃ episode, suggesting that high-level O₃ episodes usually occur under the
 328 weather conditions with high temperature and low humidity. The value of 2-m relative humidity at
 329 NJ is relatively higher than those at SH and HZ and remains more stable. This extremely hot and

330 dry weather condition at SH, HZ, and NJ are successively relieved on August 12, 13 and 15, which
 331 coincide well with the reduction of surface O₃ concentrations in Shanghai, Hangzhou, and Nanjing
 332 (Fig. 2). With respect to the observed surface wind (Fig. 4b), the 10-m wind speed at SH and HZ is
 333 comparatively lower during the period of the O₃ episode, while it is suddenly intensified after
 334 August 12. Meanwhile, the wind direction is fluctuating from August 7 to 12, while it maintains
 335 southeasterly wind after August 12 as well. The growth of wind speed is more distinct at SH, with
 336 the maximum value of approximately 10 m/s. The wind speed at NJ has an obviously diurnal
 337 variation from August 4 to 8, and the minimum value occurs on August 10.
 338

339
 340 **Fig. 4. Temporal variations of the main meteorological parameters at Shanghai, Hangzhou and Nanjing**
 341 **meteorological stations during August 4-15 2013, including (a) 2-m air temperature (the red solid line) and**
 342 **2-m relative humidity (the green solid line); (b) 10-m wind speed (the gray solid line) and 10-m wind**
 343 **direction (the blue scatter points).**

344

345 Fig. 5 displays the weather charts for the 500hPa layer over the East Asia at 00:00 (UTC) on
 346 August 6, 8, 10, and 12 2013, which can illustrate the main synoptic patterns causing the O₃
 347 pollution. Obviously, during the period of the selected O₃ episode, the whole YRD region is under
 348 the control of the strong Western Pacific subtropical high, which is stronger and extends much
 349 farther west than normal. The anomaly of the subtropical high might be the direct and leading
 350 cause of the abnormally high temperature shown in Fig. 4a (Peng et al., 2014). The intensity of the

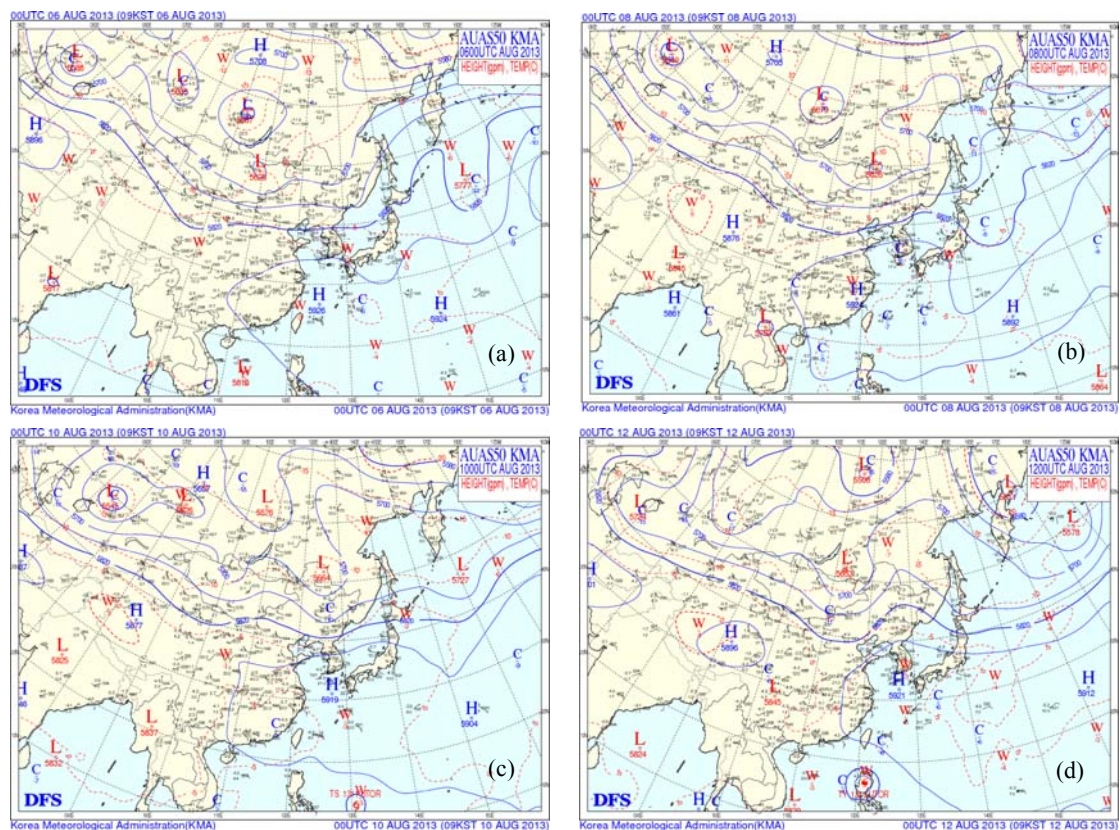

351 subtropical high is usually characterized by the area index, defined as the total number of grid
352 points that have geopotential heights of 588 decameters or greater in the region of 110-180°E and
353 northward of 10°N. As shown in Fig. 5, the 588-decameter area covers most of southeast China,
354 and the high pressure center (592-decameter area) is located in the southeastern coastal areas as
355 well as the surrounding sea areas, which means the subtropical high is very intensive. This high
356 pressure strengthens and remains over the YRD region for several days (from August 6 to 12),
357 implying that the air subsides to the ground. The downward air acts as a dome capping the
358 atmosphere, and helps to trap heat as well as air pollutants at the surface. Without the lift of air,
359 there is little convection and therefore little cumulus clouds or rains. The end result is a continual
360 accumulating of solar radiation and heat on the ground, which may greatly enhance the
361 photochemical reactions between the abundant build-up air pollutants.

362 The other weather system worthy of note is Typhoon Utor (shown in Fig. 5c and d). Typhoon
363 Utor is one of the strongest typhoons in the 2013 Pacific typhoon season. It is formed early on
364 August 8, develops into a tropical storm on August 9, undergoes an explosive
365 intensification within a half of day, and achieves typhoon status on early August 10. After landing
366 in Luzon of the Philippines on late August 11, it reemerges in the South China Sea on August 12.
367 Typhoon Utor hits the land of Guangdong Province in China on August 14, and thereby is finally
368 weakened into a tropical storm. In the end, it is ultimately dissipated on August 18. It was reported
369 that ozone episodes during the hot season are usually associated with the passage of tropical
370 cyclones close to the territory (Huang et al., 2005; Wang et al., 2006b; Jiang et al., 2008; Cheng et
371 al., 2014; Hung and Lo, 2015). When a site is at the front of moving typhoon system, it can be
372 controlled by the downward airflow induced by the typhoons' peripheral circulation. So, the
373 typhoon system can cause the local weather around the site with high temperature, low humidity,
374 strong solar radiation and small wind for a short time, before it is close enough to bring winds and
375 rains. All these changes of meteorological conditions can help to form the severe continuous O₃
376 pollution (Jiang et al., 2008). In this O₃ episode, the YRD region may be influenced by the
377 peripheral circulation of Typhoon Utor as well. Especially on August 10-11, the downward airflow
378 in the troposphere is significantly strengthened (shown in Fig. 7), which may enhance the build-up
379 of heat and air pollutants, and thereby result in worse air quality shown in Fig. 2.

380 Moreover, with the approaching of Typhoon Utor from August 12 to 14, the near-surface

381 breeze over the YRD region gradually turns to be the prevailing southeasterly or southerly wind
 382 (Fig. 5d), with the highest wind speed up to 6-10 m/s in Shanghai (Fig. 4). The strengthened wind
 383 can bring the clean marine air from ocean to inland, and thereby effectively mitigate the O₃
 384 pollution. Meantime, Typhoon Utor also gradually affects the position and strength of the Western
 385 Pacific subtropical high. As the typhoon continuously approaching and finally landing on
 386 Guangdong, the high pressure system is forced to retreat easterly and move northwards. When the
 387 high pressure center completely moves to the oceans, the YRD region is totally under the control
 388 of the typhoon system. In the end, the hot weather is relieved and the O₃ pollution is mitigated.
 389 The coastal cities in CSR are closer to the typhoon system, so they are firstly influenced during
 390 this period. Thus, the wind at SH in CSR firstly changes, followed by HZ in CIR and NJ in NIR.
 391 In the same way, 2-m air temperature and O₃ concentrations also successively decrease from
 392 southeast (SH in CSR) to northwest (NJ in NIR) owing to the scavenging effect.

393

394 Fig. 5. Weather charts at the 500hPa layer over the East Asia at 00:00 (UTC) on (a) August 6, (b) August 8,
 395 (c) August 10, and (d) August 12 2013 (from Korea Meteorological Administration).

396

397 **4 Modeling results and discussions**

398 4.1 Evaluation of model performance

399 To evaluate the simulation performance, the hourly modeling results during the period of
400 August 4-15 2013 are compared with the observation records. Table 3 presents the performance
401 statistics, including the values of the correlation coefficient (R), the normalized mean bias (NMB),
402 and the root-mean-square error (RMSE), which are all calculated for 2-m air temperature (T_2),
403 2-m relative humidity (RH_2), 10-m wind speed (W_{spd10}), 10-m wind direction (W_{dir10}), surface
404 ozone concentrations (O_3), and surface nitrogen dioxide concentrations (NO_2) in Shanghai (SH),
405 Nanjing (NJ), and Hangzhou (HZ).

406 As indicated in Table 3, the simulated results of surface air temperature and relative humidity
407 from WRF show good agreement with the observations. The highest correlation coefficient of 2-m
408 air temperature (T_2) is found to be 0.91 at SH, followed by 0.84 at NJ and 0.80 at HZ (statistically
409 significant at 95% confident level). The corresponding correlation coefficients for 2-m relative
410 humidity (RH_2) are 0.85, 0.83 and 0.78, respectively. The values of RMSE for T_2 at SH, NJ and
411 HZ are 4.15, 2.91 and 3.09 °C, and those for RH_2 are 19.3%, 9.41% and 13.96% respectively. Our
412 simulation underestimates T_2 and overestimates RH_2 to some certain extent, with the values of
413 NMB for T_2 at SH, NJ and HZ being -5.68%, -5.98% and -6.53%, and those for RH_2 being
414 12.64%, 4.52% and 16.36%. These biases might be attributed to the uncertainty caused by the
415 SLAB scheme, which can underestimate temperature in summer (Liao et al., 2014). However,
416 according to the relevant studies (Li et al., 2012; Liao et al., 2015; Xie et al., 2016a), this level of
417 over- or under-estimation is still acceptable. The wind components are closely related to the
418 transport processes. As shown in Table 3, our modeling results of wind speed and direction
419 basically reflect the characteristics of wind fields. For 10-m wind speed (W_{spd10}), R is 0.77 at SH,
420 0.74 at NJ, and 0.75 at HZ, respectively. Though the values of NMB (1.53%, 5.92%, and 9.21%)
421 and RMSE (2.18, 2.41 and 2.39) display that the simulated wind speeds are a little overestimated,
422 the biases are still reasonable and acceptable. For 10-m wind direction (W_{dir10}), the simulated
423 values also fit the observation records well, with the R values of 0.63 at SH, 0.57 at NJ and 0.58 at
424 HZ. Comparing the mean values from SIM and OBS, we can find that WRF model generally
425 simulates the prevailing wind direction during this period. In summary, the abovementioned
426 performance statistics numbers illustrate that the WRF simulation can reflect the major
427 characteristics of meteorological conditions of this O_3 episode, and the meteorological outputs can

428 be used in the pollutant concentration simulation.

429

	O ₃ (ppb)	76.57	84.51	0.83	10.37%	33.95
	NO ₂ (ppb)	31.06	27.21	0.66	-12.40%	16.86

432 ^a Sites indicates the city where the observation sites locate, including Shanghai (SH), Nanjing (NJ), and Hangzhou
 433 (HZ); ^b Vars indicates the variables under validation, including 2-m air temperature (T₂), 2-m relative humidity
 434 (RH₂), 10-m wind speed (Wspd₁₀), 10-m wind direction (Wdir₁₀), ozone (O₃), and nitrogen dioxide (NO₂). The
 435 words between the parentheses behind variables indicate the unit; ^c OBS indicates the observation data; ^d SIM
 436 indicates the simulation results from WRF/CMAQ; ^e R indicates the correlation coefficients, with statistically
 437 significant at 95% confident level; ^f NMB indicates the normalized mean bias; ^g RMSE indicates the
 438 root-mean-square error.

439

440 Fig. 6 shows the comparisons between the modeling results from CMAQ and the observed
 441 hourly concentrations of O₃ in Shanghai, Nanjing, and Hangzhou during August 4-15 2013.
 442 Obviously, the observations and the simulated results present reasonable agreement at each site,
 443 with the correlation coefficients of 0.81 to 0.83, NMB of -6% to 12.12%, RMSE of 33.95 to 38.79
 444 ppb. Moreover, the simulation also reproduces the diurnal variation of O₃, which shows that the
 445 concentration reaches its maximum at around noon time and gradually decreases to its minimum

446 after midnight. With respect to the O₃ precursor, comparisons of NO₂ concentrations between
447 simulation results and observations show that the correlation coefficient at each city is about 0.6
448 (given in Table 3), which further prove that the process of O₃ formation is captured reasonable
449 well over the YRD region and throughout the episode. However, CMAQ overestimates NO₂ and
450 underestimates O₃ in Shanghai, while underestimates NO₂ and overestimates O₃ in Nanjing and
451 Hangzhou. These biases of O₃ and NO₂ should mainly be attributed to the uncertainties in
452 emissions of O₃ precursors (NO_x and VOC_s) (Li et al., 2012; Liao et al., 2015; Xie et al., 2016).
453 Because of the VOC-sensitive O₃ chemistry in the daytime and NO_x titration at night in the YRD
454 region (Xie et al., 2014), higher estimation of NO_x emission in Shanghai may lead to higher NO₂
455 and lower O₃ predictions, while lower NO_x estimations in Nanjing and Hangzhou may result in
456 lower NO₂ and higher O₃ modeling results. The undervalued NO₂ and overvalued O₃ in Nanjing
457 and Hangzhou can also be related with the overestimations in WS₁₀ and the negative biases in T₂.
458 Moreover, the uncertainties in nonlinear chemical reactions coupled in CMAQ may also have
459 important effects on model predictions. For example, the modeling results cannot catch the low O₃
460 values observed at night in Nanjing and Hangzhou (Fig. 6), implying there may be some
461 imperfections in the nocturnal chemistry of CMAQ. Nevertheless, the performance of CMAQ
462 model is comparable to the other applications (Goncalves et al., 2009; Li et al., 2012; Zhu et al.,
463 2016). Compared to these previous related studies, the simulation in this study attains an
464 acceptable and satisfactory result. Thus, the consistency of simulation and observation
465 demonstrates that the modeling results are capable of capturing and reproducing the characteristics
466 and changes of photochemical pollutants, and can be used to provide valuable insights into the
467 governing processes of this O₃ episode.

468

469
470

471 **Fig. 6. Hourly variations of the observed and the simulated O₃ concentrations in Shanghai, Nanjing, and**
472 **Hangzhou. The red solid lines show the modeling results, the black dot lines give the observations, and the**
473 **solid gray lines represent the national standard for the hourly O₃ concentration, which is 200 μg/m³.**

474

475 **4.2 Characteristics of the vertical airflows**

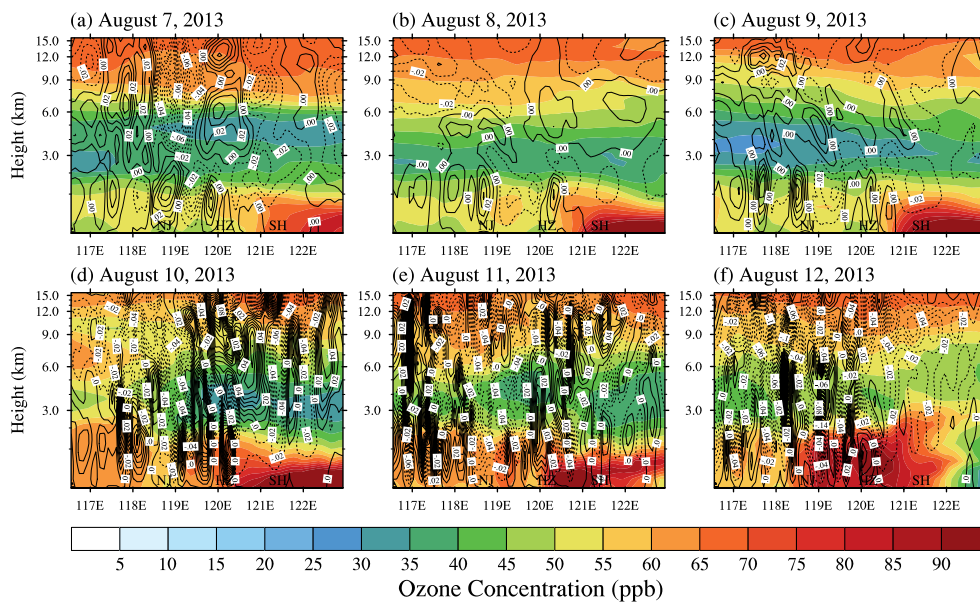

476 Fig. 7 presents the daytime vertical wind velocity as well as the vertical distribution of O₃
477 concentrations from 116.5°E to 122.9°E along the latitude of 31.40°N (where Shanghai is located)
478 during August 7-12 2013. The simulation results clearly illustrate that there are strong downward
479 airflows over the YRD region during the period of the regional high-level O₃ pollution, which can
480 be attributed to the fact that these areas are under the control of the subtropical high and the
481 sinking airflow is predominant (as discussed in Sect. 3.2).

482 From August 7 to 9 2013, except for the mentioned regional sinking airflows, there are still
483 some local thermal circulations continually occurring at the lower atmospheric layers (< 2 km)
484 along the vertical cross-section of Hangzhou (HZ) - Nanjing (NJ). These circulations are related
485 with urban heat islands. Usually high pressures are accompanied by more stagnant and fair dry
486 weather, so the upward and the downward flows caused by urban-breeze circulations can easily
487 appear in the urban areas. For the vertical distribution of O₃, its high concentrations (> 50 ppb)
488 generally appear from the surface to 1.5km height above the cities. As discussed in Sect. 3.2, air
489 pollutants tend to be trapped on the ground due to the regional sinking airflows. Moreover, the
490 local circulations over the cities make the urban areas to be the convergence zones, and thereby
491 more air pollutants can be accumulated in and around these cities. Under the weather conditions
492 induced by the subtropical high, such as high air temperature, stronger solar radiation and less

493 water vapor, the chemical reactions between the build-up air pollutants can be enhanced to form
 494 the high-level O₃ pollution. Additionally, Fig. 7a-c also show that there are maximum O₃
 495 concentrations (> 90 ppb) occurring near the surface in and around SH. This phenomenon should
 496 be explained by the fact that the coastal city (SH) is firstly affected by Typhoon Utor

497 From August 10 to 12, with the approaching of Typhoon Utor, the vertical air movements
 498 over the YRD region are not restricted at the lower atmosphere any more. As shown in Fig. 7d-f,
 499 there are stronger downward airflows from the surface to the top of troposphere. As discussed in
 500 Sect. 3.2, the YRD cities are at the front of the moving typhoon system, so the peripheral
 501 circulation of Typhoon Utor may enhance the sinking of atmosphere, which can lead to higher air
 502 temperature, lower humidity, and stronger solar radiation. Affected by the enhanced downward air
 503 movement as well as the relevant changes of meteorological conditions, O₃ concentrations over
 504 the YRD region maintain a high pollution level, with the O₃ concentrations over 60 ppb below the
 505 height of 1.5 km (Fig. 7d-f). Furthermore, the high value center of O₃ concentrations (>90 ppb)
 506 moves westwards during August 10-12, implying that the peripheral circulation of Typhoon Utor
 507 can drive the air from the coastal areas to the inland areas.

508

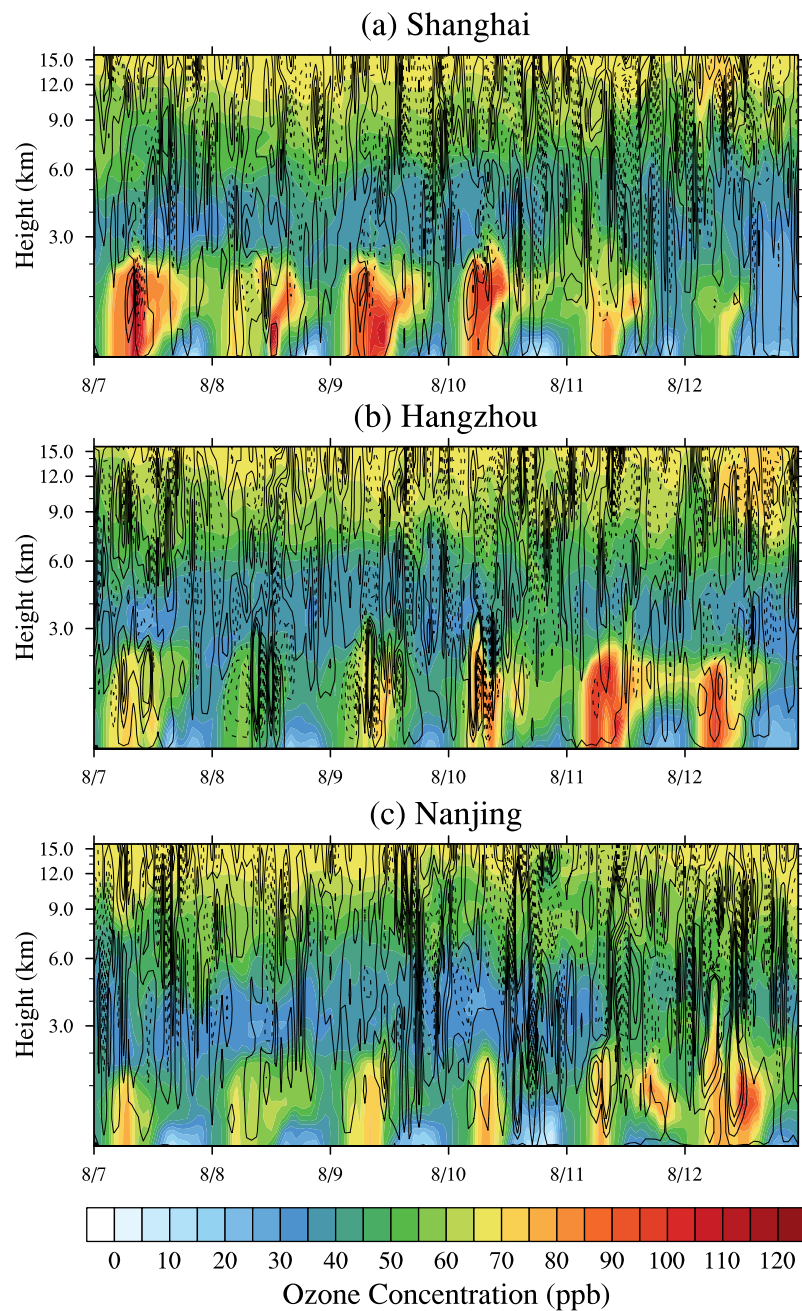

509

510 **Fig. 7. Simulated daytime vertical wind velocity and vertical distribution of O₃ concentrations from 116.5°E**
 511 **to 122.9°E along the latitude of 31.40°N (where Shanghai is located) during August 7 to 12 2013. The marks**
 512 **of SH, HZ and NJ point out the longitudes of Shanghai, Hangzhou, and Nanjing, respectively. The dotted**
 513 **lines show the negative wind speeds and represent downward airflow, while the solid lines show the positive**
 514 **wind speeds and zero vertical velocity. The interval is 0.01 m/s.**

515

516 The vertical changes of wind velocity and O₃ concentrations above Shanghai, Hangzhou and
517 Nanjing are further illustrated in Fig. 8. Similarly, the atmospheric subsidence can also be found in
518 the troposphere (usually occur at more than 1 km above the surface) during the period of the
519 high-level O₃ pollution. With respect to Shanghai, affected by the extremely high temperature,
520 more active photochemical reactions lead to higher O₃ concentrations in the whole atmospheric
521 boundary layer. The downward airflows induced by the subtropical high trap and enhance the
522 accumulation of surface O₃ as time passes. Thus, high O₃ concentrations are formed below 2 km
523 above the urban areas of Shanghai, and the high concentration centers occur near the surface
524 below 500 m. It is interesting that O₃ concentration on August 8 is comparatively lower, which can
525 be seen in Fig. 2 as well. This phenomenon can be explained by the fact that the transient upward
526 airflow occurs at above 300 m over Shanghai and inhibits the accumulation of the O₃ pollution at
527 the surface (shown in Fig. 8a). Additionally, Fig. 8a also presents the possible effects of Typhoon
528 Utor on the formation of O₃. On August 10, when the typhoon system approaches to the eastern
529 coastal areas of China, the sinking air above Shanghai is apparently strengthened, and thereby
530 enhances the intensity of O₃ pollution as well as the scope of the pollution. But after August 12,
531 when Typhoon Utor changes the wind and even impacts the subtropical high, high temperature is
532 alleviated and the build-up O₃ is transported to other places. Thus, the pollution is mitigated. As to
533 Hangzhou (Fig. 8b), from August 7 to 9, owing to weaker photochemical reactions, lower O₃
534 concentrations than that in Shanghai are found in the boundary layer. However, the O₃
535 concentration can exceed the national standard from August 10 to 12 (Fig. 2), which should be
536 influenced by the typhoon system. The influence process is similar to the above discussion for
537 Shanghai, that is, the upper downward airflows (over 1 km above the surface) are enhanced
538 significantly since August 10. But for Nanjing, the O₃ concentration does not exceed the national
539 O₃ standard during August 7-12 (Fig.2 and 8), which should be attributed to the fact that Nanjing
540 is far away from the coastal areas and thereby hardly affected by the downward flow in the
541 typhoon periphery. Though the O₃ concentration in Nanjing increases on August 12, it should
542 mainly be caused by the local photochemical reactions because the vertical movement below 2 km
543 above Nanjing is dominated by upward airflows.

544

546

547 **Fig. 8. Temporal variations of the vertical wind velocity and the vertical distribution of O₃ concentrations**
 548 **above (a) Shanghai, (b) Hangzhou and (c) Nanjing during August 7 to 12 2013. The dotted lines show the**
 549 **negative wind speeds and represent the downward airflows, while the solid lines show the positive wind**
 550 **speeds and zero vertical velocity. The interval is 0.005 m/s.**
 551

552 It is also should be mentioned that the near-surface vertical velocities around these cities are
 553 much lower than those at higher altitudes (Fig.8). Especially in the planetary boundary layer (< 1
 554 km), lots of zero-velocity lines appear near the ground. This phenomenon may be related with the
 555 upward airflow caused by Urban Heat Islands. Thus, the maximum centers of O₃ occur near the
 556 surface below 500 m, and the vertical diffusion process plays a more important role in the

557 accumulation of surface O₃. The essential role of the vertical diffusion process in the O₃ episode is
558 similar to that reported by Zhu et al. (2015).

559

560 **4.3 Process analysis for ozone formation**

561 **4.3.1 Typical cities in the YRD region**

562 Fig. 9 shows the daytime contributions of different atmospheric processes to the formation of
563 O₃ in Shanghai (SH), Nanjing (NJ), and Hangzhou (HZ) at the first modeling layer from August 4
564 to 15 2013. As shown in the figure, for all cities during this period, the major contributors to high
565 O₃ concentrations include the vertical diffusion (VDIF), the dry deposition (DDEP), the gas-phase
566 chemistry (CHEM), and the total advection (TADV). TADV is the sum of the horizontal advection
567 (HADV) and the vertical advection (ZADV). In this study, HADV and ZADV are considered
568 together as TADV because they are inevitably linked as the inseparable parts of air circulation. As
569 discussed in Sect. 3.2, the strong sinking air causes slow wind on the ground and little clouds in
570 the sky, so the contributions of horizontal diffusion (HDIF) and cloud processes (CLDS) are quite
571 small during this episode.

572 In the first layer of the urban areas of Shanghai (Fig. 9a), the averaged contributions from the
573 vertical diffusion (VDIF), the gas-phase chemistry (CHEM), the advection process (TADV), and
574 the dry deposition (DDEP) during the daytime of August 4-15 are 9.95, 10.10, -11.74 and -7.28
575 ppb/h, respectively. Obviously, VDIF and CHEM exhibit significant positive contributions to O₃
576 during most days, while TADV and DDEP mainly show the consumption contributions. The
577 sinking air caused by the weather system discussed in Sect. 3.2 can trap heat and air pollutants on
578 the ground, and make VDIF be the most import source of surface O₃. Meanwhile, the hotter and
579 dryer weather with more sunshine, above 40 °C and comparatively low relative humidity (shown
580 in Fig. 4), which is related with the sinking air, can enhance the photochemical reactions. So,
581 CHEM can form more O₃ on the ground. Compared with the time series of CHEM and DDEP in
582 which there are no obvious fluctuations, the values of VDIF and TADV significantly change with
583 the time, with the daytime mean contributions varying from 3.99 to 28.45 ppb/h for VDIF and
584 from -2.56 to -28.13 ppb/h for TADV. These time variations should be related with the changes of
585 vertical air movement. For example, the value of VDIF on August 8 is only 3.99 ppb/h, which can
586 be attributed to the local transient upward airflow over Shanghai (shown in Fig. 8a). On August 10,

587 however, VDIF can contribute 28.45 ppb O₃ per hour, which may be related with the enhanced
588 downward air movement caused by the peripheral circulation of Typhoon Utor. Moreover, during
589 the high-level O₃ episode from August 7-12, the mean values for VDIF, CHEM, TADV and DDEP
590 are 13.41, 11.21, -8.37 and -14.74 ppb/h. But after August 12, the mean contributions of VDIF,
591 CHEM, TADV and DDEP decrease to 5.35, 9.53, -5.52 and -10.85 ppb/h. These reductions should
592 be related with the process that the subtropical high moves eastward and northward forced by
593 Typhoon Utor (Fig. 5d). By quantifying the relative importance of each process to O₃ formation,
594 the IPR analysis provides a fundamental explanation for the synthetical influence of the high
595 pressure and the typhoon system, which has been discussed in Sect. 3.2 and 4.1, and further
596 illustrates the exact mechanism.

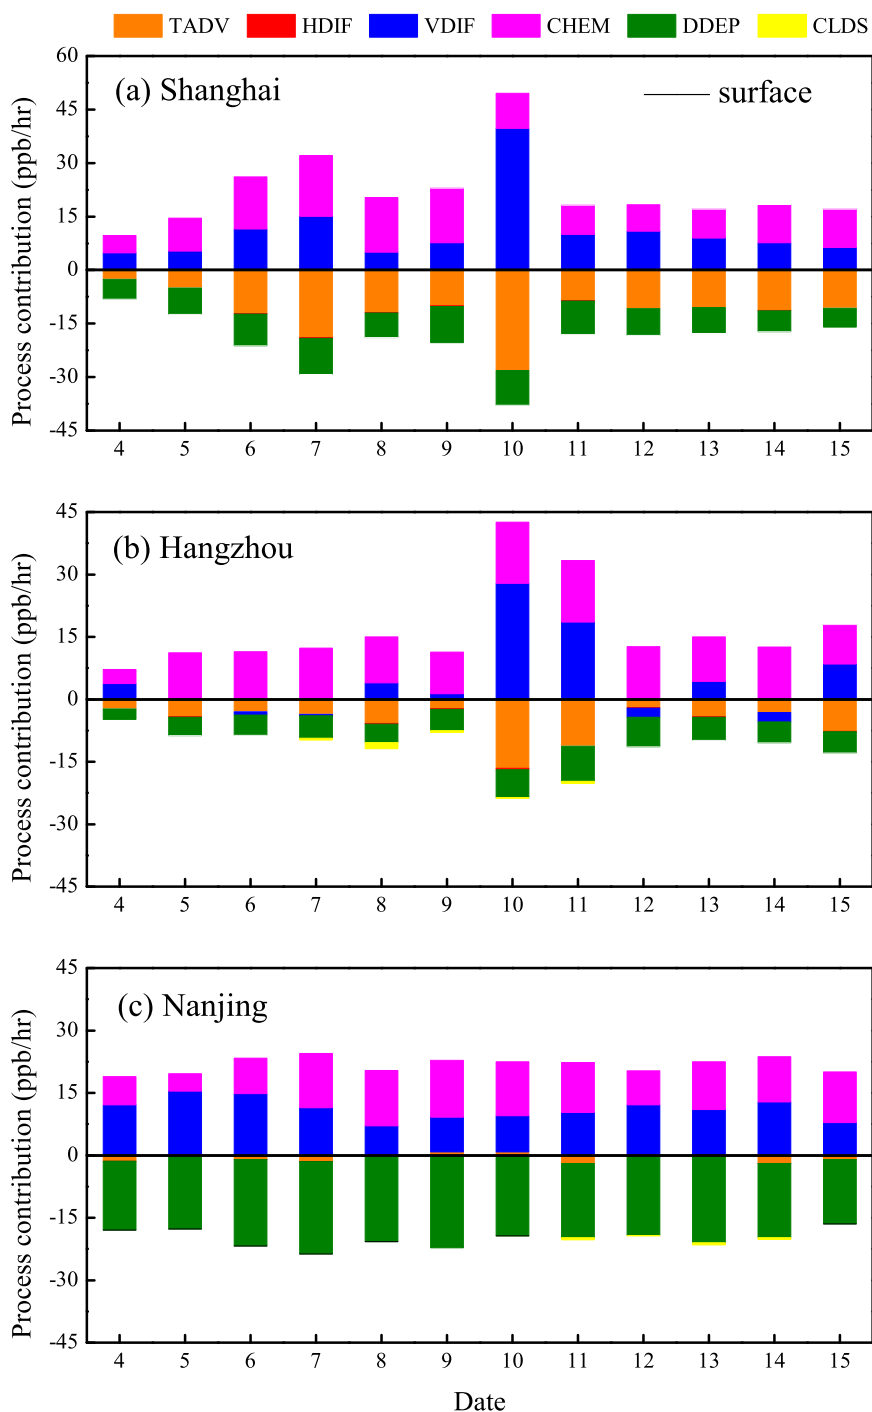

597 Fig. 9b presents the result of IPR analysis for Hangzhou. During August 4-15, VDIF and
598 CHEM are the major source of surface O₃ with the average contribution of 5.36 ppb/h for VDIF
599 and 10.97 ppb/h for CHEM, while TADV and DDEP are two important sinks for O₃ with the
600 average contribution of -9.63 ppb/h for TADV and -5.14 ppb/h for DDEP. Synthetically impacted
601 by Western Pacific subtropical high and Typhoon Utor, the mean contributions during the O₃
602 episode (from August 7 to August 12) for VDIF, CHEM, TADV and DDEP increase to 7.21, 12.61,
603 -11.51 and -5.92 ppb/h, respectively. The highest VDIF contribution occurs on August 10-11, and
604 the over-standard of O₃ concentration appears on August 10-12 as well, which may be attributed to
605 the effect of typhoon's peripheral circulation, implying Typhoon Utor also plays an essential role
606 in the formation of O₃ pollution in Hangzhou. After Typhoon Utor approaches close enough to
607 Hangzhou, the wind direction is mainly dominated by the southeast wind (Fig. 4b), and the mean
608 values of VDIF, CHEM, TADV and DDEP finally decrease to 4.84, 10.08, -8.92 and -4.78 ppb/h,
609 respectively. In a word, Hangzhou is located close to Shanghai, so the temporal variations of VDIF,
610 CHEM, TADV and DDEP in Hangzhou are similar to those in Shanghai.

611 However, the similar variation pattern of VDIF, CHEM, TADV and DDEP occurring in
612 Shanghai and Hangzhou does not appear in Nanjing. As shown in Fig. 9c, the mean contributions
613 of VDIF, CHEM, TADV and DDEP to surface O₃ in Nanjing are 11.31, 9.55 -1.34 and -17.57
614 ppb/h during the whole period, while the values during 7-12 August are 10.32, 10.70, -0.99 and
615 -18.42 ppb/h. There are no apparent fluctuations or sudden increases of these contributors during
616 the period from August 4 to 15, so are the O₃ concentration (Fig. 2), temperature and relative

617 humidity (Fig. 4a), implying Nanjing is generally under the control of the Western Pacific
618 subtropical high and can hardly be affected by the typhoon system. As a typical city in the
619 northwest inland area of the YRD region (NIR), Nanjing is located far away from the sea, which
620 means it may not be easily affected by the peripheral circulation of the typhoon system.

621 Additionally, at the altitude of 500 m and 1500 m above Shanghai, Nanjing, and Hangzhou
622 (not shown), CHEM is also the major contributor to O₃ formation, with the values a litter lower
623 than those at the surface, suggesting that there are strong photochemical reactions in the whole
624 boundary layer of these YRD cities. In contrast, VDIF has an opposite effect in the middle of the
625 boundary layer, with the negative contributions for O₃ of -3.26 ppb/h in Shanghai, -2.37 ppb/h in
626 Hangzhou, and -3.21 ppb/h in Nanjing, respectively (not shown). The loss of O₃ at higher
627 atmospheric level caused by VDIF further proves the essential role of the downward vertical
628 movement in this O₃ episode.

 635 **chemistry (CLDS).**

636

637 4.3.2 Spatial distribution of the contributors for the O₃ episode over the YRD region

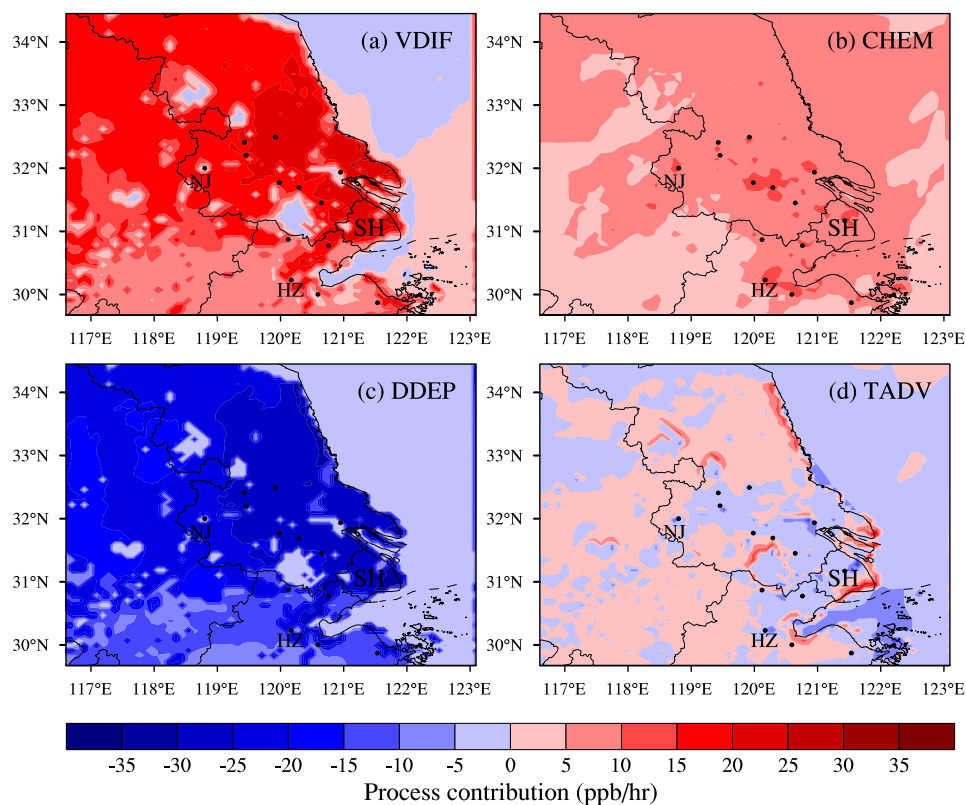

638 Fig. 10 demonstrates the spatial distribution of the mean contributions of main processes

639 (VDIF, CHEM, DDEP and TADV) to the ozone formation at the lowest modeling layer in domain
640 3 during this high-level O₃ episode. The modeling results from 7 to 12 August are averaged to
641 provide the mean values.

642 Similar to the results shown in Fig. 9, Fig. 10 illustrates that the vertical diffusion (VDIF) and
643 the gas-phase chemistry (CHEM) exhibit significant positive contributions to O₃ over the YRD
644 region and the surrounding areas during the high-level O₃ episode. The contributions of VDIF in
645 domain 3 (Fig. 10a) range from 5 to 25 ppb/h, with the high values (> 20 ppb/h) occurring in the
646 southeast coastal areas. For CHEM (Fig. 10b), the contributions vary within the range of 0-15
647 ppb/h, with the high values over 10 ppb/h appearing in and around the big cities. As discussed
648 above, these regional positive contributions of VDIF and CHEM over domain 3 should be related
649 to the facts that the whole region is under the control of the Western Pacific subtropical high. With
650 respect to the higher contributions of CHEM in the urban areas, they should be attributed to the
651 spatial distribution of the emissions of O₃ precursors, which is also higher in the cities.
652 Furthermore, higher air temperature in the cities related with the urban heat island may enhance
653 the chemical reactions and form more O₃ in these areas as well.

654 For DDEP, it is the main critical factor of the consumption of O₃, with the negative
655 contributions varying from 0 to -25 ppb/h over the modeling domain 3 (Fig. 10c). Small values
656 usually occur on the water, which may be related with less air pollution over rivers, lakes and
657 oceans. High values can be found on land, especially in the southeast coastal areas. For the
658 contributions of TADV, the values in domain 3 range from -10 to 10 ppb/h, with the positive
659 contributions generally occurring on land while the negative ones appearing on the water (Fig.
660 10d). The maximum positive contributions of TADV are usually found along the boundary
661 between the land and the water, which should be explained by the facts that the land-sea breeze
662 circulations can play an important role in the redistribution of the formed O₃. On account of the
663 high-pressure system and so-caused sinking airflows in the YRD region, the background wind is
664 relatively weak in comparison to the local atmospheric circulation, thus the sea breeze can easily
665 bring more generated O₃ to the seashore.

666

667

668 **Fig. 9. The contributions of main processes to O₃ formation over the YRD region, including (a) vertical**
 669 **diffusion (VDIF), (b) gas chemistry (CHEM), (c) dry deposition (DDEP), and (d) total advection (TADV).**
 670 **The values are averaged from August 7 to 12 2013.**

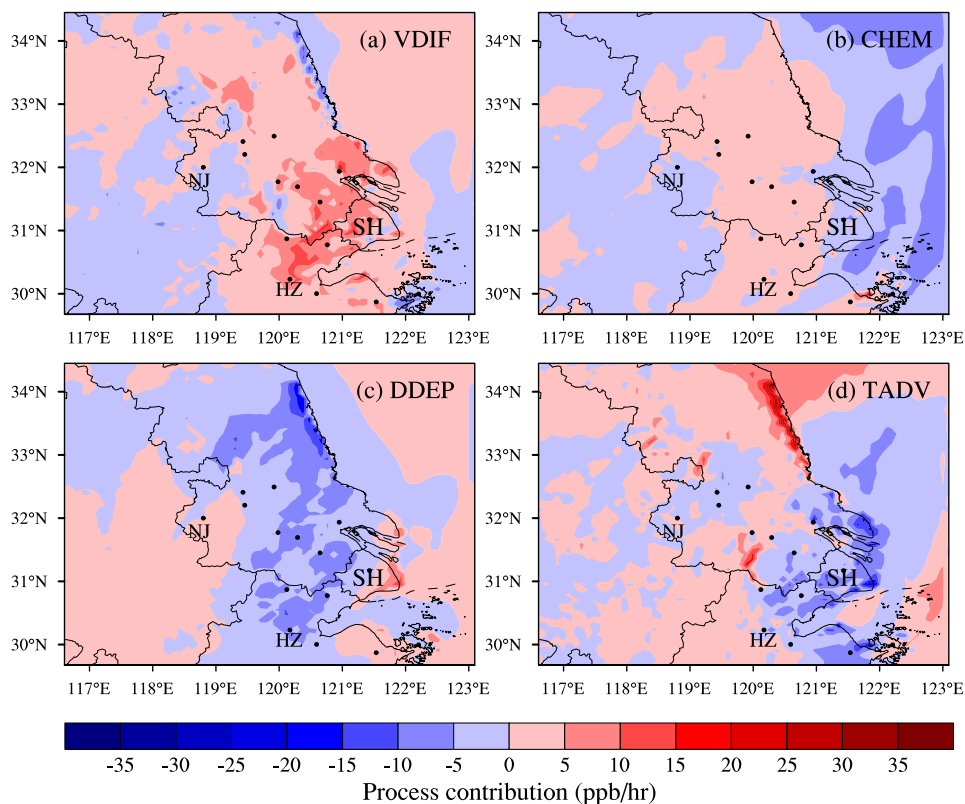

671

672

673 From the discussion in Section 3 and 4.2, it can be deduced that typhoon Utor plays an
 674 important role in the formation of ozone over the YRD region during August 10-12. To clearly
 675 clarify the effect of the typhoon system in this O₃ pollution episode, we firstly average the
 676 modeling results of VDIF, CHEM, DDEP and TADV during August 10-12 to show their
 677 contributions to O₃ formation when the typhoon system plays an important role. Secondly, the
 678 modeling results of these processes from August 7 to 9 are also averaged to provide their
 679 contributions when only the subtropical high dominates the episode. Finally, the differences of the
 680 contributions of VDIF, CHEM, DDEP and TADV between the period of August 7-9 and August
 681 10-12 are calculated to reveal the role of the typhoon system in this severe high O₃ episode (Fig.
 682 11). As shown in Fig. 11a, when YRD is affected by the peripheral circulation of Typhoon Utor,
 683 the contributions of VDIF over the YRD region increase by 0-15 ppb/h, with the higher increment
 684 values (> 30 ppb/h) occurring in the southeast coastal region (SCR) and center inland region (CIR),

685 implying that SCR and CIR can be largely affected by the peripheral subsidence airflows of the
 686 typhoon system. As to the contributions of CHEM, the increases caused by the typhoon system are
 687 0-5 ppb/h over the YRD region, and the higher increment also appears in the coastal areas (Fig.
 688 11b). For DDEP, influenced by typhoon Utor, its negative contributions decrease up to -20 ppb/h,
 689 with the largest reduction along the coastline (Fig. 11c). For TADV, with the approaching of
 690 typhoon Utor, the contributions of TADV particularly decrease by 0-20 ppb/h, especially in the
 691 southeast coastal region (Fig. 11d).

692 In all, during this high-level O₃ pollution episode, more active photochemical reactions and
 693 the vertical diffusion play a significant role in the accumulation of surface O₃ over the YRD region.
 694 The major driving factor should be the Western Pacific subtropical high. Moreover, the changes in
 695 the contributions of VDIF, CHEM, DDEP, and TADV between August 7-9 and August 10-12
 696 exhibit a similar spatial pattern with the high values mostly concentrating in the southeast coastal
 697 areas (Fig. 12), implying the Typhoon Utor also plays a collaborative effect.
 698

699
 700 **Fig. 11. The difference of daytime mean contributions of main processes to O₃ formation over the YRD**
 701 **region between the period of August 10-12 and August 7-9, including (a) vertical diffusion (VDIF), (b) gas**
 702 **chemistry (CHEM), (c) dry deposition (DDEP), and (d) total advection (TADV) .**

703

704 **5. Conclusions**

705 In this study, the characteristics and the essential impact factors of a typical regional
706 continuous O₃ pollution over the YRD region is investigated by means of observational analysis
707 and numerical simulation. The episode lasted for nearly a week from August 7 to 12 2013, with
708 the O₃ concentration exceeding the national air quality standard in more than half of the cities over
709 the YRD region. The analysis of weather systems and the modeling results from WRF/CMAQ all
710 illustrate that the continuous strong Western Pacific subtropical high is the leading factor of the
711 abnormally high temperature weather and the heavy O₃ pollution, by inducing more sinking air to
712 trap heat as well as air pollutants at the surface. Meanwhile, the development of this episode is
713 closely related to the movement of Typhoon Utor as well. The temporal variations of the vertical
714 wind velocity and O₃ concentrations show that when the YRD region is at the front of moving
715 typhoon system, the downward airflow is enhanced in the boundary layer with fine weather, and
716 thereby the air pollutants are trapped and accumulated near the surface. Moreover, in the last stage
717 of the O₃ episode, the activity of Typhoon Utor weakens the strength of the subtropical high and
718 forces it to retreat easterly and move northward, and the prevailing southeasterly surface wind
719 related with the approaching of Typhoon Utor contributes to the mitigation of the O₃ pollution.

720 The Integrated Process Rate (IPR) analysis implemented in CMAQ is specially carried out to
721 quantify the relative contributions of individual processes and give a fundamental explanation.
722 During the high-level O₃ episode from August 7-12, the vertical diffusion (VDIF) and the
723 gas-phase chemistry (CHEM) exhibit significant positive contributions to surface O₃ over the
724 YRD region, with the high values over 20 ppb/h for VDIF and over 10 ppb/h for CHEM. The dry
725 deposition (DDEP) is the major sink of surface O₃, while the total advection (TADV) can give the
726 positive contribution on land and the negative contribution on the water. Moreover, on August
727 10-12, the YRD region is apparently affected by the periphery circulation of Typhoon Utor, with
728 the contributions of VDIF over the YRD region increasing by 0-15 ppb/h, the contributions of
729 CHEM increasing by 0-5 ppb/h, and the contributions of DDEP and TADV decreasing. Especially
730 in the coastal cities, such as Shanghai and Hangzhou, the effects of the typhoon system are more
731 obvious. In contrast, the cities in the northwest inland area of the YRD region, which are far away
732 from the sea, can hardly be affected by the typhoon system. In the end, when the typhoon system

733 significantly weakens the high pressure system, the contributions of VDIF, CHEM, TADV, and
734 DDEP decrease to a low level in all cities.

735 WRF/CMAQ model system shows a relatively good performance in simulation of the O₃
736 episode, with the simulated meteorological conditions and air pollutant concentrations basically in
737 agreement with the observations in most YRD cities. Our results in this study can provide an
738 insight for the formation mechanism of regional O₃ pollution in East Asia, and help to forecast the
739 O₃ pollution synthetically impacted by the Western Pacific subtropical high and the tropical
740 cyclone system.
