Abstract

The Surface PARTiculate mAtter Network (SPARTAN) is a long-term project that includes characterization of chemical and physical attributes of aerosols from filter samples collected worldwide. This manuscript discusses the ongoing efforts of SPARTAN to define and quantify major ions and trace metals found in fine particulate matter (PM_{2.5}). Our methods infer the spatial and temporal variability of PM_{2.5} in a cost-effective manner. Gravimetrically-weighed filters represent multi-day averages of PM_{2.5}, with a collocated nephelometer sampling air continuously. SPARTAN instruments are paired with AERosol RObotic NETwork (AERONET) sun photometers to better understand the relationship between ground-level PM_{2.5} and columnar aerosol optical depth (AOD).

We have examined the chemical composition of PM_{2.5} at 12 globally dispersed, densely populated urban locations and a site at Mammoth Cave (US) National Park used as a background comparison. Each SPARTAN location has so far been active between the years 2013 and 2016 over 2 to 26 month periods, with an average period of 12 months per site. These sites have collectively gathered over 10 site-years of quality aerosol data. The major PM_{2.5} constituents across all sites (relative contribution \pm SD) are ammoniated sulfate (20% \pm 11%), crustal material (13.4% \pm 9.9%), black carbon (11.9% \pm 8.4%), ammonium nitrate (4.7% \pm 3.0%), sea salt (2.3% \pm 1.6%), trace element oxides (1.0% \pm 1.1%), water (7.2% \pm 3.3%) at 35% RH, and residual matter (40% \pm 24%).

Analysis of filter samples reveals that several PM_{2.5} chemical components varied by more than an order of magnitude between sites. Ammoniated sulfate ranges from 1.1 $\mu\text{g m}^{-3}$ (Buenos Aires, Argentina) to 17 $\mu\text{g m}^{-3}$ (Kanpur, India [dry season]). Ammonium nitrate ranged from 0.2 $\mu\text{g m}^{-3}$ (Mammoth Cave, in summer) to 6.8 $\mu\text{g m}^{-3}$ (Kanpur, dry season). Equivalent black carbon ranged from 0.7 $\mu\text{g m}^{-3}$ (Mammoth Cave) to over 8 $\mu\text{g m}^{-3}$ (Dhaka, Bangladesh and Kanpur, India). Comparison of SPARTAN versus coincident measurements from the Interagency Monitoring of Protected Visual Environments (IMPROVE) network at Mammoth Cave yielded a high degree of consistency for daily PM_{2.5} ($r^2 = 0.76$, slope = 1.12), daily sulfate ($r^2 = 0.86$, slope = 1.03) and mean fractions of all major PM_{2.5} components (within 6%). Major ions generally agree well with previous studies at the same urban locations (e.g. sulfate fractions agree within 4% for eight out of 11 collocation comparisons). Enhanced anthropogenic dust fractions in large urban areas (e.g. Singapore, Kanpur, Hanoi and Dhaka) are apparent from high Zn:Al ratios.

The expected water contribution to aerosols is calculated via the hygroscopicity parameter κ_v for each filter. Mean aggregate values ranged from 0.15 (Ilorin) to 0.28 (Rehovot). The all-site parameter mean is 0.20 ± 0.04 . Chemical composition and water retention in each filter measurement allows inference of hourly PM_{2.5} at 35% relative humidity by merging with nephelometer measurements. These hourly PM_{2.5} estimates compare favorably with a beta attenuation monitor (MetOne) at the nearby US embassy in Beijing, with a coefficient of variation $r^2 = 0.67$ ($n = 3167$), compared to $r^2 = 0.62$ when κ_v was not considered. SPARTAN continues to provide an open-access database of PM_{2.5} compositional filter information and hourly mass collected from a global federation of instruments.

60 1. Introduction

61

62 Fine particulate matter with a median aerodynamic diameter less than, or equal to, 2.5 μm
63 ($\text{PM}_{2.5}$), is a robust indicator of premature mortality (Chen et al., 2008; Laden et al., 2006).

64 Research on long-term exposure to ambient $\text{PM}_{2.5}$ has documented serious adverse health effects,
65 including increased mortality from chronic cardiovascular disease, respiratory disease, and lung
66 cancer (WHO, 2005). Outdoor fine particulate matter ($\text{PM}_{2.5}$) is recognized as a significant air
67 pollutant, with an Air Quality Guideline set by the WHO at 10 $\mu\text{g m}^{-3}$ annual average (WHO,
68 2006). Many regions of the world far exceed these long-term recommendations (Brauer et al.,
69 2015; van Donkelaar et al., 2015), and the impact on health is substantial. The 2013 Global
70 Burden of Disease estimated that outdoor $\text{PM}_{2.5}$ caused 2.9 million deaths (3 % of all deaths) and
71 70 million years of lost healthy life on a global scale (Forouzanfar et al., 2015). Atmospheric
72 aerosol is also the most uncertain agent contributing to radiative forcing of climate change
73 (IPCC, 2013). Aerosol mass and composition also play a critical role in atmospheric visibility
74 (Malm et al. 1994). Additional observations are needed to improve the concentration estimates
75 for $\text{PM}_{2.5}$ as a global risk factor, and to better understand the chemical components and sources
76 contributing to its formation.

77

78 The chemical composition of $\text{PM}_{2.5}$ offers valuable information to identify the
79 contributions of specific sources, and to understand aerosol properties and processes that could
80 affect health, climate and atmospheric conditions. Spatial mapping of aerosol type and
81 composition using satellite observations and chemical transport modelling can help elucidate the
82 global exposure burden of fine particulate matter composition (Kahn and Gaitley, 2015;
83 Lelieveld et al., 2015; Patadia et al., 2013; Philip et al., 2014a), however ground-level sampling
84 remains necessary to evaluate these estimates and provide quantitative detail. Furthermore, the
85 long-term health impacts of specific chemical components are not well understood (e.g. Lepeule
86 et al., 2012). The health-related impacts of specific PM composition have been reviewed
87 previously (Lippmann, 2014). Although $\text{PM}_{2.5}$ composition can be implicated in the variance
88 observed in cardiovascular health effects, there is insufficient long-term $\text{PM}_{2.5}$ characterization
89 for adequate health impact assessments of specific aerosol mixtures (e.g. Bell et al., 2007). More
90 generally, urban $\text{PM}_{2.5}$ speciation is not yet consistently characterized on a global scale.
91 Continental sampling has been conducted in North America (Hand et al., 2012) and Europe
92 (Putaud et al., 2004, 2010), however there remains a need for a global network that consistently
93 measures $\text{PM}_{2.5}$ chemical composition in densely populated regions.

94

95 No global $\text{PM}_{2.5}$ protocol exists for relative humidity (RH) filter equilibration. The U.S.
96 EPA measurements are between 30-40% RH, European measurements are below 50% RH, and
97 different protocols exist elsewhere. Ambient humidity affects the relationship of dry $\text{PM}_{2.5}$ with
98 satellite observations of aerosol optical depth. Aerosol water also influences the relationship
99 between dry $\text{PM}_{2.5}$ and aerosol scatter. A large body of literature has examined the relationship
100 of aerosol composition with hygroscopicity (e.g. IMPROVE (Hand et al., 2012; IMPROVE,
101 2015), Chemical Species Network (CSN) (Chu, 2004; USEPA, 2015), ISORROPIA (Fountoukis
102 and Nenes, 2007), and Aerosol Inorganic Model (AIM) (Wexler and Clegg, 2002)). More
103 recently Petters and Kreidenweis (2007, 2008, 2013) have developed κ -Kohler theory, which
104 assigns individual hygroscopicity parameters κ to all major components, from insoluble crustal
105 materials to sea-salt. Mixed values can then be weighted by local aerosol composition.

106
107 Ground-based observations of $PM_{2.5}$ have insufficient coverage at the global scale to
108 provide assessment of long-term human exposure. Satellite remote sensing offers a promising
109 means of providing an extended temporal record to estimate population exposure to $PM_{2.5}$ on a
110 global scale, and especially for areas with limited ground-level $PM_{2.5}$ measurements (Brauer et
111 al., 2015; van Donkelaar et al., 2015). Even in areas where monitor density is high, satellite-
112 based estimates provide additional useful information on spatial and temporal patterns in air
113 pollution (Kloog et al., 2011, 2013; Lee et al., 2012). However, there are outstanding questions
114 about the accuracy and precision with which ground-level aerosol mass concentrations can be
115 inferred from satellite remote sensing. Standardized $PM_{2.5}$ measurements, collocated with
116 ground-based measurements of aerosol optical depth, are needed to evaluate and improve $PM_{2.5}$
117 estimates from satellite remote sensing. To meet these sampling needs, the ground-based
118 network SPARTAN (Surface PARTiculate mAtter Network) is designed to evaluate and enhance
119 satellite-based estimates of $PM_{2.5}$ by measuring fine particle aerosol concentrations and
120 composition continuously over multi-year periods at sites where aerosol optical depth is also
121 measured (Holben et al., 1998; Snider et al., 2015). The network includes air filter sampling and
122 nephelometers that together provide long-term and hourly $PM_{2.5}$ estimates at low RH (35%).
123

124 We discuss the ongoing efforts of the SPARTAN project to quantify major ions and trace
125 metals found in aerosols worldwide. Section 2 describes the methodology used to infer $PM_{2.5}$
126 composition. Section 3 defines categories of aerosol types (crustal and residual material, black
127 carbon, ammonium nitrate, ammoniated sulfate, sea salt, and trace metal oxides) as a function of
128 specific chemical species. Section 4 describes the implementation of sub-saturated κ -Kohler
129 theory to estimate aerosol water content based on aerosol compositional information. Section 5
130 compares relative aerosol composition with that reported in available literature, and assesses the
131 general consistency of our findings across all sites. Section 6 evaluates hourly $PM_{2.5}$ estimates
132 (35% RH) at Beijing with a beta attenuation monitor at the US Embassy.
133

134 2. Overview of Methodology

135

136 SPARTAN has been collecting $PM_{2.5}$ on PTFE filters for at least two months, across 13
137 SPARTAN sites, between 2013 and 2016, with an average period of 12 months per site. Snider
138 et al. (2015) provide an overview of the SPARTAN PM observation network, the cost-effective
139 sampling methods employed and post sampling instrumental methods of analysis. Each site
140 utilizes a combination of continuous monitoring by nephelometry and mass concentration via
141 filter-based sampling. Nephelometer scatter is averaged to hourly intervals at three wavelengths
142 (457nm, 520nm, 634nm), and converted to 550 nm via a fitted Angstrom exponent. Total scatter
143 is proportional to $PM_{2.5}$ mass and volume (Chow et al., 2006). Hence we provide dry (35% RH)
144 hourly $PM_{2.5}$ estimates by combining scatter at 550 nm at ambient RH with filter mass and
145 chemical composition information used to determine water content as described below.
146

147 Briefly, filter-based measurements are collected with an AirPhoton SS4i automated air
148 sampler. Each sampler houses a removable filter cartridge that protects seven sequentially active
149 25 mm diameter filters plus a field blank. Air samples first pass through a bug screen and then a
150 greased impactor plate to remove particles larger than 10 μm in diameter. Aerosols are collected
151 in sequence on a preweighed Nuclepore filter membrane (8 μm , SPI) that removes coarse-mode

152 aerosols with diameters from 2.5 - 10 μm in diameter (PM_{10}), while fine aerosols ($\text{PM}_{2.5}$) are then
153 collected on pre-weighed PTFE filters (2 μm , SKC). For each filter, sampling is timed at regular,
154 staggered 24-hour intervals throughout a 9-day period. Sampling ends for each filter at 09:00
155 when temperatures are low, to reduce loss of semi-volatile components. As described by Snider
156 et al (2015), loss rates of ammonium nitrate during passive air flow were an order of magnitude
157 less than during active air flow. Thus the sampling protocol is designed to actively sample for
158 one diurnal cycle and to avoid daytime sampling after collecting nighttime PM. Following the
159 IMPROVE protocol (Hand and Malm, 2006), filters are transported at room temperature in
160 sealed containers between measurement sites and the central SPARTAN laboratory at Dalhousie
161 University, where analysis is conducted.

162
163 Site locations are designed to sample under a variety of conditions, including biomass
164 burning, (e.g. West Africa and South America), biofuel emissions (e.g. South Asia), monsoonal
165 conditions (e.g. West Africa and Southeast Asia), suspended mineral dust (e.g. West Africa and
166 the Middle East) and urban crustal material. Each SPARTAN site provides a representative
167 example of local and regional conditions in highly populated areas. Site selection prioritizes
168 under-represented globally-dispersed, population-dense regions; no SPARTAN sites yet exist in
169 Europe. The sites of Atlanta and Mammoth Cave are included for instrument inter-comparison
170 purposes with other networks.

171 2.1. Filter weighing

172 Filters (PTFE, capillary) are both pre and post-weighed in triplicate using a Sartorius Ultramicro
173 balance with 0.1 μg precision. Gravimetric weighing is performed in a cleanroom facility at $35 \pm$
174 5% RH and $20\text{-}23^\circ\text{C}$. A total of 497 quality-controlled filters have been weighed across all
175 SPARTAN sites. The median collected material on sampled filters, as well as the lower and
176 upper quintiles (in parentheses), are 72 (42, 131) μg for Teflon and 90 (44, 154) μg for
177 Nuclepore. The combined uncertainty ($\pm 2\sigma$) of quality-assured single filter PM mass
178 measurements is $\pm 4.0 \mu\text{g}$. These filters are subsequently analyzed for water-soluble ions, trace
179 metals, and surface reflectance to obtain black carbon.

180 2.2. Equivalent Black Carbon (EBC)

181 We define the equivalent black carbon (EBC) as the black carbon content of PTFE filters derived
182 via surface reflectance R using the Diffusion Systems Smoke Stain Reflectometer EEL 43M
183 (Quincey et al., 2009) as further discussed in Sect. 4.6. We use the term equivalent black carbon
184 following the recommendation of Petzold et al. (2013) for data derived from optical absorption
185 methods.

186 2.3. Trace metals

187 To maximize the information extracted from the filters, each one is cut in half with a ceramic
188 blade following approaches similar to Zhang et al. (2013) and Gibson et al. (2009). One filter
189 half is analyzed for relevant trace metals, i.e. crustal components Zn, Mg, Fe, and Al. We digest
190 this half by adding it to 3.0 mL of 7% trace metal grade nitric acid, similar to Fang et al. (2015).
191 The acid/filter combination is boiled at 97°C for 2 hours, and the liquid extract is submitted for
192 quantitative analysis via inductively coupled plasma mass spectrometry (ICP-MS, Thermo
193 Scientific X-Series 2).

194 2.4. Water soluble ions

195 Water-soluble ions NO_3^- , SO_4^{2-} , NH_4^+ , K^+ , Na^+ are detected using the second filter half. The filter
196 is spiked with 120 μL of isopropyl alcohol and immersed in 2.9 mL of 18 M Ω Milli-Q water.
197 Filters and liquid extracts are sonicated together for 25 min before being passed through a 0.45
198 μm membrane filter to remove larger matrix components. Extractions are analyzed by ion
199 chromatography (IC) via a Thermo Dionex ICS-1100 instrument (anions) and a Thermo Dionex
200 ICS-1000 (cations) instrument (Gibson et al., 2013a, 2013b).

201

202 3. $\text{PM}_{2.5}$ aerosol composition

203

204 Section 2 defined the methodology of basic physical and chemical properties obtained in
205 SPARTAN filters. Section 3 describes the chemical definitions used to infer each chemical
206 component as discussed in turn below. Table 1 contains a summary of equations and
207 accompanying references used to quantify SPARTAN $\text{PM}_{2.5}$ chemical composition.

208 3.1. Sea Salt (SS)

209 We take 10% of $[\text{Al}]$ to be associated with Na and remove this crustal sodium component
210 (Remoundaki et al., 2013). Sea salt is then represented as $2.54[\text{Na}^+]_{\text{ss}}$ to account for the
211 associated $[\text{Cl}^-]$ (Malm et al., 1994).

212 3.2. Ammonium nitrate (ANO_3)

213 We treat all nitrate as neutralized by ammonium as NH_4NO_3 . The corresponding mass of ANO_3
214 is a 1:1 molar ratio of $\text{NH}_4:\text{NO}_3$, or $1.29[\text{NO}_3^-]$ based on molecular weight.

215 3.3. Sodium sulfate (Na_2SO_4)

216 Sodium sulfate is treated as a fraction of measured sodium, $0.18[\text{Na}^+]_{\text{ss}}$ (Henning et al., 2003);
217 however, it contributes negligibly to total aerosol mass ($< 0.1\%$) at all sites.

218 3.4. Ammoniated sulfate (ASO_4)

219 Ammonium not associated with nitrate, and sulfate not associated with sodium, are assumed to
220 mutually associate as a mixture of NH_4HSO_4 and $(\text{NH}_4)_2\text{SO}_4$.

221 3.5. Crustal material (CM)

222 Crustal material consists of re-suspended road dust, desert dust, soil, and sand. Following the
223 elemental composition of natural desert dusts by Wang (2015), we generalize that natural CM is
224 approximately $10 \times [\text{Al} + \text{Fe} + \text{Mg}]$. Aluminum, iron, and magnesium are chosen due to their
225 collectively consistent composition in natural mineral dust and frequency above detection limit
226 ($> 95\%$). Silicon is not available. Titanium was found not to contribute significantly ($< 1\%$) to
227 CM mass.

228 3.6. Equivalent Black Carbon (EBC)

229 The amount of EBC carbon (μg) is logarithmically related to concentration, as determined by
230 relative surface reflectance R/R_0 . For a given exposed filter area, absorption cross-section and
231 light path, reflectance is related to concentration via

$$[\text{EBC}] = \frac{-A}{qv} \ln\left(\frac{R}{R_0}\right) \quad \text{Eq. 1}$$

232 where v is volume of air (0.9 to 5.8 m³), A is the filter surface area (3.1 cm²), and q is the product
 233 of the effective reflectivity path p and mass-specific absorption cross section σ_{SSR} (cm²/μg). The
 234 absorption coefficient σ_{SSR} used here is 0.06 cm²/μg based on prior literature (Barnard et al.,
 235 2008; Bond and Bergstrom, 2006), adjusted to the 620 nm detection peak of the SSR. The
 236 effective light path p here is taken to be 1.5 for our thick PTFE filters (e.g. Taha et al., 2007). We
 237 treat water uptake by EBC as negligible.

238 3.7. Trace elemental oxides (TEO)

239 Trace elemental oxides are the summation of oxides for all measured ICP trace elements, and
 240 make up a negligible portion of total mass (< 1%). We include these concentrations for
 241 completeness. Water uptake by TEO is treated as negligible.

242 3.8. Particle-bound water (PBW) associated with inorganics

243 We estimate the water-mass uptake for the inorganic chemical components of sea salt (SS),
 244 ammonium nitrate (ANO₃) and ammoniated sulfate (ASO₄). The mass of particle-bound water
 245 (PBW) associated with chemical component X is

$$PBW_X = [X] \kappa_{m,x} \frac{\text{RH}}{100 - \text{RH}} \quad \text{Eq. 2}$$

246 The total mass of inorganic (IN) PBW is then $PBW_{\text{IN}} = \sum_X PBW_X$.

247 3.9. Residual matter (RM)

248 Residual matter, which is treated as mainly organics, is estimated by subtracting dry inorganic
 249 mass (IN) and its associated water (referenced to our weighing conditions of 35 ± 5 % RH) from
 250 total PM_{2.5} mass:

$$\text{RM}_{35\%} = \text{PM}_{2.5,35\%} - [\text{IN}] - [\text{PBW}_{\text{IN}}] \quad \text{Eq. 3}$$

251 Negative RM_{35%} values are retained if reconstructed inorganic mass at 35% RH exceeds total
 252 PM_{2.5} by less than 10%, otherwise values are flagged and excluded from the mass average.
 253 Negative values occur, on average, 2% of the time. Water-free RM (0% RH) is estimated by
 254 subtracting organic-associated PBW using an estimated hygroscopic parameter $\kappa_{m,\text{RM}} = 0.1$ as
 255 discussed in section 4.

257 4. Aerosol hygroscopicity

258
 259 We apply the single-parameter measure of aerosol hygroscopicity (κ) developed by Petters
 260 and Kreidenweis (2007, 2008, 2013) to represent the contribution of water uptake by individual
 261 components. The κ parameter is defined from 0 (insoluble materials) to greater than 1 for sea
 262 salt. Although initially developed for supersaturated CCN conditions, hygroscopic parameters κ
 263 have been more recently used in sub-saturated conditions (Chang et al., 2010; Dusek et al., 2011;
 264 Giordano et al., 2013; Hersey et al., 2013). For particle diameters that dominate the mass fraction
 265 of PM_{2.5} (larger than 50 nm), the difference in κ between CCN and sub-saturated aerosols is

266 small (Dusek et al., 2011). The water retention of internal mixtures of aerosol components is
 267 often predicted within experimental error (Kreidenweis et al., 2008). Aged, polarized organic
 268 material, which is a major component of PM_{2.5}, shows comparable growth factors both in super-
 269 and sub-saturated regions (Rickards et al., 2013).

270
 271 The volume hygroscopicity parameter κ_v is defined as a function of particle volume V and
 272 water activity a_w

$$\frac{1}{a_w} = 1 + \kappa_v \frac{V_d}{V_w} \quad \text{Eq. 4}$$

273 where V_d and V_w are the dry particulate matter and water volumes, respectively. To a first-order
 274 approximation $a_w = \text{RH}/100$. Aerosol volume growth is related via κ and RH by defining $f_v(\text{RH})$
 275 as the humidity-dependent ratio of wet and dry aerosol volume:

$$f_v(\text{RH}) \equiv \frac{V_{tot}}{V_d} = \frac{V_d + V_w}{V_d} = a + \kappa_v \frac{\text{RH}}{100 - \text{RH}} \quad \text{Eq. 5}$$

276 Combining the previous equations and relating to a diameter D growth factor ($GF \equiv D/D_d$) yields

$$GF = \left(a + \kappa_v \frac{\text{RH}}{100 - \text{RH}} \right)^{1/3} \quad \text{Eq. 6}$$

277 where $a = 1$, except for sea salt as discussed in Sect. 3.1. Reliable estimates of κ_v are available
 278 for individual components (*c.f.* Table 2).

279
 280 The next sections outline how we apply κ to represent mass and volume hygroscopic growth
 281 in major hygroscopic aerosol components. Four components directly contribute to water uptake:
 282 ammonium nitrate (ANO₃), ammoniated sulfate (ASO₄), sea salt (SS), and organics. We treat
 283 black carbon (EBC), crustal material (CM), and trace oxides (TEO) as non-hygroscopic. We
 284 evaluated inorganic component growth curves using the AIM model (Wexler and Clegg, 2002)
 285 for RH = 10 – 90% except for sea salt, which included RH = 0%. Hygroscopic parameters were
 286 matched to modeled fits. Aerosols are treated as internally mixed, without deliquescence or
 287 efflorescence points, as discussed further below.

288 4.1. Inorganic behavior

289 Figure 1 shows the hygroscopic growth for inorganics. The κ_v value of 0.51 for ASO₄
 290 best matches the AIM model over RH = 10-90% and is similar to the GF -derived $\kappa_v = 0.53$
 291 estimated by Petters and Kreidenweis (2007). Our AIM-derived ANO₃ growth curve is smaller
 292 than ASO₄, at $\kappa_v = 0.41$. Although both ammonium compounds share the same $GF = 1.6$ at RH =
 293 85% (Sorooshian et al., 2008), ANO₃ is less hygroscopic at lower RH.

294
 295 Sea salt accounts for a small fraction of aerosol mass over land, however its hydrophilic
 296 nature makes it significant for water retention. A 1:1 volume ratio with water as RH approaches
 297 0% (Kreidenweis et al., 2008) yields $a = 2$ (Eq. 2 and 3). A hygroscopic constant $\kappa_v = 1.5$ then
 298 best fits AIM from the deliquescence point up to 90% RH.

299

300 We follow the widely used convention (e.g. Pitchford et al. (2007)) that $PM_{2.5}$ under
 301 variable sub-saturated RH does not exhibit deliquescent phase transitions. There is compelling
 302 evidence to adopt smooth hygroscopic growth curves. Various experiments show sub-
 303 micrometer, internally mixed aerosols will not deliquesce as readily as pure compounds. For
 304 example, Badger et al. (2006) observed ASO_4 aerosol deliquescence is clearly inhibited by the
 305 presence of humic acids. A smooth growth curve has been observed over the range $RH = 10 -$
 306 85% for ambient aerosols at Jungfraujoch (Swietlicki et al., 2008). Analysis of submicron aerosol
 307 mixtures consisting of SS, ASO_4 , ANO_3 , and levoglucosan also showed no apparent phase
 308 transition (Svenningsson et al., 2006).

309 4.2. Organic matter behavior

310 Identifying a representative organic hygroscopic parameter is challenging, as many volume
 311 growth curves are available based on a variety of laboratory experiments and field campaigns.
 312 Organic composition varies by site, and by season. The Appendix table A1 contains a collection
 313 of hygroscopic parameters from the literature. Values for $\kappa_{v,OM}$ range from 0 to 0.2. We choose a
 314 single $\kappa_{v,OM}$ value based on the oxygen/carbon ratio (O:C), which is a function of oxidation,
 315 hence age of the organics. Generally O:C ratios are between 0.2 – 0.8 in urban environments
 316 (Rickards et al., 2013). We select an O:C ratio of 0.5 to represent the populated nature of
 317 SPARTAN sites (e.g. Robinson et al., 2013). This corresponds to an organic parameter of
 318 $\kappa_{v,OM} = 0.1$ for a variety of organic mixtures (Jimenez et al., 2009).

319 4.3. Aerosol water in multi-component systems

320 Mass-based hygroscopic water uptake κ_m is more convenient than κ_v to estimate water
 321 retention in gravimetric analysis. The parameters κ_v and κ_m are related by water-normalized
 322 density, $\kappa_{m,X} = \kappa_{v,X}/\rho_X$. Table 2 contains κ_v values identified for major aerosol chemical
 323 components and densities. For a multi-component system we estimate aerosol water mass using a
 324 mass-weighted combination of κ_m values:

$$\kappa_{m,tot} = \frac{1}{M} \sum_X m_X \kappa_{m,X} \quad \text{Eq. 7}$$

325 Mass calculations are used to determine residual aerosol mass as described in Sect 4.9.
 326 Estimates of total water uptake by volume are applied to aerosol light scatter in Sect. 5. The
 327 volume parameter $\kappa_{v,tot}$ is similarly determined by a linear combination of volume-weighted
 328 components X (e.g. Bezantakos et al., 2013):

$$\kappa_{v,tot} = \frac{1}{V} \sum_X v_X \kappa_{v,X} \quad \text{Eq. 8}$$

329 The hygroscopic growth of ASO_4 and organic mixtures are treated as linear combinations of pure
 330 compounds (Robinson et al., 2013). Errors in aerosol water uptake are less significant in mixtures
 331 than for individual species due to dilution effects (Kreidenweis et al., 2008). For ambient aerosols,
 332 empirically measured $\kappa_{v,tot}$ usually lies between 0.14 and 0.39 (Carrico et al., 2010).
 333

334 4.4. Sources of Uncertainty

335 Uncertainty in atmospheric PM_{2.5} concentrations can be separated into air volume and PM_{2.5}
336 mass. We estimated total flow volume variance to be $\pm 10\%$, while 2σ pre and post gravimetric
337 mass measurement varied by a combined $\pm 4 \mu\text{g}$. Characterization of hourly PM_{2.5} uncertainties
338 can be found in Appendix A2.

339
340 Of concern is the loss of semivolatiles after sampling. In the laboratory semivolatile loss
341 is inhibited by storing filters in closed containers. As discussed in Section 2, the sampling
342 protocol is designed to minimize semi-volatile loss. We tested the retention of semivolatile
343 material in the field by examining the trend in PM_{2.5} and ANO₃ mass from the first filter sampled
344 (54 day residence time in instrument) through the last filter sampled (negligible residence time in
345 instrument). Statistically insignificant trends were found for both PM_{2.5} ($-0.09 \pm 0.46 \mu\text{g m}^{-3}$
346 ³/position) and ANO₃ ($0.06 \pm 0.15 \mu\text{g m}^{-3}$ /position) providing confidence in retention of
347 semivolatiles on filters in the cartridge.

348
349 Other uncertainties include absolute equivalent black carbon mass due to the reflectivity
350 path p ($\pm 30\%$) and absorption cross section σ ($\pm 30\%$), which combine to in quadrature $\pm 42\%$.
351 Trace metal recovery yields were tested using a sequential second digestion with 20% nitric acid.
352 Each acid-digested element was quantified by five dilutions of a 25 element standard (25 – 500
353 *ppb*) plus three internal calibration metals (Sc, In, Tb). The elemental comparison of crustal
354 materials varies regionally (Wang, 2015), which contributes to CM uncertainty of $\pm 30\%$ based
355 on Al, Fe and Mg composition. Recovery of individual water-soluble elements was determined
356 through 5-point anion and cation standards curves each with $r^2 > 98\%$ and $<10\%$ mass
357 uncertainty for most elements at environmentally-relevant concentrations, including sulfate,
358 nitrate, and ammonium. Based on lab filter spike tests, water-soluble ion extractions show $> 95\%$
359 extraction efficiency. Uncertainties of water-soluble ion yields are generally $\pm 5\%$, except when
360 close to limit of detection (approximately $0.1 \mu\text{g m}^{-3}$, depending on filter sampling duration).
361 Errors in the component values affect our estimate of κ_v , which will affect the inferred aerosol
362 water. Network evaluation is ongoing task that will continue over time.

363

364 5. Mass speciation results

365 5.1. Overview of PM_{2.5} mass speciation

366 Gravimetrically-weighed PM_{2.5} concentrations within the period June 2013 to February 2016
367 span an order of magnitude, from under $10 \mu\text{g m}^{-3}$ (e.g. Atlanta) to almost $100 \mu\text{g m}^{-3}$ (Kanpur).
368 Sites include a variety of geographic regions including partial desert (Ilorin, Rehovot, Kanpur),
369 coastline (Buenos Aires, Singapore), and developing megacities (Dhaka). Table 3 and Figure 2
370 contain the resulting PM_{2.5} mass, composition, and location of each SPARTAN site. The mean
371 SPARTAN composition over all sampling sites in descending concentration is 40% RM
372 (primarily organic), 20% ASO₄, 13% CM, 12% EBC, 4.7% ANO₃, 2.3% SS and 1.0% TEO.

373

374 There is significant variation of relative and absolute speciation from these long-term
375 averages. ASO₄ concentrations range from $1 \mu\text{g m}^{-3}$ (Buenos Aires, summer) to $17 \mu\text{g m}^{-3}$
376 (Kanpur, dry season). The fraction of sulfate in PM_{2.5} exhibits much weaker spatial variation (10-

377 30%) as increases in ASO₄ coincide with increases in total PM_{2.5}. Hence locations with enhanced
378 sulfate tend to have enhancements in other aerosol components.

379
380 ANO₃ concentrations exhibit a larger spatial heterogeneity than sulfate. Absolute values
381 range over 30-fold, from 0.2 μg m⁻³ (Mammoth Cave, summer) to 6.8 μg m⁻³ (Kanpur, dry
382 season). Corresponding mass fractions are 7-8 % in Kanpur, Beijing, and Buenos Aires, and
383 below 2% in Bandung. This heterogeneity reflects large spatial and temporal variation in NH₃
384 and NO_x (NO + NO₂) sources. There were noticeable seasonal increases in ANO₃ during
385 wintertime periods in Beijing, Kanpur, and Dhaka, coinciding with lower temperatures.

386
387 CM concentrations span an order of magnitude from 1.0 μg m⁻³ (Atlanta) to 16 μg m⁻³
388 (Beijing). The fraction of CM in PM_{2.5} exhibits pronounced variation (5-25%). Except during
389 dust storms, CM does not show clear patterns of temporal or regional variation. This could be
390 explained by non-seasonal road dust, which may account for over 80% of CM in regions with
391 heavy urban traffic (Huang et al., 2015).

392
393 We used Zn:Al ratios to assess the relative importance of local road dust (*c.f.* Table 3).
394 Aluminum is mostly natural in origin (Zhang et al., 2006) whereas Zn is primarily from tire wear
395 (Begum et al., 2010; Councell et al., 2004). For example, ratios are above 3 for Dhaka and
396 Hanoi, but less than 0.3 for Mammoth Cave and South Dekalb site (Atlanta). In fine-mode
397 aerosols, the ratio tends to be highest in large cities distant from natural CM. In coarse-mode
398 aerosols, a low Zn:Al ratio (< 0.1) indicates the aerosol CM component is dominated by regional
399 dust.

400
401 Absolute EBC spans an eight-fold concentration range from 1.1 μg m⁻³ (Atlanta) to above 8
402 μg m⁻³ (Dhaka and Kanpur). Mass fractions of EBC ranged from 4% (Singapore) to 25%
403 (Manila). Trace element oxide (TEO) material is mainly composed of Zn, Pb, Ni, Cu, and Ba,
404 hence also derived mainly from anthropogenic sources. TEO contributes negligibly to total mass
405 (1%), as expected. Sea salt remains a consistently small contributor (2%) to total mass, except
406 for Buenos Aires and Rehovot (5-6%) due to coastal winds. Particle-bound water (PBW) mass at
407 35% humidity is determined from the growth parameter κ_m. PBW mass contribution is similar to
408 EBC (7%). At low humidity, the combined mass of ANO₃, EBC, TEO, sea salt, and PBW
409 account for 15-35 % of aerosol mass.

410
411 RM as inferred from mass reconstruction of inorganic compounds, PBW, and total filter-
412 weighed mass is implicitly treated as the organic aerosol mass fraction. In terms of relative
413 composition, RM spans a factor of two, from 30% mass in Buenos Aires to almost 60% in
414 Kanpur. Temporal changes in RM tend to coincide with increases in ASO₄, with an all-site r² =
415 0.92. Although RM is not fully independent of ASO₄, this relationship implies related sources.

416
417 We interpret the abundance of water-soluble potassium K relative to Al as an indicator of
418 wood smoke (e.g. Munchak et al., 2011). K:Al ratios averaged over each site range from < 2
419 (Mammoth Cave, Atlanta) to 16 (Kanpur), where combustion activity is apparent. Singapore was
420 downwind of significant Indonesian forest fire smoke during its sampling period of Aug-Nov
421 2015, averaging to K:Al = 13. The correlation between K:Al and RM across all SPARTAN sites
422 is r² = 0.73, supporting the attribution of RM as mostly organic.

423
424 Across all sites, coarse and fine mode mass fractions are approximately equal (0.50), with
425 fractions ranging from below 0.40 (Hanoi, Buenos Aires, and Manila) to above 0.55 (e.g.
426 Bandung, Kanpur, Atlanta, Mammoth Cave). The two size modes can be temporally correlated
427 per site, though sometimes weakly, from $r^2 = 0.15$ (Hanoi) to $r^2 = 0.76$ (Rehovot). We observe
428 strong temporal correlations between sulfate and ammonium in $PM_{2.5}$ ($r^2 = 0.72 - 0.99$). Nitrate
429 and ammonium are less consistently related (Table 3), ranging from higher values in Singapore
430 ($r^2 = 0.66$), Kanpur ($r^2 = 0.58$), Beijing ($r^2 = 0.28$), to weaker values in Ilorin and Manila ($r^2 <$
431 0.1). The strength of correlations with ammonium could be influenced by excess ammonium
432 relative to sulfate. The $[NH_4^+]/[SO_4^{2-}]$ ratio in $PM_{2.5}$ is 2.6 in Kanpur and 1.3 in Ilorin.

433 5.2. Collocation overview

434 We compare SPARTAN $PM_{2.5}$ speciation with previous studies available from the literature
435 and focus on collocated relative $PM_{2.5}$ composition of major components within the last 10 years.
436 TEO is omitted due to lack of significant mass contribution. Aerosol water content is also
437 omitted as it was not directly measured in any of the collocation studies. If not provided, CM is
438 treated as defined in Sect 4.5 where possible. Organic mass (OM) to organic carbon (OC) ratios
439 are from Philip et al. (2014b) with updates from Canagaratna et al. (2015).

440
441 Figure 3 provides an overview of the comparison studies organized by SPARTAN data
442 availability. Only sampling at Mammoth Cave sampling was temporally coincident with the
443 comparison data. SPARTAN compositional information is generally consistent with previous
444 studies, considering inter-annual chemical variation and measurement uncertainty. For example,
445 both SPARTAN and comparative studies find that $PM_{2.5}$ is composed of between 10-30% ASO_4
446 and 5-20% CM for sampled sites. SPARTAN EBC mass fraction generally matches within 5
447 percentage points of collocated studies, except for Bandung and Kanpur. SPARTAN and prior
448 studies find that ANO_3 is usually a small fraction of total mass, except at Beijing and Kanpur (7-
449 8%) due to their high agricultural and industrial activity. All studies find that sea-salt is below
450 3% of total mass. SPARTAN-derived RM has potentially the largest potential error, yet typically
451 is consistent with the combined organic and unknown masses of other studies. This offers further
452 evidence that SPARTAN measurements of RM are predominantly organic in nature.

454 5.3. Individual site characteristics

455 Below we discuss each site in more detail. We also examine how our chemical composition
456 from a global array of sites relate to local anthropogenic activities and surrounding area.
457 References to land type at specific sites are derived from Latham et al. (2014), unless otherwise
458 indicated. The number of filters is given in parentheses.

460 5.3.1 Beijing, China ($n = 114$)

461 Beijing has attracted considerable attention for its air pollution (Chen et al., 2013).
462 Agricultural areas to the west and the Gobi Desert to the north surround the city's 19 million
463 dwellers. The SPARTAN air sampler is located on the Tsinghua University campus, 15 km
464 northwest of the downtown center. This is our longest-running site, with 2.5 years of near-
465 continuous sampling. It reports the third-highest $PM_{2.5}$, at $69 \mu g m^{-3}$, the third highest ASO_4 (12
466 $\mu g m^{-3}$) and the highest CM ($16 \mu g m^{-3}$) of all sites. The significant ANO_3 ($5.5 \mu g m^{-3}$) reflects

467 significant urban NO_x near agricultural NH₃ sources. ANO₃ values were highest during winter,
468 as expected from ammonium-nitrate thermodynamics. A high CM component in the springtime
469 reflects regional, natural CM sources. The mean PM_{2.5} Zn:Al ratio is lower than other large cities
470 (0.51) likely due to larger fraction of natural dust sources and the sampling location in the
471 northwest quadrant of the city, upwind of many traffic sources. The lowest coarse-mode Zn:Al
472 mass ratios are observed in April 2014 (0.07) and April 2015 (0.06) during the annual Yellow
473 dust storm season. This is balanced by urban dust sources throughout the year, in agreement with
474 Lin et al. (2015) who found evidence of high CM in industrial areas of Beijing.

476 *Beijing Comparison:* Relative masses in Beijing compare well with previous studies.
477 SPARTAN ASO₄ (19%) is close to Yang et al. (2011) (17%) and Oanh et al. (2006) (20%)
478 and the RM of 37% is similar to combined OM (33 and 29%) and unknown fractions (10 and
479 24%) of comparison studies. SPARTAN ANO₃ concentrations (8.5%) are relatively higher
480 than most other locations, though lower than either previous study (11-12%), possibly due to
481 different sampling periods. CM is greater than Yang et al. (2011) (25% vs. 19%), and
482 significantly higher than Oanh et al. (2006) (5%), potentially due to a difference in
483 definitions.

485 **5.3.2 Bandung, Indonesia (n = 77)**

486 Bandung is located inland on western Java surrounded by a volcanic mountain range and
487 agriculture (e.g. tea plantations). The sampler is located on the Institute of Technology Bandung
488 campus, 5 km north of the city center. Almost two years of sampling have resulted in a mean
489 PM_{2.5} concentration of 31 μg m⁻³. Sea salt is low at this elevated (826 m) inland site. ANO₃ and
490 CM levels are also low, but RM is moderately high compared with other sites, at 55%. This
491 could be explained by large amounts of vegetative burning; organic PM_{2.5} mass fractions can rise
492 above 70% during combustion episodes (Fujii et al., 2014). Volcanic sources of sulfur, in
493 addition to industrial sources, may explain the relatively higher ASO₄ compared with Manila or
494 Dhaka (Lestari and Mauliadi, 2009). Influxes of volcanic dust from the Sinabang volcano from
495 August – September 2014 (2000 km northwest of Bandung) could explain why coarse-mode
496 Zn:Al ratios drop to 0.09 for this period compared to the annual mean of 0.21.

497 *Bandung Collocation:* Bandung is a volcanically active area, so that composition, in
498 particular ASO₄, differs due to naturally variable circumstances. SPARTAN ASO₄ (21%) is
499 higher than the 4% fraction reported by Lestari and Mauliadi (2009), but is identical with
500 measurements by Oanh et al. (2006). SPARTAN EBC (13%) is less than either previous
501 study (19% and 25%) and the more recent analysis of 19% BC (Santoso et al., 2013).
502 SPARTAN ANO₃ is 2% by mass, lower than measured by Oanh et al. (2006) (13%) but
503 similar to Lestari and Mauliadi (2009). Both of the earlier studies show lower RM fractions
504 (36%, and 42%) compared with 54% RM in this study.

507 **5.3.3 Manila, Philippines (n = 63)**

508 Manila is a coastal city located in Manila Bay, adjacent to the South China Sea and
509 surrounded by mountains. The sampling station, located at the Manila Observatory, is about 40
510 m higher in altitude than the central city. The PM_{2.5} concentrations at the observatory (18 μg m⁻³)
511 are expected to be lower than in the main city, but still influenced by vehicular traffic, fuel
512 combustion and industry (Cohen et al., 2009). Compared to the all-site average, the CM fraction

513 in Manila is typical (11%), but black carbon is twice as great (25%). The high EBC agrees with
514 previous observations, attributable to a relatively high use of diesel engines (Cohen et al., 2002).

515
516 *Manila Collocation:* SPARTAN fractions of ASO₄ and EBC are similar to Cohen et al.
517 (2009). Our RM (43%) is lower than OM (57%), whereas SPARTAN CM was greater than
518 Cohen et al. (2009). These differences could reflect sampling differences, or emission
519 changes over the last decade.

520 521 **5.3.4 Dhaka, Bangladesh (n = 41)**

522 Dhaka is a densely populated city (17,000 persons/km²) in a densely populated country
523 (1,100 persons/km²). The sampler is situated in the heart of downtown Dhaka, on the University
524 of Dhaka rooftop, and is influenced by air masses from the Indo Gangetic Plain (Begum et al.,
525 2012). More than half the country is used for agricultural purposes (Ahmed, 2013). Local
526 contributing PM_{2.5} sources include coal and biomass burning, and heavy road traffic combustion
527 products and dust (Begum et al., 2010, 2012). PM_{2.5} concentrations are the fourth highest of any
528 SPARTAN site, at 52 µg m⁻³. Dhaka has the second-highest absolute EBC of any site, at 8.4 µg
529 m⁻³, which can be explained by the abundance of truck diesel engines (Begum et al., 2012). We
530 estimate 41% of PM_{2.5} in Dhaka is RM. Crop or bush burning on both local and regional scales
531 contribute significantly to organics (Begum et al., 2012). The high mean PM_{2.5} Zn:Al ratio of 3.4
532 reflects a large contribution from urban traffic.

533 534 **5.3.5 Ilorin, Nigeria (n = 40)**

535 Ilorin is located in a rural area with low-level agriculture and shrub vegetation. The sampler
536 is sited on the university campus, 15 km east of the city of 500,000 people. Aerosol loadings
537 have seasonal cycles from agricultural burning events and dust storms (Generoso et al., 2003).
538 The RM accounted for two thirds of total PM_{2.5} mass, among the largest, influenced by biomass
539 burning. There is evidence of biomass burning in the PM_{2.5} peak in late spring 2014, and again in
540 2015. Lower ASO₄ (12%) compared to other SPARTAN sites reflects the sparse surrounding
541 industry. CM levels are comparable to other locations, except during dust storms. During a dust
542 storm (between April 14th - May 2nd 2015), CM increased to two thirds of PM_{2.5} mass. The PM_c
543 Zn:Al ratio during the storm decreased to 0.01 versus 0.25 during non-storm days.

544 545 **5.3.6 Kanpur, India (n = 33)**

546 Kanpur is a city of 2.5 million people. The sampler is located at the IIT Kanpur campus
547 airstrip, about 10 km northwest of the city. The city lies in the Indo-Gangetic Plain, where
548 massive river floodplains are used for agricultural and industrial activity (Ram et al., 2012). We
549 sampled from December 2013 – May 2014, and September-November 2014, capturing one dry
550 season. SPARTAN-measured PM_{2.5} for this period was 99 µg m⁻³, the highest of any SPARTAN
551 site, of which 59% is RM, 19% ASO₄, and 7.4% ANO₃. The absolute values of all three
552 components are also the highest among those measured. Molar [NH₄⁺]:[SO₄²⁻] ratios are higher
553 in Kanpur (2.6) than elsewhere. High background ammonia has been observed in the region
554 from satellite (e.g. Clarisse et al., 2009) which could explain the high levels of ANO₃. Wood
555 smoke is apparent from the high K:Al ratio (16), associated with organic matter burning during
556 winter dry months. We detected significant Zn concentrations (Zn:Al = 1.0), which is in
557 agreement with Misra et al. (2014) observations of a tripling of zinc during anthropogenic
558 sourced dust.

559
560 *Kanpur Collocation:* Relative fractions among the major species CM, salt, ASO₄ & ANO₃ all
561 match well with previous studies (Behera and Sharma, 2010; Chakraborty et al., 2015; Ram
562 et al., 2012) that also sampled during winter dry seasons. Chakraborty et al. (2015) measured
563 70% organic mass composition and found a combined mass of 28% for ASO₄ + ANO₃
564 compared to SPARTAN mass (26%). SPARTAN ASO₄ (19%) compares well to 13% of
565 Ram et al. (2012) and 18% for Behera and Sharma (2010), and ANO₃ (7.4%) is close to
566 previous values (6.1% and 6.6%). By comparison SPARTAN slightly overestimates EBC by
567 4-6%. SPARTAN CM (4.8%) is lower than Behera and Sharma (2010) (10%). Notably the
568 combined OM + unknown fractions from these previous two studies account for two thirds of
569 aerosol mass, 58% for Behera and Sharma (2010) and 63% for Ram et al. (2012), similar to
570 our 59% RM estimate. SPARTAN PM_{2.5} concentrations, as well as RM, reach a maximum
571 during the month of December. This is consistent with recent work (Villalobos et al., 2015),
572 who attribute this increase to agricultural burning and stagnant air.

573 574 **5.3.7 Buenos Aires, Argentina (n = 31)**

575 Buenos Aires has a metropolitan population of 12 million. SPARTAN instruments are
576 located on the urban CITEDEF campus 20 km west of the central downtown. The megacity, the
577 southernmost in our study, is surrounded by grassland and farming on the west and the Atlantic
578 Ocean on the east. The latter explains the relatively high proportion (6%) of sea salt. Total PM_{2.5}
579 (10 µg m⁻³) and relative RM (31%) are low compared with other large metropolitan areas, likely
580 influenced by clean maritime air. In addition to sea salt and natural CM, the contribution of EBC
581 is 17%, which could reflect significant local truck diesel combustion (Jasan et al., 2009).

582 583 **5.3.8 Rehovot, Israel (n = 30)**

584 Rehovot is located on a four-story rooftop on the Weizmann Institute campus, 11 km from
585 the Mediterranean Sea and 20 km south of Tel Aviv. The city is surrounded by semi-arid, mixed-
586 use cropland, and the region experiences occasional Saharan desert dust outbreaks. Typical PM_{2.5}
587 concentrations are low (16 µg m⁻³), with the composition in Rehovot consisting of 29% ASO₄,
588 and 20% CM. The RM fraction is smaller in Rehovot (16% total PM_{2.5} mass) than at other
589 SPARTAN sites. Aerosol sources in Israel include agriculture, desert dust, traffic and coal-based
590 power plants (Graham et al., 2004). Relative sodium concentrations are high in Rehovot (4%),
591 similar to Buenos Aires and Ilorin, and may include a contribution from dust.

592
593 *Lag Ba'Omer festival:* We measured high ASO₄ concentrations on May 7-18, 2015, during
594 which time a large number of bonfires were lit nearby. During the festival, over 75% of total
595 aerosol mass came from ASO₄ + ANO₃, leading to a brief doubling of the hygroscopic
596 parameter κ_v . We observed a K:Al ratio of 38 for May 6th of the festival, the highest for any
597 single filter.

598
599 *Saharan dust storm:* We had the opportunity to measure a severe dust storm in Rehovot from
600 a filter sampling February 4-13, 2015. The coarse filter Zn:Al ratio dropped to 0.02 during
601 the Saharan dust storm from the typical value of 0.3. On the coarse filter we obtained an
602 absolute CM mass of 950 µg, which accounts for half of the collected mass during the storm.
603 13% of dust storm PM_c is combined sea salt, ANO₃, and ASO₄, leaving 35% RM. Although

604 this RM fraction may imply an incomplete CM extraction, it is possible that a significant
605 portion of desert dust carries adsorbed organic material (Falkovich et al., 2004).

606 **5.3.9 Mammoth Cave NP, US (n = 19)**

607 The Mammoth Cave sampling site straddles National Park mountainous terrain to the north
608 and east, with farmland to the south and west. It is about 35 km from the closest town, Bowling
609 Green, KY, with about 50,000 residents. Sources of PM are expected to be non-local, hence we
610 consider it our ‘background’ site.
611

612 *Mammoth Cave National Park Collocation:* This temporary SPARTAN site was deployed
613 for comparison with the IMPROVE network station (IMPROVE, 2015). Unique among our
614 sites, sampling was temporally coincident with IMPROVE’s 1-in-3 day regimen. We
615 obtained quality-controlled samples from June-August 2014. Temporal variation in daily
616 values is consistent with IMPROVE for sulfate ($r^2 = 0.86$, slope = 1.03) and total mass of
617 $PM_{2.5}$ ($r^2 = 0.76$, slope = 1.12). Differences between IMPROVE vs. SPARTAN are small for
618 ASO_4 (36% vs. 33%), ANO_3 (2.4% vs. 1.2%), CM (7% vs. 11%), and EBC (3.0% vs. 5.6%),
619 respectively. The combined OM + unknown + water fraction IMPROVE was 51%, similar to
620 the SPARTAN RM mass fraction of 49%.
621

622 **5.3.10 Atlanta, US (n = 13)**

623 Atlanta represents a major urban area in a developed country. The temporary SPARTAN site
624 was located at the South Dekalb supersite 15 km east of downtown Atlanta. Air sampling was
625 performed for a 4-month period spanning winter to spring 2014. Over the past 10 years
626 significant decreases in $PM_{2.5}$ have been observed here and across the eastern United States
627 (Boys et al., 2014). The surrounding region is tree-covered or agricultural.
628

629 *Atlanta (South Dekalb) Collocation:* Co-sampled filters from the Atlanta CSN station
630 (USEPA, 2015) provide a comparison with the summer 2014 SPARTAN data. The EPA OM
631 fraction (43%) agrees well with the SPARTAN mean RM (48%). Crustal, SS, EBC and
632 ASO_4 are within 2% relative to total composition. SPARTAN component fractions in Atlanta
633 are also consistent with respect to Butler et al. (2003); components CM (12% vs. 10%),
634 ASO_4 (23% vs. 28%), ANO_3 (3.5% vs 4%) and RM and OM (48% vs 55%) closely match,
635 except for EBC (11% vs. 3%), perhaps reflecting different time periods.
636

637 **5.3.11 Singapore, Singapore (n = 12)**

638 Singapore is a densely populated coastal city-state at 7,770 people/km². The sampler is
639 located on a rooftop at the National University of Singapore (NUS), near the center of the city.
640 Transportation is mixed-use, including taxis, rail, and bicycles, which may help explain the
641 relatively low EBC and CM of 3%. Despite this, the Zn:Al ratio remains high at 1.5, implying a
642 dominant traffic-based contribution to CM. SPARTAN instruments have observed significant
643 biomass burning downwind from Indonesia, causing an increase in absolute $PM_{2.5}$ from 32 in
644 August to 120 $\mu g m^{-3}$ in September 2015, as well as an increase in RM from 44% to 62%. The
645 K:Al ratio steadily increased during this same period, from 7.2 (Jul 24 – Aug 2, 2015) to 17 – 24
646 (Aug 11 – Sept 25).
647

650 **5.3.12 Hanoi, Vietnam (n = 10)**

651 Hanoi is an inland megacity surrounded by grassland and agriculture. The sampler itself is on
652 a building rooftop at the Vietnam Academy of Science, 5 km northwest of the city center.
653 Motorbikes are the main forms of transportation downtown and the primary source of mobile-
654 based PM_{2.5} (Vu Van et al., 2013). In Hanoi, the PM_{2.5} Zn:Al ratio was 3.7, also the highest of
655 any SPARTAN site, indicative of significant traffic and tire wear.

656
657 *Hanoi Comparison:* SPARTAN PM_{2.5} composition is generally consistent with Cohen et
658 al.(2010). Slight differences are perhaps related to differences in sampling season and
659 location. SPARTAN sea salt fraction was larger (2.5% vs. 0.6%), but with a lower ASO₄
660 fraction (17%) compared with Cohen et al. (2010) (29%). Sulfate tends to be lower in the
661 spring-summer seasons, coinciding with our measurement period, which may explain the
662 discrepancy. SPARTAN EBC (10%) is close to the Cohen et al. (2010) value of 8%, whereas
663 SPARTAN RM (51%) and CM (16%) masses are slightly higher.

664
665 **5.3.13 Pretoria, South Africa (n = 5)**

666 Pretoria is a high-altitude city (1300 m) surrounded by arid, low-intensity agriculture and
667 extensive grasslands. The SPARTAN sampler is located on a 10m CSIR building rooftop 12 km
668 east of downtown area (*pop.* 700,000). Preliminary measurements of south-hemisphere
669 springtime show absolute PM_{2.5} concentrations to be low, at 6.4 μg m⁻³. There are significant
670 fractions of CM (22%) and EBC (22%), and low RM (14%). The PM_{2.5} Zn:Al ratio (0.69)
671 indicates vehicle traffic contributes to CM.

672 **6. Refining estimates of dry hourly PM_{2.5} using κ_v**

673 Our assessment of PM_{2.5} hygroscopicity is determined by site-specific chemical composition. We
674 then use the time-varying hygroscopicity to refine the PM_{2.5} values inferred from nephelometer
675 scatter.

676 **6.1. Relating PM_{2.5} composition to κ_v**

677 The outer pie charts of Figure 2 show the site-mean hygroscopic growth constant κ_v,
678 surrounded by the water contributions at 35% RH. The major contributors to PBW are ASO₄,
679 ANO₃, RM, and sea salt, as inferred from the values listed in Table 2 and weighted by
680 composition as in Eq. 5. ASO₄ and RM contribute similarly to total aerosol water whereas ANO₃
681 contributes less to PM_{2.5} hygroscopicity due to its smaller mass. The contribution of sea salt to
682 hygroscopicity can be significant, and makes a dominant contribution in both Rehovot and
683 Buenos Aires.

684
685 The parameter κ_v, when averaged across all sites, is 0.20, matching the generic estimate
686 κ_{v,tot} = 0.2 applied in the initial SPARTAN study (Snider et al., 2015). Recently Brock et al.
687 (2016) estimate κ_v values between 0.15 and 0.25 for ambient aerosols with 50% organic
688 composition at subsaturated humidity. The local SPARTAN value in Atlanta (0.17) is consistent
689 the value of 0.16 ± 0.07 by Padró et al. (2012) in Atlanta. We found significant long-term
690 differences in κ_{v,tot} between cities, from 0.15 in Ilorin to 0.28 in Rehovot, and differences
691 between filters at single sites (σ ~ 0.05). There is little correlation of κ_{v,tot} with changes in mass
692 (r² < 0.01). However, there are significant changes in κ_{v,tot} due to seasonality and specific

693 events (e.g. dust storms, fires). In Beijing, aerosol hygroscopicity was 50% higher in mid
694 summer (August) due to increased sulfate, and in late winter (March) due to a relative increase in
695 sea salt. A summertime sulfate peak also agrees with observations by Yang et al. (2011). Table 3
696 shows the site-specific PBW in $PM_{2.5}$. At RH =35%, PBW ranges from 0.6 – 6 $\mu\text{g m}^{-3}$,
697 comparable in absolute values to EBC. Above 80% RH PBW will account for more than half of
698 aerosol mass. Accounting for this water component in nephelometer scatter motivates the
699 following section.

700 6.2. Relating nephelometer scatter to dry (RH=35%) $PM_{2.5}$

701 We apply a temporally resolved, site-specific κ_v to refine our relationship between total
702 nephelometer scatter and $PM_{2.5}$. We calculate a 45-day running mean aerosol volume-weighted
703 κ_v at each SPARTAN site. We then use the hygroscopic growth factors to estimate dry hourly
704 $PM_{2.5}$ from hourly nephelometer measurements of ambient scatter and hourly measured RH.
705 Appendix A2 describes the procedure in more detail.

706
707 We compared our hourly $PM_{2.5}$ in Beijing with $PM_{2.5}$ measurements from a Beta Attenuation
708 Monitor (MetOne) at the US Embassy, located 15 km away. The left panel of Figure 4 shows the
709 time series of hourly dry $PM_{2.5}$ concentrations predicted by SPARTAN during the summer.
710 Pronounced temporal variation is apparent, with $PM_{2.5}$ concentrations varying by more than an
711 order of magnitude. A high degree of consistency is found with the BAM ($r^2 = 0.67$). The
712 exclusion of water uptake in hourly $PM_{2.5}$ estimates (by setting all $\kappa_v = 0$) decreased hourly
713 correlations slightly to $r^2 = 0.62$. The average humidity in Beijing was 47% for the measurement
714 period, corresponding to a mean 17% volume contribution by water ($\kappa_v = 0.19$). Hygroscopic
715 growth should play a more significant role under more humid conditions (e.g. Manila and
716 Dhaka).

717
718 The right panel shows daily-averaged $PM_{2.5}$ ($n = 148$). In 2014 there were 3167
719 coincidentally available hours with which to compare. The coefficient of variation for averaged
720 24-hour measurements remained high ($r^2 = 0.70$). There was a mean offset of 10 $\mu\text{g m}^{-3}$.
721 However the slope is near unity (0.98), suggesting excellent proportionality between our
722 nephelometer and the BAM instrument for $PM_{2.5}$ concentrations below 200 $\mu\text{g m}^{-3}$. Above this
723 concentration, nephelometer signals become non-linear. The agreement remained similar for
724 hourly values ($r^2 = 0.67$).

726 7. Conclusions

727
728 We have established a multi-country network where continuous monitoring with a 3-
729 wavelength nephelometer is combined with a single multi-day composite filter sample to provide
730 information on $PM_{2.5}$. Long-term average aerosol composition is inferred from the filters,
731 including equivalent black carbon, sea salt, crustal material, ammoniated sulfate, and ammonium
732 nitrate. This composition information was applied to calculate aerosol hygroscopicity, and in turn
733 the relation between aerosol scatter at ambient and controlled RH. These data provide a
734 consistent set of compositional measurements from 13 sites in 11 countries.

735

736 We report ongoing measurements of fine particulate matter (PM_{2.5}), including compositional
737 information, in 13 locations in two month or greater intervals all within a three-year span (2013-
738 2016). The mean composition averaged for all SPARTAN sites is ammoniated sulfate (20% ±
739 11%), crustal material (13.4% ± 9.9%), black carbon (11.9% ± 8.4%), ammonium nitrate (4.7%
740 ± 3.0%), sea salt (2.3% ± 1.6%), trace element oxides (1.0% ± 1.1%), water (7.2% ± 3.3%) at
741 35% RH, and residual matter, which is probably primarily organic (40% ± 24%).

742
743 Analysis of filter samples reveals that several PM_{2.5} chemical components varied by more
744 than an order of magnitude between sites. Ammoniated sulfate ranged from 1 µg m⁻³ in Buenos
745 Aires to 17 µg m⁻³ in Kanpur (dry season). Ammonium nitrate ranged from 0.2 µg m⁻³
746 (Mammoth Cave, summertime) to 6.8 µg m⁻³ (Kanpur, dry season). Equivalent black carbon
747 ranged from 0.7 µg m⁻³ (Mammoth Cave) to 8 µg m⁻³ (Dhaka and Kanpur). Locations with
748 enhanced sulfate tend to have enhancements in other PM components. For example, ammoniated
749 sulfate and residual matter (probably organic) are highly correlated across sites ($r^2 = 0.92$).

750
751 Crustal material concentrations ranged from 1 µg m⁻³ (Atlanta) to 16 µg m⁻³ (Beijing).
752 Measuring Zn:Al ratios in PM_{2.5} was an effective way to determine anthropogenic contribution
753 to crustal material. Ratios larger than 0.5 identified sites with significant road dust contributions
754 (e.g. in Hanoi, Dhaka, Manila, and Kanpur). Some locations, such as Beijing and Buenos Aires,
755 had both high anthropogenic and natural crustal material. Low coarse Zn:Al ratios were apparent
756 during natural dust storms. Anthropogenic crustal material is an aerosol component neglected by
757 most global models and which may deserve more attention.

758
759 Potassium is a known marker for wood smoke. Enhanced K:Al ratios were found in
760 Singapore downwind of Indonesian forest fires, in Kanpur during the winter dry season from
761 agricultural burning, and in Rehovot during a bonfire festival. Furthermore, these ratios were
762 correlated with RM concentrations ($r^2 = 0.73$), supporting the attribution of RM as mostly
763 organic.

764
765 SPARTAN measurements generally agree well with previous collocated studies. SPARTAN
766 sulfate fractions are within 4% of fractions measured at eight of the ten collocated, though
767 temporally non-coincident, studies. Dedicated contemporaneous collocation with IMPROVE at
768 Mammoth Cave yielded a high degree of consistency with daily sulfate ($r^2 = 0.86$, slope = 1.03),
769 daily PM_{2.5} ($r^2 = 0.76$, slope = 1.12), and mean fractions for all major PM_{2.5} components (within
770 2%). Crustal material is typically consistent with the previous measurements, at 5-15%
771 composition. SPARTAN equivalent black carbon ranged broadly, from 3% (Singapore) to 25%
772 (Manila), and matched within a few percent of most previous works. Ammonium nitrate (4%)
773 generally matched other sites, though it was sometimes lower, as in Beijing and Atlanta. Sea-salt
774 was consistently low, as found in previous measurements. Sea salt fractions were highest in
775 Buenos Aires and Rehovot (6%), reflecting natural coastal aerosols. SPARTAN residual matter
776 is consistent with the combined organic and unknown masses. Comparing with collocated
777 measurements supports the expectation that most of the RM is partially organic. Residual matter
778 could also include unaccounted-for particle bound water, measurement error, and possibly
779 unmeasured inorganic materials.

780

781 We calculated the hygroscopic constant κ_v for individual $PM_{2.5}$ filters to estimate water at
782 variable humidity, and to infer wet and water-free residual matter. Based on a range of literature,
783 we treated residual matter as mostly organic, with constant $\kappa_{v, RM} = 0.1$. Residual matter and
784 ammoniated sulfate largely determined overall water uptake in aerosols. These individual
785 species, along with sea salt and ammonium nitrate, resulted in a mean mixed hygroscopic
786 constant of 0.20, implying that for many sites, water content above 80% RH will account for
787 more than half of aerosol mass. For cleanroom conditions of low humidity (35% RH), mean
788 water composition was estimated to be 7% by mass.

789
790 Water retention calculations allow for volumetric fluctuation estimates of aerosol water at
791 variable RH. We subtracted the water component to predict dry nephelometer scatter as a
792 function of time, anchored to filter masses at 35% RH. For Beijing, we assessed the consistency
793 of SPARTAN predictions of hourly $PM_{2.5}$ values with BAM measurements taken 15 km away,
794 and found temporal consistency ($r^2 = 0.67$), with a slope near unity (0.98). The explained
795 variance decreased to $r^2 = 0.62$ when setting $\kappa_v = 0$. This comparison tested both SPARTAN
796 instrumentation and our treatment of aerosol water uptake.

797
798 These measurements provide chemical and physical data for future research on $PM_{2.5}$.
799 Collocation with sun photometer measurements of AOD connects satellite observations to
800 ground-based measurements and provides information needed to evaluate chemical transport
801 model simulations of the $PM_{2.5}$ to AOD ratio. As sampling expands, SPARTAN will provide
802 long-term data on fine aerosol variability from around the world. Ongoing work includes an
803 analysis of trace metal concentrations and interpreting SPARTAN measurements with a
804 chemical transport model. The data are freely available as a public good at [www.spartan-](http://www.spartan-network.org)
805 [network.org](http://www.spartan-network.org). We welcome expressions of interest to join this grass-roots network.

1167 **Figures and Tables**

1168 **Table 1: Summary of speciation definitions**

Species (at 0% RH)	Measurement Method	Species Mass (μg). For concentrations, divide masses by sampling volume v	Reference
SS	IC (anion and cation)	$2.54[\text{Na}^+]_{\text{SS}}$, where $[\text{Na}^+]_{\text{SS}} = [\text{Na}^+]_{\text{tot}} - 0.1[\text{Al}]$	(Remoundaki et al., 2013) (Malm et al., 1994)
ANO ₃		$1.29[\text{NO}_3^-]$	(Malm et al., 1994)
ASO ₄		$[\text{SO}_4^{2-}]_{\text{non-ss}} + [\text{NH}_4^+] - 0.29[\text{NO}_3^-]$, where $[\text{SO}_4^{2-}]_{\text{non-ss}} = [\text{SO}_4^{2-}]_{\text{total}} - 0.12[\text{Na}^+]$	(Dabek-Zlotorzynska et al., 2011; Henning et al., 2003)
Na ₂ SO ₄		$0.18[\text{Na}^+]_{\text{SS}}$	
CM	ICP-MS & IC	$10 \times ([\text{Al}] + [\text{Mg}] + [\text{Fe}])$	(Wang, 2015)
EBC	SSR	$20.7 \times \ln(R_o/R)$	(Taha et al., 2007)
TEO	ICP-MS	$1.47[\text{V}] + 1.27[\text{Ni}] + 1.25[\text{Cu}] + 1.24[\text{Zn}] + 1.32[\text{As}] + 1.2[\text{Se}] + 1.07[\text{Ag}] + 1.14[\text{Cd}] + 1.2[\text{Sb}] + 1.12[\text{Ba}] + 1.23[\text{Ce}] + 1.08[\text{Pb}]$	(Malm et al., 1994)
PBW _{inorg}	$\kappa_{m,X}$	$\sum_X [f_{m,X}(\text{RH}) - 1][X]$	(Kreidenweis et al., 2008)
PBW _{RM}		$\text{RM}(1 - 1/f_{m,\text{RM}})$	Table 2
RM(35%)	Mass Balance	$[\text{PM}_{2.5}] - \{[\text{EBC}] + [\text{CM}] + [\text{TEO}] + [\text{ANO}_3] + [\text{SS}] + [\text{ASO}_4] + [\text{Na}_2\text{SO}_4] + [\text{PBW}]_{\text{inorg}}\}$	This Study
RM(0%)	Mass Balance $\kappa_{m,\text{OM}} = 0.07$	$\text{RM}(35\%) - \text{PBW}_{\text{RM}}$	Organic growth factors: (Jimenez et al., 2009; Sun et al., 2011)

1169 **Species:** EBC = Equivalent black carbon, TEO = Trace metal oxides, CM = Crustal Material, ANO₃ = Ammonium
 1170 nitrate, ASO₄ = Ammoniated sulfate, PBW = particle-bound water, RM = residual matter (assumed representative of
 1171 organic matter), [X] = concentration of any hygroscopic species. **Measurement Instruments:** IC = Ion
 1172 Chromatography, ICP-MS Inductively coupled plasma mass spectrometry, SSR = Smoke Stain Reflectometer, $\kappa_{m,X}$
 1173 = single-parameter hygroscopicity by mass (Kreidenweis et al., 2008). RH = Relative Humidity,

1174

1175 **Table 2: κ -Kohler constants for volume (κ_v), mass (κ_m), and related quantities**

Compound [X]	$\kappa_{v,X}$	Approximate Density ($\rho_X/\rho_{\text{water}}$)	$\kappa_{m,X}$	PBW(% mass) at	
				RH = 35%	RH = 80%
Crustal	0	2.5 ^a	0	0	0
EBC	0	1.8 ^b	0	0	0
TEO	0	2.5	0	0	0
RM	0.1 ^c	1.4	0.07	2	12
ANO ₃	0.41	1.72	0.24	17	61
ASO ₄	0.51	1.76	0.29	15	56
Na ₂ SO ₄	0.68 ^d	2.68 ^d	0.25	12	50
SS	1.5 ^e	2.16	0.69	22	68

1176 PBW = Particle-bound water. EBC = Equivalent black carbon, TEO = Trace Element Oxides, RM = Residue Matter
 1177 (associated with organics), ANO₃ = ammonium nitrate, ASO₄ = Ammoniated sulfate. ^aWagner et al. (2009), ^bBond
 1178 and Bergstrom (2006), ^cAssuming an urban O:C ratio of 0.5 then $\kappa_{v,\text{OM}} = 0.1$ Jimenez et al. (2009), ^dPetters and
 1179 Kreidenweis (2007). ^eFitted using non-deliqesced, subsaturated AIM Model III values, plus 0% RH endpoint by
 1180 Kreidenweis et al. (2008).

^aValues in parentheses are 1 σ standard deviations. RH = Relative Humidity, ANO₃ = ammonium nitrate, ASO₄ = Ammoniated sulfate, CM = Crustal material, EBC = Equivalent black carbon, TEO = Trace Element Oxides, RM = Residue Matter, PBW = Particle-bound water. Mean Na₂SO₄ was not significant (< 0.1 $\mu\text{g m}^{-3}$) at any SPARTAN site. ^bGeometric mean of ratio

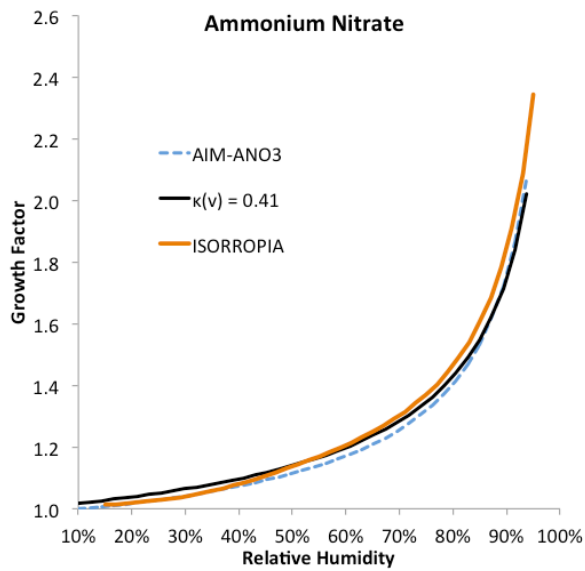

Figure 1: Hygroscopic growth factors for ASO_4 (top), ANO_3 (centre), and sea salt (bottom). GADS = Global Aerosol Dataset estimated from empirical data (Koepke et al., 1997). ISORROPIA = Aerosol thermodynamic model at $T=298\text{K}$ (reverse mode) and assuming linear water/solvent volume additivity (Fountoukis and Nenes, 2007). AIM = Aerosol Inorganic Model calculated metastable growth for ASO_4 and ANO_3 at $T=298\text{K}$ (Wexler and Clegg, 2002), Laboratory ASO_4 fit is $GF = 1.49 + 2.81 \cdot RH^{24.6}$ (with deliquescence at 80%) for bulk pure ASO_4 (Wise et al., 2003). All components are fit using Eq 6.

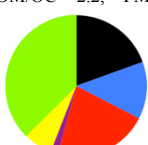

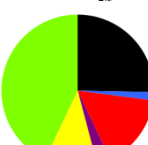

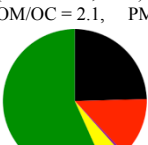

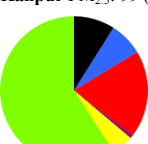

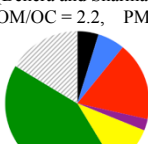

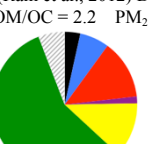

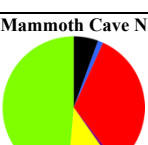

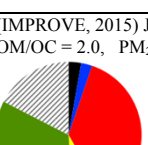

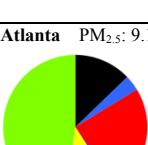

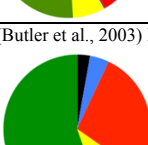

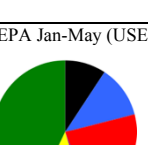

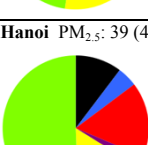

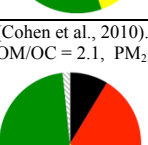

Figure 2: PM_{2.5} mass (inner circle, μg m⁻³) and composition mass fraction (filled colors) is shown in interior pie charts. Exterior pie charts contain site-mean κ_v surrounded by the relative contribution of PBW water at 35% RH.

Figure 3: Comparison of SPARTAN water-free aerosol composition with 11 collocated speciation studies. The numbers in parentheses show 1- σ deviations of averaged masses. The number of filters sampled is n . Dark green = organic, Light green = residual, black = equivalent black carbon, red = Ammoniated sulfate, blue = ammonium nitrate, purple = sea salt, yellow = crustal, and grey stripes = unknown. OM/OC ratios are from Philip et al. (2014b) and Canagaratna et al. (2015). Relative mass percentages are based on water-free aerosol components. SPARTAN percentages are renormalized to 100% after omission of species not found in comparison studies.

Appendix A1:

Table A1: Hygroscopicity parameter κ_v for various studies on organic material

κ_v (OM)	Comments	Reference
0.045	Fitted to an aged organic mixture, subsaturated	(Varutbangkul et al., 2006)
0	IMPROVE network, subsaturated	(Hand and Malm, 2006)
0.10 ± 0.04	RH > 99%, fitted to SOA precursors	(Prenni et al., 2007)
-0.067 + 0.33(O:C)	Fitted, RH > 99%	(Jimenez et al., 2009)
0.29(O:C)	RH > 99%, 0.3 < O:C < 0.6	(Chang et al., 2010)
0.05	Best estimate from aged mixtures, subsaturated	(Dusek et al., 2011)
0.01 – 0.2	Field studies & smog chamber, subsaturated	(Duplissy et al., 2011)
0.16	RH > 99%	(Asa-Awuku et al., 2011)
0.05 – 0.13	Lab experiments, aged with H ₂ O ₂ and light; subsaturated	(Liu et al., 2012)
0.1	RH > 99%, D _{dry} < 100 nm	(Padró et al., 2012)
0.12$\epsilon_{\text{WSOM}}^{\#}$	RH > 99%	(Latham et al., 2013)
-0.005 + 0.19(O:C)	Fitted, RH > 99% 100 nm particle	(Rickards et al., 2013)
0.03, 0.1	HDTMA-measure, subsaturated	(Bezantakos et al., 2013)
0.1	Subsaturated	Selected for this study

[#] ϵ_{WSOM} = fraction of water-soluble organic material.

Appendix A2:

Dry aerosol scatter ($b_{sp,dry}$) is related to relative humidity (RH) by

$$b_{sp,dry} = \frac{b_{sp}(RH)}{f_v(RH)} \quad \text{Eq. A1}$$

Changes in scatter are also proportional to mass (Chow et al., 2006; Wang et al., 2010)

$$b_{sp,dry} = \alpha PM_{2.5,dry} \quad \text{Eq. A2}$$

where α ($\text{m}^2 \text{g}^{-1}$) is the mass scattering efficiency and a function of aerosol size distribution, effective radius, and dry composition. In this study we treat composition, density, and size distribution as constant over each of our 9-day intermittent sampling periods so that $\alpha \approx \langle \alpha \rangle_{9d}$. Under this assumption the predicted mass changes in low humidity (35% RH) are proportional to water-free aerosol scatter:

$$PM_{2.5,dry} = \langle PM_{2.5,dry} \rangle \frac{b_{sp,dry}}{\langle b_{sp,dry} \rangle} \quad \text{Eq. A3}$$

where $\langle \rangle$ indicates 9-day averages. The explicit compensation for aerosol water is then

$$[PM_{2.5,dry}] = \frac{\langle [PM_{2.5,dry}] \rangle}{\langle b_{sp}(RH)/f_v(RH) \rangle} \cdot \frac{b_{sp}(RH)}{f_v(RH)} \quad \text{Eq. A4}$$

where $[\]$ indicates concentration in $\mu\text{g m}^{-3}$. Uncertainties are a function of replicate weighing measurements ($\pm 4 \mu\text{g}$), flow volume ($\pm 10\%$), %RH (± 2.5), aerosol scatter ($\pm 5\%$), and κ_v (± 0.05).

$$\left(\frac{\delta[PM_{2.5,h}]}{[PM_{2.5,h}]} \right)^2 \approx \left(\frac{\delta PM_{2.5}}{PM_{2.5}} \right)^2 + \left(\frac{\delta V}{V} \right)^2 + \left(\frac{\delta b_{sp}}{b_{sp}} \right)^2 + \left(\frac{\delta f_v}{f_v} \right)^2 \quad \text{Eq. A5}$$

where

$$\left(\frac{\delta f_v}{f_v} \right)^2 = \frac{(f_v - 1)^2}{f_v^2} \left[\left(\frac{\delta \kappa}{\kappa} \right)^2 + \left(\frac{\delta RH}{RH \cdot (100 - RH)} \right)^2 \right] \quad \text{Eq. A6}$$

The average relative 2- σ $PM_{2.5}$ uncertainty was 26% for dry hourly predictions, increasing with higher RH cutoffs. A cut-off of RH = 80% has been applied to our data, above which hygroscopic uncertainties, as well as total water mass, dominate.
