

39 **Abstract**

40 The occurrence of non-liquid and liquid physical states of submicron atmospheric
41 particulate matter (PM) downwind of an urban region in central Amazonia was investigated.
42 Measurements were conducted during two Intensive Operating Periods (IOP1 and IOP2) that
43 took place during the wet and dry seasons, respectively, of the GoAmazon2014/5 campaign. Air
44 masses representing variable influences of background conditions, urban pollution, and regional
45 and continental scale biomass burning passed over the research site. As the air masses varied,
46 particle rebound fraction, an indicator of physical state, was measured in real time at ground
47 level using an impactor apparatus. Micrographs collected by transmission electron microscopy
48 confirmed that liquid particles adhered while non-liquid particles rebounded. Relative humidity
49 (RH) was scanned to collect rebound curves. When the apparatus RH matched ambient RH, 95%
50 of the particles adhered as a campaign average. Secondary organic material, produced for the
51 most part by the oxidation of volatile organic compounds emitted from the forest, produces
52 liquid PM over this tropical forest. During periods of anthropogenic influence, by comparison,
53 the rebound fraction dropped to as low as 60% at 95% RH. Analyses of the mass spectra of the
54 atmospheric PM by positive-matrix factorization (PMF) and of concentrations of carbon
55 monoxide, total particle number, and oxides of nitrogen were used to identify time periods
56 affected by anthropogenic influences, including both urban pollution and biomass burning. The
57 occurrence of non-liquid PM at high RH correlated with these indicators of anthropogenic
58 influence. A linear model having as output the rebound fraction and as input the PMF factor
59 loadings explained up to 70% of the variance in the observed rebound fractions. Anthropogenic
60 influences can contribute to the presence of non-liquid PM in the atmospheric particle population
61 through the combined effects of molecular species that increase viscosity when internally mixed

62 with background PM and increased concentrations of non-liquid anthropogenic particles in
63 external mixtures of anthropogenic and biogenic PM.

64 **1. Introduction**

65 Particulate matter (PM) directly affects the Earth's climate by scattering and absorbing
66 solar radiation and indirectly by effects on clouds (Ramanathan et al., 2001). The magnitude of
67 these effects depends in part on the physical and chemical properties of the particulate matter
68 (Andreae and Rosenfeld, 2008). The physical state of PM, as liquid or non-liquid, can influence
69 the growth rates of small particles and ultimately the production of cloud condensation nuclei
70 (CCN) (Riipinen et al., 2011; Perraud et al., 2012). Liquid particles pose negligible in-particle
71 diffusion barriers for condensing species and therefore can grow rapidly. By comparison, non-
72 liquid particles, referring to both semisolid and solid particles, can have a different behavior. For
73 some conditions, semisolid particles can grow slowly because of in-particle limits on rates of
74 molecular diffusion, and solid particles can grow even more slowly when limited to surface
75 adsorption (Riipinen et al., 2012; Shiraiwa and Seinfeld, 2012; Li et al., 2015). Liquid compared
76 to non-liquid PM can also affect reactivity (Kuwata and Martin, 2012; Li et al., 2015). The
77 consequences of the differing growth mechanisms can be that the growth of small particles is
78 relatively disfavored in a population of liquid particles of heterogeneous sizes, as compared to a
79 similar population of non-liquid particles (Zaveri et al., 2014). An implication can be that CCN
80 concentrations are ultimately greater for a population of non-liquid particles that grows to CCN
81 sizes, as compared to a population of liquid particles.

82 Secondary organic material (SOM), produced by the oxidation of biogenic volatile
83 organic compounds (BVOCs), is a major source of atmospheric PM, especially over forested
84 regions where SOM often dominates the mass concentration of submicron PM (Hallquist et al.,
85 2009; Jimenez et al., 2009). The physical state of SOM has been studied in both laboratory
86 (Vaden et al., 2011; Kuwata and Martin, 2012; Perraud et al., 2012; Saukko et al., 2012; Renbaum-

87 Wolff et al., 2013; Kidd et al., 2014; Bateman et al., 2015; Li et al., 2015; Liu et al., 2015; Pajunoja
88 et al., 2015; Song et al., 2015) and ambient environments (Virtanen et al., 2010; O'Brien et al.,
89 2014; Bateman et al., 2016; Pajunoja et al., 2016). For background conditions of the Amazonian
90 tropical forest, a region dominated by isoprene-derived SOM and high RH, PM was mostly
91 liquid (Bateman et al., 2016). For a boreal forest in northern Europe, a region dominated by
92 pinene-derived SOM and low RH, PM was largely non-liquid (Virtanen et al., 2010). The
93 combined set of laboratory and ambient studies show that the physical state of PM having high
94 SOM content depends on the surrounding relative humidity (RH). This effect arises in part
95 because organic particles are hygroscopic to various extents depending on composition. Water
96 absorption, which is favored at elevated RH, has a plasticizing effect on physical state (Koop et
97 al., 2011).

98 The physical state of PM affected by urban pollution over forests remains largely
99 unexplored. A single day of ambient observations in central Amazonia suggested that ambient
100 PM affected by urban pollution tended toward a non-liquid state (Bateman et al., 2016), and
101 laboratory studies support the idea of an important modulating role of pollution in the physical
102 state of SOM. A non-liquid state was favored for SOM produced from single-ring aromatic
103 species (Liu et al., 2015; Song et al., 2015) as well as mixed with polycyclic aromatic
104 hydrocarbons (PAHs) (Zelenyuk et al., 2012; Abramson et al., 2013; Berkemeier et al., 2014).
105 Organic molecules associated with urban pollution and industrial activities tend to be less
106 hygroscopic than biogenic SOM (Hersey et al., 2013). When internally mixed within biogenic
107 SOM, the anthropogenic molecules have a tendency to reduce water uptake and thereby increase
108 the viscosity of the mixed particles. A similar line of reasoning leads to an identical hypothesis
109 for the effects of biomass burning emissions. Compared to prevailing background conditions of

110 SOM dominance over many forests, PM produced by biomass burning leads to a net effect of
111 decreased water uptake when the PM mixes into the background particle population (Dusek et
112 al., 2011).

113 The data sets presented herein provide observational evidence on the effects of
114 anthropogenic influences on the physical state of ambient particulate matter. All other factors
115 being equal, the lack of particle rebound is an indicator of liquid PM (Bateman et al., 2015).
116 Conversely, the occurrence of particle rebound is an indicator of non-liquid PM. Rebounding and
117 adhering particles were separately collected for conventional and chemical imaging. The data
118 sets were collected during the two Intensive Operating Periods (IOP1 and IOP2) of the
119 GoAmazon2014/5 experiment, corresponding to the wet and dry seasons, respectively (Martin et
120 al., 2016). The research site (-3.2133° , -60.5987°), called “T3”, was located 70 km downwind of
121 the city of Manaus, population two million, in central Amazonia. Air masses representing
122 background conditions, urban pollution, and regional and continental scale biomass burning
123 passed over the research site. Herein, anthropogenic influence refers to all but background
124 conditions. Under background conditions, the submicron PM in this region is dominated by
125 biogenic SOM (Chen et al., 2009; Chen et al., 2015).

126 **2. Experimental**

127 An impactor apparatus was used for the study of particle rebound (Bateman et al.,
128 2014; Bateman et al., 2015; Bateman et al., 2016; Li et al., 2016). The apparatus was housed
129 inside a temperature-controlled research trailer at the T3 site. Particulate matter was sampled at 5
130 m above ground through copper tubing having an outer diameter of 13 mm (0.5 inch). In
131 sequence, a drying unit reduced the sampled flow to 25% RH or lower, a Differential Mobility
132 Analyzer (DMA, TSI 3085) selected a subpopulation of dried particles having a narrow

133 distribution of electric mobility, and a humidification unit (Nafion tubes; Perma Pure, MD 110)
134 elevated the RH of the mobility-filtered flow to the targeted RH of a measurement. The drying
135 unit consisted of a Nafion drier in series with a silica gel diffusion drier, and the silica gel was
136 replaced every two days. After passing the dryer, DMA, and humidifier, the resulting flow was
137 split and passed through three impactors operated in parallel. Labels *i*, *ii*, and *iii* refer to each of
138 the three impactors. Each impactor was operated at a flow rate of 1.0 Lpm, corresponding to a
139 setpoint aerodynamic diameter d_a^* of 84.9 ± 5.4 nm (Bateman et al., 2014). Particle number
140 concentrations, denoted by N_i , N_{ii} , or N_{iii} , exiting the impactors were measured by three
141 independent condensation particle counters (CPC, TSI 3010). Measurements were conducted
142 from February 14 to March 16, 2014, during IOP1 and from September 4 to October 15, 2014,
143 during IOP2.

144 The three impactors differed from one another by having uncoated, coated, or no
145 impaction plate. The impactor having the uncoated plate passed both non-impacted and
146 rebounded particles. The impactor having the coated plate (Dow Corning High-Vacuum Grease)
147 passed only non-impacting particles. The impactor having no plate passed all particles. Its
148 purpose was to serve as a compensation arm for possible miscellaneous particle losses, such as
149 wall loss. Based on the particle number concentrations measured downstream of the impactors,
150 the rebound fraction was calculated as follows (Bateman et al., 2014):

151
$$f = \frac{N_i - N_{ii}}{N_{iii} - N_{ii}} \quad (1)$$

152 The terms N_i , N_{ii} , and N_{iii} represent the particle number concentration measured downstream of
153 the impactors having uncoated, coated, and no impaction plate, respectively. The standard

154 deviation of the rebound fraction was based on error propagation for an uncertainty in N of $N^{1/2}$
155 (Agarwal and Sem, 1980).

156 A rebound curve representing $f(\text{RH})$ constituted an individual data set. For most
157 measurements, the DMA setting for electric mobility was held constant (typically 190 nm), the
158 RH in the humidification unit was changed stepwise every few minutes, and f was continuously
159 recorded. Additional protocols of DMA settings and RH profiles were used in a few cases. All
160 protocols, including differences between IOP1 and IOP2, are described in Section S1 of the
161 Supplement.

162 In conjunction with the rebound measurements, particles were collected for imaging by
163 transmission electron microscopy (TEM) and scanning transmission X-ray microscopy (STXM).
164 Images in some cases can directly suggest the liquid or non-liquid state of individual particles
165 (O'Brien et al., 2014; Wang et al., 2016). Samples for imaging were collected as follows. A fourth
166 impactor was added in parallel with the other three impactors. Imaging substrates were affixed to
167 the impaction plate, and multiple substrates were mounted to the plate for concurrent collection
168 for the various microscopy techniques. Substrates included grids coated with Formvar (EMJapan
169 Co., Tokyo, Japan) or lacey carbon (Ted Pella Inc., USA) for TEM and silicon nitride membrane
170 windows (Silson, UK) for STXM. The flow rate and setpoint aerodynamic diameter of the fourth
171 impactor were the same as for the other three impactors. The collected particles represented
172 those that adhered to the substrate at impact, and an assumption in the analysis is that rebound
173 from the substrate was similar to that from the uncoated plate. The flow through this fourth
174 impactor was pulled by an in-line TEM autosampler (Arios Inc., Tokyo, Japan (Adachi et al.,
175 2014)). In this way, the setup separately collected particles that adhered to the grids on the
176 impaction plate and particles that rebounded from the impaction plate and passed to the

177 autosampler. The autosampler collected particles having aerodynamic diameters from 60 to 350
178 nm. Particles adhered to the TEM substrates in the autosampler yet rebounded from the TEM
179 substrates in the impactor because of the significantly different particle impact velocities
180 between the two impactors (i.e., cut-point and impactor design). Samples were collected for
181 TEM analysis between September 30 and October 15, 2014. Samples were collected for STXM
182 analysis between 1:00 and 10:00 (UTC) on October 1, 2014.

183 Microanalysis of individual particles of the collected PM was performed using two
184 instruments: (1) a transmission electron microscope (TEM; JEOL, JEM-1400) equipped with an
185 energy-dispersive X-ray spectrometer (EDS; Oxford Instruments) and (2) a scanning
186 transmission X-ray microscope interfaced for near-edge X-ray absorption fine structure
187 spectroscopy (STXM/NEXAFS; Advanced Light Source, Berkeley). For TEM, imaging was by
188 bright-field microscopy, and particle composition was investigated by EDS. For STXM, at a
189 fixed photon energy an image was obtained by detecting the transmitted light at each pixel while
190 raster scanning the sample. Spatially resolved NEXAFS spectra were obtained from a set of
191 images recorded at different photon energies. The NEXAFS spectra provided chemical bonding
192 information and quantitative elemental ratios (Moffet et al., 2010a;Moffet et al., 2010b;O'Brien
193 et al., 2014;Piens et al., 2016). Section S2 of the Supplement presents further technical
194 information concerning the TEM and STXM/NEXAFS analyses.

195 Additional co-located measurements used in the data analysis herein included a High-
196 Resolution Time-of-Flight Aerosol Mass Spectrometer (AMS; Aerodyne Inc.), a Single-Particle
197 Soot Photometer (SP2; Droplet Measurement Technologies), a size-resolved Cloud
198 Condensation Nuclei Counter (CCNC; Droplet Measurement Technologies, CCNC-100), a
199 Condensation Particle Counter (TSI, CPC 3772) for measuring particle number concentrations,

200 an Integrated Cavity Output Spectroscopy (ICOS; Los Gatos) for measuring carbon monoxide
201 (CO) concentration, and a Trace Level Enhanced detector (TLE; Thermo Scientific, Model 42i,
202 with further customization) for the measuring concentrations of nitrogen oxides (NO_y). The
203 latter three instruments were deployed at the T3 site as part of the USA Department of Energy
204 (DOE) Atmospheric Radiation Measurement (ARM) Climate Research Facility, including the
205 ARM Mobile Facility One (AMF-1) and the Mobile Aerosol Observing System (MAOS)
206 (Mather and Voyles, 2013; Martin et al., 2016). This facility also collected the meteorological
207 data used herein, including temperature, relative humidity, wind direction, and wind speed. The
208 AMS measured the chemical composition in real-time of non-refractory submicron particles
209 (DeCarlo et al., 2006). The high-resolution data of the organic component in “V-mode” was used
210 in conjunction with positive-matrix factorization (PMF) analysis (Ulbrich et al., 2009) to obtain
211 statistical factors and the associated time series of factor loadings for each season (de Sá et al.,
212 2016). As a surrogate for concentrations of black carbon, the SP2 measured the time-resolved
213 scattering and incandescence produced by irradiated refractory, light-absorbing components of
214 individual particles having volume-equivalent diameters between 70 and 600 nm (Schwarz et al.,
215 2006; Moteki and Kondo, 2007). The size-resolved CCN activity was obtained by classifying dry
216 particles using a DMA (TSI 3081) and then exposing them successively to a range of
217 supersaturations inside the CCNC (Thalman et al., in preparation). The hygroscopicity and CCN
218 activity were analyzed via κ -Köhler theory, which relates particle critical supersaturation to the
219 initial dry diameter and hygroscopicity (Petters and Kreidenweis, 2007; Petters et al., 2009).

220 **3. Results and Discussion**

221 *3.1 Rebound Observations*

222 Particle rebound or particle adhesion at impact depends on the balance of energies.
223 Particle rebound occurs when the kinetic energy before impact is greater than the sum of
224 dissipation and surface adhesion energies after impact (Tsai et al., 1990; Bateman et al., 2014).
225 The dissipation energy of liquid particles is much greater than that of solid particles because of
226 additional mechanisms of dissipation available to the former. As a point of reference, the
227 transition from rebound to adhesion occurs across a viscosity transition of 10^2 to 1 Pa s for
228 sucrose particles for the operating conditions of the impactor (Bateman et al., 2015). The
229 viscosity range corresponding to the rebound transition can depend on particle composition, but
230 this aspect is not investigated herein.

231 The rebound curves of particles of 190-nm mobility diameter are shown in Figure 1a for
232 IOP1 and IOP2. For $RH < 50\%$, the rebound fraction was between 0.8 and 1.0. For $RH > 50\%$,
233 the rebound fraction decreased monotonically to a low value, typically zero. The shape of the
234 rebound curve in Figure 1a is similar to that for particles of secondary organic material produced
235 in the Harvard Environmental Chamber (Bateman et al., 2015). The rebound fraction of SOM
236 particles produced from isoprene or α -pinene became zero for $RH > 90\%$.

237 The subset of the data for which the apparatus RH matched the ambient RH is shown in
238 Figure 1b (cf. Section S3 of Supplement). In light of the distribution of ambient RH values (cf.
239 Figure 1c), the data set in Figure 1b implies that submicron PM in this tropical environment was
240 liquid most of the time. Bateman et al. (2016) reported such a result for observations under
241 background conditions at this site for data sets collected in 2013 a few months before
242 GoAmazon2014/5 began. The present results reported for GoAmazon2014/5 represent a longer

243 time series (i.e., 550 compared to 30 rebound curves) and reinforce the generality of the earlier
244 result of Bateman et al. (2016) of the prevalence of liquid PM for this forested region under
245 background conditions.

246 In the larger set of observations of the present study, what also emerges is that the
247 rebound fraction remained in median at 0.05 even at 95% RH, implicating the presence of
248 externally mixed PM in the atmosphere. Approximately 5% of the particles were non-liquid even
249 to 95% RH in both the wet and dry seasons (i.e., IOP1 and IOP2) (Figures 1a and 1b). At times,
250 rebound fractions of up to 0.4 occurred for $RH > 90\%$. Elevated rebound fractions were observed
251 more frequently in IOP2 than IOP1. During IOP2, which was extensively influenced by biomass
252 burning, non-liquid particles in median constituted a fraction of 0.3 at 70% RH and a fraction of
253 0.1 at 90%. These RH values prevailed approximately 10% of the time. Events of elevated
254 rebound fraction were associated with the pollution plume from Manaus during IOP1 in the wet
255 season and with both this urban plume as well as increased regional biomass burning during
256 IOP2 in the dry season (cf. Section 3.2).

257 Probability density functions (PDF) of rebound fraction at 75% RH based on the data
258 sets of Figure 1a are shown in Figure 2 for (a) IOP1 and (b) IOP2 for three types of air masses
259 during day and night time periods. Daytime represents 12:00 to 16:00 (local time) (16:00 to
260 20:00 UTC) and nighttime represents 23:00 to 04:00 (local time) (03:00 to 08:00 UTC). Air
261 masses were identified as background, as influenced by local to regional biomass burning, or as
262 influenced by Manaus pollution. The classification scheme was based on concentration regimes
263 of particle number, carbon monoxide, and odd nitrogen (NO_y), as presented in Section S4 of the
264 Supplement. Background conditions included contributions both from natural processes and
265 from the long-distance transport and extensive oxidation of biomass burning emissions (Chen et

266 al., 2009;Martin et al., 2010). Natural processes in this region were dominated by the production
267 of secondary organic material from oxidation of plant emissions (Martin et al., 2010;Poschl et
268 al., 2010). Figure 2a shows that the mode value of the PDF shifted higher under the influence of
269 Manaus pollution compared to background conditions, meaning that rebound became more
270 probable and indicating an increasing presence of non-liquid PM at 75% RH. In Figure 2b, the
271 mode value shifted even higher under the influence of biomass burning. For each type of air
272 mass, the nighttime mode values were higher than the daytime equivalents. The day-night
273 differences were lowest under background conditions.

274 The increase in rebound at night might be explained by a combination of interacting
275 factors. A shallow stable nocturnal boundary layer can trap and thereby concentrate
276 anthropogenic non-liquid particles emitted at night from local emissions, including smoldering
277 fires during IOP2. During the day, the boundary layer expands and dilution is more effective. In
278 addition, the production of liquid secondary organic material by biogenic processes is
279 comparatively more rapid.

280 For further analysis, the rebound curves recorded under background conditions were
281 averaged separately for IOP1 and IOP2 (cf. Figure 1a and Section S5 of the Supplement). These
282 two background-average curves served as references against which deviations in rebound
283 fraction were calculated for all air masses. Rebound deviation represents the excess non-liquid
284 PM over background conditions after detrending the data for the dependence on relative
285 humidity. The rebound deviations for IOP1 and IOP2 are plotted in Figure 3. Rebound deviations
286 as high as +0.5 in rebound fraction were observed. Statistics of Figure 3 are summarized in Table
287 S1, including for the subset of measurements matched with the ambient RH. For the full set of
288 data, including the full range of RH, rebound deviations greater than 0.1 represented 17% and

289 35% of the observations during IOP1 and IOP2, respectively. These deviations, corresponding to
290 increased rebound and thus indicating an increasing presence of non-liquid PM, corresponded to
291 the anthropogenic influences, as developed further in Section 3.2.

292 *3.2 Relationships between Rebound and Other Observations*

293 3.2.1 Case Studies

294 Transitions between background and polluted conditions across 24 hour-periods are
295 presented in Figure 4 as representative examples for each IOP. The bottom panel shows the
296 deviation in rebound fraction relative to the background-average curve (cf. Section S5 of
297 Supplement). Color coding distinguishes relative humidity. From bottom to top, other panels in
298 the figure show temperature, wind direction, wind speed, relative fractions of two groups of
299 AMS PMF factor loadings, black carbon (BC) concentration, sulfate concentration, and total
300 submicron PM mass concentration. Processes contributing to the loading of PMF group A are
301 largely associated with the background atmosphere of Amazonia, including the possibility of
302 long-range transport and extensive oxidation of biomass burning emissions. Processes
303 contributing to the loading of PMF group B are largely associated with urban pollution and local
304 and regional biomass burning (cf. Section S6 of Supplement).

305 Shifts in the deviation in the rebound fraction from the background-average curve are
306 apparent in the time series in the bottom panels of Figure 4. At these times, the fractional loading
307 of PMF group A decreased and that of PMF group B increased, indicating a shift away from
308 background conditions. Background conditions were characterized by high loadings of PMF
309 group A and small rebound deviations. In the left panel (IOP1), in an example of one type of an
310 anthropogenic event, black carbon concentration and the fractional loading of PMF group B
311 abruptly increased together. The rebound deviation simultaneously increased, indicating an

312 increasing presence of non-liquid PM, especially above 70% RH. In the right panel (IOP2), in an
313 example of a second type of an anthropogenic event, the background air mass was gently
314 replaced by an air mass characterized by small increases in rebound deviation and fractional
315 loading of PMF group B yet lacking an associated increase in black carbon concentration. In an
316 example of a third type of anthropogenic event, this air mass was later replaced by an air mass
317 characterized by a strong increase in the fractional loading of PMF group B, total PM mass
318 concentration, and rebound deviation. Around 15:00 (UTC), a convective event associated with
319 rainfall decreased temperature, changed wind direction, and increased wind velocity, and
320 background conditions returned.

321 TEM images collected during the time periods of elevated rebound corroborate the
322 foregoing interpretation of liquid and non-liquid PM for adhering compared to rebounding
323 particles. Images of particles that adhered to the TEM substrates in the impactor at 95% RH are
324 shown in Figure 5a. The images were taken at a tilt angle of 60° so that the aspect ratio of the
325 particles could be viewed. The images show that most adhering particles spread out across the
326 substrate, indicating flattening upon impact, as expected for liquid particles. Some of these
327 adhering particles had a mixed composition, appearing as solid cores surrounded by halos of
328 flattened liquid shells. The horizontal dimensions of the flattened particles approached 1 to 2 μm
329 for vertical dimensions of tens of nanometers. Pöschl et al. (2010) previously recorded similar
330 images for ambient particles in the wet season of 2008 in central Amazonia during the
331 Amazonian Characterization Experiment (AMAZE-08) (Martin et al., 2010). For comparison to
332 the images of the adhering particles, images of particles that rebounded at 95% RH from the
333 impaction plate are shown in Figure 5b. These particles were collected downstream of the
334 impactor. The images show that these particles had high vertical dimensions and spherical or

335 dome-like morphologies and thus suggest that the particles experienced little deformation upon
336 impact, as expected for solid particles.

337 3.2.2 Descriptive Statistics

338 The results of Figures 3 and 4 are further analyzed in Figure 6. Statistics of rebound
339 deviation are shown by box-whisker representation for different windows of relative humidity
340 Figure S1 of the Supplement presents an additional level of detail. The data sets were segregated
341 for presentation by IOP1/IOP2, daytime/nighttime, and air mass type. For background
342 conditions, the rebound deviations relative to their average were mostly zero, indicating that
343 there was low variability among different background air masses. The exception was for the
344 night periods of IOP1. By comparison, under anthropogenic influences, the rebound deviation
345 was positive for both IOPs. Positive deviations were most significant between 65% and 95% RH.
346 In all cases, the nighttime deviations were greater than the daytime counterparts. For IOP2, the
347 prevalence of biomass burning confounded separate classifications of urban pollution and
348 biomass burning, and a classification of biomass burning took precedent. Rebound deviations
349 were strongest during these time periods. Statistics of the analysis are further summarized in
350 Table S2 (cf. Section S7 of Supplement). The average O:C ratios for the various air-mass
351 classifications can be found in Table S3 of the Supplement.

352 3.2.3 Statistical correlations

353 Scatter plots of rebound deviation with environmental variables of ambient temperature,
354 wind speed, and wind direction show no correlation for both daytime and nighttime datasets (cf.
355 Figure S2 of the Supplement). Scatter plots of rebound deviation with some possible
356 anthropogenic influences are presented in Figure S3. Soot, typically characterized by a solid core
357 region of black carbon, is expected in abundance both in urban pollution and biomass burning

358 emissions. There was, however, no correlation between rebound deviation and black carbon
359 concentrations. There was also no correlation between rebound deviation and total particle mass
360 concentration. Rebound deviation and sulfate concentration weakly anti-correlated, which might
361 be expected given the hygroscopicity of sulfate. Sulfate concentrations, however, were a poor
362 indicator of anthropogenic influence in this region because the variability in background
363 concentrations was comparable in magnitude to any urban influence (de Sá et al., 2016). As a
364 caveat, an assumption in correlation tests is that variance arises from a single variable, and the
365 possibility of two or more contributing or interacting factors is not directly considered.

366 Given that water uptake is an important process for softening organic material, scatter
367 plots of the rebound deviation at 75% RH with the hygroscopicity parameter κ are shown in
368 Figures 7a and 7b for the data sets from IOP1 and IOP2, respectively. Lower values of κ
369 represent decreased equilibrium water uptake for a fixed RH (Petters and Kreidenweis, 2007).
370 The plots show that the rebound deviation increased as the κ value decreased, meaning that
371 particles of lower hygroscopicity were less prone to being in liquid form.

372 The apparent shift to higher κ values from IOP1 to IOP2 might be explained by
373 instrumental methods. During IOP1, κ values were measured using the impactor apparatus at
374 sub-saturated RH (i.e., < 100%) (cf. Section S8 of the Supplement). During IOP2, κ values were
375 measured using a size-resolved CCN instrument at super-saturated RH (i.e., > 100%) (Thalman
376 et al., in preparation). Sub- and supersaturated κ values can be systematically different (Petters and
377 Kreidenweis, 2007; Rühl et al., 2016).

378 3.2.4 Chemical characteristics of rebounded particles

379 An analysis of the relationship between rebound deviation and chemical characteristics is
380 presented in Figure 8 based on the fractional loading of PMF group B. The data sets are

381 segregated for presentation by IOP1/IOP2, daytime/nighttime, and four bands of fractional
382 loading. Within each panel, box-whisker statistics of rebound deviation are shown for different
383 windows of relative humidity, ranging from 50% to 95%. The figure shows that the rebound
384 deviation increased at all RH values as the fractional loading of group B increased. The
385 background-average curve used as the reference for rebound deviation corresponded to a
386 fractional loading of 0.00 to 0.15 for group B or correspondingly of 0.85 to 1.00 for group A. An
387 increasing fractional loading of group B represented greater anthropogenic influence. The
388 inference is that anthropogenic influences, represented by a combination of urban pollution and
389 biomass burning, affected chemical composition in ways that increased the presence of non-
390 liquid PM above 50% RH.

391 Scatter plots between rebound deviation at 75% RH and the fractional loading of group B
392 are shown in Figures 9a and 9b for the data sets of the two IOPs. The data points are colored
393 according to the value of the hygroscopicity parameter κ . The plots show that rebound deviation
394 increased for low hygroscopicity and high fractional loading of group B, in agreement with the
395 presentation in Figures 7a and 7b and Figure 8. Figures 9a and 9b further show in explicit
396 fashion that the highest rebound deviations occurred during time periods affected by biomass
397 burning and urban pollution, as characterized by the lowest values of κ and the highest fractional
398 loadings of group B. Smaller κ values for lower fractional loadings of group B can be explained
399 by the differences in O:C ratios between group A and B (Massoli et al., 2010): the O:C ratios
400 were 0.95/0.95 (IOP1/IOP2) and 0.42/0.54 for groups A and B, respectively.

401 A model to predict rebound deviation based on chemical characteristics was constructed.
402 The fractional loadings of PMF group A and B were used as model inputs, and model
403 coefficients represented the effects of RH across nine bands (cf. Section S9 of the Supplement).

404 The observed and predicted rebound deviations are plotted in Figure 10. The corresponding
405 coefficients R^2 of determination were 0.65 and 0.72 for IOP1 and IOP2, respectively. Predicted
406 values were biased high for low rebound deviation and biased low for high rebound deviation.
407 The magnitudes of the model coefficients represented the relative importance of the two PMF
408 groups in predicting rebound deviation (Table S5). In this regard group B dominated during both
409 IOPs. This result is consistent with the role of anthropogenic influences in shifting the PM
410 population to fewer liquid particles and more non-liquid particles.

411 Analysis by STXM/NEXAFS supports the foregoing narrative of anthropogenic
412 influence as a modulator between liquid and non-liquid PM. Rebounded particles were collected
413 on October 1 during a time period classified as influenced by biomass burning emissions. The
414 carbon K-edge spectrum is shown in Figure 11a, and the STXM image is shown in Figure 11b. A
415 notable feature of the NEXAFS spectrum of the rebounded particles is the strong double bond.
416 Pöhlker et al. (2012) previously collected NEXAFS spectra for samples collected at a
417 background site in central Amazonia, and the strong feature of a double bond was absent. The
418 spectra instead resembled those of different types of reference biogenic secondary organic
419 material.

420 For comparison to the spectrum collected of the rebounded particles, carbon K-edge
421 spectra are shown for carbonaceous particles collected in other field and laboratory studies.
422 Based on these results as well as those of the rebound measurements, a hypothesis of soot or
423 black carbon to explain the rebounding particles was ruled out on three grounds. The double-
424 bond feature was homogeneously distributed throughout the particles (Figure 11b) compared to
425 inclusions that are typical for soot (Moffet et al., 2013;Knopf et al., 2014;O'Brien et al., 2014),
426 rebound deviation and black carbon concentrations did not correlate (Figure S3), and the

427 spectroscopic signatures of rebounded particles and soot did not match (Figure 11a). A
428 hypothesis of VOC-derived secondary organic material, including possible changes because of
429 shifts from HO₂ to NO-dominant chemistry (Liu et al., 2016a;Liu et al., 2016b), was also
430 eliminated by comparison of the NEXAFS spectrum of the rebounded particles to the reference
431 spectra for laboratory samples. An important caveat to these interpretations is that some of the
432 hypotheses ruled out for this particular day might still have a role to play on other days.

433 There was exceptional uniformity in the particle population characterized by
434 STXM/NEXAFS, which could suggest that the rebounding PM represented distant sources or
435 alternatively a strong single nearby source. The gray region around the red line in Figure 11a
436 illustrates the low variability across the population of analyzed particles (Figure 11b). Moreover,
437 the variability in the O:C ratio determined by the NEXAFS analysis was just ± 0.01 for O:C =
438 $0.34 (\pm 0.03) [\pm 0.01]$, where the value in parentheses was the uncertainty of the measurement
439 and the value in the bracket was the variability across the image in Figure 11b. During the same
440 time period, the O:C ratio of the ambient PM was 0.77 ± 0.04 by AMS measurements. Hence,
441 the rebounding particles were significantly less oxidized, as consistent with increased double
442 bond (C=C) content and increased fractional loading of PMF group B.

443 Several speculations can be made for the origins of the particles leading to the data set of
444 October 1. The chemical constituents giving rise to the double bonds might derive from
445 biological degradation products from incomplete combustion, such as in biomass burning
446 (Tivanski et al., 2007;Keiluweit et al., 2010). Unexplained by this speculation, however, is the
447 absence of a potassium signature in the NEXAFS spectra, which is typical of most biomass
448 burning. Future collection of NEXAFS spectra would be well motivated for the several different
449 types of biomass burning in an Amazonian context, such as from nearby fields, regionally around

450 Manaus, two or three days away from other regions of South America, and up to a week away
451 from Africa. An alternative speculation for this data set is that solid organic particles produced
452 by the impact of raindrops on wet soil surfaces could be making a contribution to the rebounded
453 PM analyzed here (Joung and Buie, 2015). Wang et al. (2016) recently reported detection of the
454 airborne soil organic particles generated by this mechanism over agricultural fields in the central
455 plains of the USA, and the corridor from Manaus to T3 has many agricultural fields. The
456 rebounded particles collected at T3 and the agricultural particles reported in Wang et al. (2016)
457 both had a homogeneous distribution of double bonds and similar elemental ratios and
458 absorption features. Even so, preliminary analysis across the extended data set at T3 between
459 rebound and nearby precipitation did not show a clear correlation. Another speculation relates to
460 the importance of aromatic compounds as hardening agents. Several gas-phase aromatic
461 compounds, laden with double bonds, were measured during IOP1 and IOP2, including toluene,
462 benzene, trimethylbenzene, and xylenes by proton-transfer mass spectrometry (Liu et al., 2016b).
463 Rebound deviation correlated positively with the concentrations of these compounds during both
464 IOPs, and the correlation was stronger during the night. Laboratory studies show that the uptake
465 of polycyclic aromatic hydrocarbons during the formation of biogenic PM can increase the
466 viscosity of the PM (Vaden et al., 2011; Zelenyuk et al., 2012; Abramson et al., 2013; Liu et al.,
467 2015).

468 **4. Conclusions**

469 Under background conditions, particles composed primarily of highly-oxidized biogenic
470 PM were hygroscopic, and they were liquid for the RH values prevailing over Amazonia at
471 surface level. Anthropogenic influences of urban pollution and biomass burning decreased
472 hygroscopicity, and non-liquid PM became more favored. The shift in physical state correlated

473 with increasing concentrations of C=C functionalities and increasing fractional loadings of AMS
474 PMF group B, both of which were indicative of anthropogenic influences. These results
475 demonstrate the importance of anthropogenic influences for altering the physical properties of
476 ambient particulate matter over tropical forests.

Acknowledgments. Institutional support was provided by the Central Office of the Large Scale Biosphere Atmosphere Experiment in Amazonia (LBA), the National Institute of Amazonian Research (INPA), and Amazonas State University (UEA). The Office of Biological and Environmental Research of the Office of Science of the United States Department of Energy is acknowledged for funding, specifically the Atmospheric Radiation Measurement (ARM) Climate Research Facility, the Atmospheric System Research (ASR) Program, the Division of Chemical Sciences, Geosciences, and Biosciences (Advanced Light Source at Lawrence Berkeley National Laboratory, Beamlines 5.3.2 and 11.0.2), the Environmental Molecular Sciences Laboratory (EMSL), and Pacific Northwest National Laboratory (PNNL). Further funding was provided by the Amazonas State Research Foundation (FAPEAM), the São Paulo State Research Foundation (FAPESP), the Brazil Scientific Mobility Program (CsF/CAPES), the USA National Science Foundation, and the Japanese Ministry of the Environment. The work was conducted under scientific licenses 001030/2012-4 of the Brazilian National Council for Scientific and Technological Development (CNPq).

Figure Captions

- Figure 1.** Rebound fraction as a function of apparatus relative humidity during IOP1 (blue) and IOP2 (red), corresponding respectively to the wet and dry seasons in central Amazonia. Panel (a) shows all measurements. Panel (b) shows the subset of data for which the apparatus RH matched the ambient relative humidity (cf. Supplement S3). Panel (c) represents the probability density function of relative humidity at the T3 site during the wet and dry seasons of 2014. Points represent rebound measurements for particles having mobility diameters of 190 nm. Statistics of measurements group by relative humidity are represented in box-whisker format. The horizontal line within a box indicates the median of the points, the horizontal lines at the box boundaries indicate quartiles, and horizontal lines most distant from the box indicate 10% and 90% quantiles. For comparison, the black line shows the rebound curve for particles of secondary organic material produced by photooxidation of an isoprene/ α -pinene mixture in the Harvard Environmental Chamber (Bateman et al., 2015).
- Figure 2.** Probability density function of rebound fraction during (a) IOP1 and (b) IOP2 for categorization by type of air mass and time of day: background conditions (green), Manaus pollution (red), and biomass burning (orange). Solid and dashed lines respectively represent daytime (12:00 to 16:00, local time; 16:00 to 20:00, UTC) and nighttime measurements (23:00 to 04:00, local time; 03:00 to 08:00 UTC). Results are shown for an apparatus RH of 75% and for particles having a mobility diameter of 190 nm. No data sets fit the classification of Manaus pollution during the nighttime of IOP2 (i.e., absence of red dashed line in panel (b)).

- Figure 3.** Deviation in rebound fraction relative to the average curve for background conditions during (a) IOP1 and (b) IOP2. Red, purple, and green coloring correspond respectively to the RH regions of rebound, transition, and adhesion for the background-average curve. Results are shown for particles having a mobility diameter of 190 nm.
- Figure 4.** Time series of representative species during two pollution events for IOP1 and IOP2 (left and right sides of figures, respectively). “Total mass concentration” plotted in the figure represents the sum of the AMS and black carbon mass concentrations measured for submicron PM. The PMF mass fractions are expressed in relative terms to one another and necessarily sum to unity. Time on the abscissa is expressed in UTC.
- Figure 5.** Representative TEM images of (a) adhering and (b) rebounding PM at 95% RH collected between 14:15 and 18:15 (UTC) on September 30, 2014, during IOP2. The rebound fraction during the time period of collection approached 0.3. The arrows in panel (b) highlight the locations of particles having high vertical dimensions and spherical or dome-like morphologies, as expected for solid particles.
- Figure 6.** Deviation in rebound fraction for categorization by type of air mass and time of day. The box-whisker representation of the 10%, 25%, 50%, 75%, and 90% quantiles of statistics for each RH bin is explained in the caption to Figure 1. Air mass categorization is as for Figure 2. Results are shown for particles having a mobility diameter of 190 nm.

Figure 7. Scatter plot of rebound deviation with the hygroscopicity parameter κ for (a) IOP1 and (b) IOP2. For clarity of presentation, data points are shown for apparatus RH values between 73 and 78%, although the trend applies more broadly. As a guide to the eye, in each panel data are divided into four groups, and medians and quartiles of the groups are plotted as black circles and whiskers, respectively. Different techniques were used to measure κ_G and κ_{CCN} , as described in the main text.

Figure 8. Deviation in rebound fraction for categorization by chemical characteristics. The box-whisker representation of the 10%, 25%, 50%, 75%, and 90% quantiles of rebound fraction is explained in the caption to Figure 1. The chemical characteristics are categorized by the fractional loading of PMF group B as < 0.15 (green), 0.15 to 0.3 (blue), 0.3 to 0.6 (orange), and > 0.6 (red).

Figure 9. Scatter plot of rebound deviation with the fractional loading of PMF group B for (a) IOP1 and (b) IOP2. The data points are colored according to the corresponding hygroscopicity parameter κ . For clarity of presentation, data points are shown for apparatus RH values between 73 and 78%, although the trend applies more broadly. As a guide to the eye, in each panel data are divided into four groups, and medians and quartiles of the groups are plotted as black circles and whiskers, respectively.

Figure 10. Scatter plot of observed compared to predicted rebound deviation for (a) IOP1 and (b) IOP2. Predictions are based on linear combinations of the loadings of the two PMF groups. The linear coefficients used in the prediction were optimized as a function of RH (Table S5). The solid line represents a one-to-one correlation, and the dashed line represents the best linear fit. Coefficients R^2 of determination were

0.65 and 0.72 for the IOP1 and IOP2 datasets, respectively. Points are color-coded by relative humidity.

Figure 11. STXM/NEXAFS analysis of particles collected after rebound from the impaction plate. Samples were collected between 1:00 and 10:00 (UTC) of October 1, 2014. (a) Carbon K-edge spectrum of rebounded particles (red). Lines at 285.4 and 288.5 eV highlight absorption by double bonds (C=C) and carboxylic acids (-COOH), respectively. The line in the region of 286.5 to 286.7 eV can have contributions from ketones, carbonyl-substituted aromatics, and phenolic species. For comparison, spectra are shown for carbonaceous particles collected in other field and laboratory studies: soil organic particles from central USA (Wang et al., 2016), soot from the ambient environment, atmospheric particles collected at a background site in central Amazonia (Pohlker et al., 2012), and three laboratory samples of secondary organic material. Data sources: isoprene-derived SOM produced under HO₂-dominant conditions (O'Brien et al., 2014); isoprene-derived SOM produced under NO-dominant conditions (O'Brien et al., 2014), and toluene-derived SOM produced under NO-dominant conditions (this study). (b) STXM image from which the NEXAFS spectrum of panel (a) was obtained. Coloring is by red for absorption at 285.4 eV (i.e., double bonds). Coloring is by green for other types of functionalities. The pixelation visible in the image corresponds to the STXM spatial resolution during data collection.
