30 **Abstract.** Asian dust particulate is one of the primary aerosol constituents in the  
31 Earth-atmosphere system that exerts profound influences on environmental quality,  
32 human health, marine biogeochemical cycle and Earth's climate. To date, the  
33 absorptive capacity of dust aerosol generated from Asian desert region is still an open  
34 question. In this article, we compile columnar key absorption and optical properties of  
35 mineral dust over East and Central Asia areas by utilizing the multi-year quality  
36 assured datasets observed at 13 sites of the Aerosol Robotic Network (AERONET).  
37 We identify two types of Asian dust according to threshold criteria from previously  
38 published literature. (I) The particles with high aerosol optical depth at 440 nm  
39 ( $AOD_{440} \geq 0.4$ ) and low Ångström wavelength exponent at 440-870 nm ( $\alpha < 0.2$ ) are  
40 defined as Pure Dust (PDU) that decrease disturbance of other non-dust aerosols and  
41 keep high accuracy of pure Asian dust. (II) The particles with  $AOD_{440} \geq 0.4$  and  
42  $0.2 < \alpha < 0.6$  are designated as Transported Anthropogenic Dust (TDU), which are  
43 mainly dominated by dust aerosol and might mix with other anthropogenic aerosol  
44 types. Our results reveal that the primary components of high AOD days are  
45 predominant by dust over East and Central Asia regions even if their variations rely  
46 on different sources, distance from the source, emission mechanisms, and  
47 meteorological characteristics. The overall mean and standard deviation of  
48 single-scattering albedo, asymmetry factor, real part and imaginary part of complex  
49 refractive index at 550 nm for Asian PDU are  $0.935 \pm 0.014$ ,  $0.742 \pm 0.008$ ,  
50  $1.526 \pm 0.029$ ,  $0.00226 \pm 0.00056$ , respectively, while corresponding values are  
51  $0.921 \pm 0.021$ ,  $0.723 \pm 0.009$ ,  $1.521 \pm 0.025$ , and  $0.00364 \pm 0.0014$  for Asian TDU.  
52 Aerosol shortwave direct radiative effects at the top of the atmosphere (TOA), at the  
53 surface (SFC), and in the atmospheric layer (ATM) for Asian PDU ( $\alpha < 0.2$ ) and TDU  
54 ( $0.2 < \alpha < 0.6$ ) computed in this study, are a factor of 2 smaller than the results of  
55 [Optical Properties of Aerosols and Clouds \(OPAC\)](#) Mineral accumulated (Mineral  
56 acc.) and transported (Mineral tran.) modes. Therefore, we are convinced that our  
57 results hold promise of updating and improving accuracies of Asian dust  
58 characteristics in present-day remote sensing applications and regional or global

59 climate models.

## 60 **1. Introduction**

61 Airborne dust particle (also called mineral dust) is recognized as one of the most  
62 important aerosol species in the tropospheric atmosphere, which accounts for about  
63 30% of the total aerosol loading and extinction aerosol optical depth on a global scale  
64 (Perlwitz et al., 2001; Kinne et al., 2006; Chin et al., 2009; Huang et al., 2014). High  
65 concentrations of dust aerosols hanging over desert source regions and invasive  
66 downstream areas would seriously exacerbate air quality, degrade visibility, affect  
67 transportation safety, and do adverse effects on public health during the prevalent  
68 seasons of dust storms (Chan et al., 2008; Morman and Plumlee, 2013; Wang et al.,  
69 2016). When mineral dusts are deposited onto the Earth's surface, they play a key role  
70 in biogeochemical cycles of terrestrial ecosystem or ocean (Okin et al., 2004; Jickells  
71 et al., 2005; Shao et al., 2011), as well as alter snow and ice albedo (Aoki et al., 2006;  
72 Huang et al., 2011; Wang et al., 2014). Last but not least, dust particles can modulate  
73 the Earth's energy budget and drive the climate change directly by scattering and  
74 absorption of solar/terrestrial radiation (Charlson et al., 1992; Wang et al., 2010b;  
75 Huang et al., 2014), and indirectly by acting as effective cloud condensation nuclei or  
76 ice nuclei, influencing the cloud microphysics and precipitation processes  
77 (Ramanathan et al., 2001; Rosenfeld et al., 2001; DeMott et al., 2003; Huang et al.,  
78 2005, 2006, 2010a; Wang et al., 2010c; Creamean et al., 2013). Numerous studies  
79 (Sokolik and Toon, 1999; Lafon et al., 2004, 2006) have confirmed that dust particle  
80 is one kind of light absorbing substances, and its mass absorption efficiencies at 325  
81 nm ( $0.06\sim 0.12\text{ m}^2/\text{g}$ ) are about 6 times larger than *that* at 660 nm ( $0.01\sim 0.02\text{ m}^2/\text{g}$ ),  
82 owing to the greater absorbing potential of iron oxides at short wavelengths (Alfaro et  
83 al., 2004). However, the way of iron oxides mixed with quartz or clay is complicated  
84 and strongly impacts the resulting absorption (Claquin et al., 1998, 1999; Sokolik and  
85 Toon, 1999). And these mineralogical studies indicate that a lack of consideration of  
86 these mixing mechanisms is a significant limitation of the previous dust absorption  
87 computations. Although the absorptive ability of dust is two orders of magnitude

88 lower than for black carbon (Yang et al., 2009), the atmospheric mass loading of the  
89 former is the same magnitude larger than that of the latter, leading to the total  
90 absorption in solar spectrum comparable to black carbon. Chin et al. (2009) evaluated  
91 that dust may account for about 53% of global averaged aerosol absorption optical  
92 depth at 550 nm, which undoubtedly changes the aforementioned  
93 dust-cloud-precipitation interaction and exerts a significant effect on hydrological  
94 cycle of the Earth-atmosphere system.

95 East and Central Asia territories are the major source regions of dust aerosols on  
96 Earth, which produce a large amount of dust particles every year that become  
97 entrained into the upper atmosphere by cold fronts (Zhang et al., 1997; Huang et al.,  
98 2009, 2010a, 2014). They can travel over thousands of kilometers, even across the  
99 Pacific Ocean and reach the western coast of North America about one week with the  
100 prevailing westerly wind (Husar et al., 2001; Uno et al., 2009, 2011), and then modify  
101 the climate and environment over extensive area of Asia-Pacific rim. Thus far, there  
102 have been a great deal of fruitful field campaigns for exploring Asian dust (e.g.,  
103 U.S.S.R.-U.S., ACE-Asia, ADEC, PACDEX, EAST-AIRC), however, most focus on  
104 intensive observation period (Golitsyn and Gillette, 1993; Huebert et al., 2003;  
105 Nakajima et al., 2003; Mikami et al., 2006; Huang et al., 2008a; Li et al., 2011) and  
106 lack of long-term and quantitative knowledge of dust optical, microphysical  
107 characteristics (especially absorption properties) and chemical compositions over  
108 these regions. Hence, the absorptive capacity of Asian dust aerosol is still an  
109 outstanding issue. The variations of dust optical features in model calculations are  
110 closely related to the uncertainties in particle size distribution and prescribing a value  
111 for complex refractive index. Whereas the key parameters of Asian dust aerosols in  
112 present-day climate models are still prescribed to the predetermined properties of  
113 Saharan mineral dust.

114 Wang et al. (2004) inferred the refractive index of pure minerals at Qira in  
115 Taklimakan Desert during April 12-14, 2002 via combination of [theoretical](#)  
116 [calculation](#) and composition analysis of aerosol samples, and showed that the value of  
117 imaginary part is 0.00411 at 500 nm, which is consistent with the Central Asian dust

118 of  $0.004 \pm 0.001$  (Tadzhikistan Desert; Sokolik and Golitsyn, 1993). Uchiyama et al.  
119 (2005) determined the single-scattering albedo (SSA) of Aeolian dust from sky  
120 radiometer and in situ measurements, and concluded that unpolluted Aeolian dust  
121 (source from Taklimakan Desert) has low absorption (with  $SSA_{500}$  of  $0.93 \sim 0.97$ ). Kim  
122 et al. (2004) analyzed multiyear sky radiation measurements over East Asian sites of  
123 Skyradiometer Network (Nakajima et al., 1996; Takamura et al., 2004) and showed  
124 the  $SSA_{500}$  of dust particles are around 0.9 in arid Dunhuang of northwest China and  
125 Mandalgovi Gobi desert in Mongolia. Bi et al. (2014) also reported the similar  $SSA_{550}$   
126 ( $0.91 \sim 0.97$ ) of dust aerosol at Dunhuang during spring of 2012. Xu et al. (2004)  
127 gained  $SSA_{530}$  of  $0.95 \pm 0.05$  in Yulin, China, from a Radiance Research nephelometer  
128 and a Particle Soot Absorption Photometer (PSAP) and suggested that both desert dust  
129 and local pollution sources contributed to the aerosol loading in Yulin during April  
130 2001. Whereas Ge et al. (2010) examined dust aerosol optical properties at Zhangye  
131 (a semiarid area of northwest China) from multifilter rotating shadowband radiometer  
132 (MFRSR) during spring of 2008 and found that although there are low aerosol optical  
133 depth values ( $AOD_{670}$  ranging from  $0.07 \sim 0.25$ ), dust particles have strong absorption  
134 (with  $SSA_{500}$  of  $0.75 \pm 0.02$ ) due to mixing with local anthropogenic pollutants. This  
135 result is close to the New Delhi over India ( $0.74 \sim 0.84$  for  $SSA_{500}$ ; Pandithurai et al.,  
136 2008). Lafon et al. (2006) revealed that due to containing of less calcite and higher  
137 fraction of iron oxide-clay aggregates, mineral dusts in Niger (Banizoumbou,  $13^{\circ}31'N$ ,  
138  $2^{\circ}38'E$ ) have much lower SSA in the visible wavelengths than that of Chinese (Ulan  
139 Buh,  $39^{\circ}26'N$ ,  $105^{\circ}40'E$ ) and Tunisian (Maouna,  $33^{\circ}01'N$ ,  $10^{\circ}40'E$ ) desert locations.  
140 Therefore, complete clarification of the climate-relevant impacts of Asian dust  
141 aerosols requires extensive and long-term measurements of the optical, microphysical  
142 and chemical properties, along with their spatial and temporal distributions.

143 There have been several world-famous aerosol long-term monitoring networks  
144 over Asian region for examining aerosol features and its radiative effects, for instance,  
145 AERONET—Aerosol RObotic NETwork (Holben et al., 1998),  
146 SKYNET—aerosol-cloud-radiation interaction ground-based observation network  
147 (Nakajima et al., 1996; Takamura et al., 2004; Che et al., 2008), and

148 [CARSNET—China Aerosol Remote Sensing Network \(Che et al., 2009a, 2014, 2015\)](#).  
149 In this paper, we investigate optical characteristics of Asian dust from multi-year  
150 AERONET measurements at 13 sites in and around arid or semi-arid regions of East  
151 and Central Asian desert sources. The key quantities include single-scattering albedo  
152 (SSA), asymmetry factor (ASY), real part (Re) and imaginary part (Ri) of complex  
153 refractive index, volume size distribution ( $dV/d\ln r$ ), which are needed for climate  
154 simulating and remote sensing applications. We mainly compare the vital absorption  
155 and optical properties between pure and transported anthropogenic dust over East and  
156 Central Asia. This article is arranged as follows. Section 2 introduces the site  
157 description and measurement. The identification method and detailed Asian dust  
158 optical features are described in Section 3. Discussion of spectral absorption  
159 behaviors of different dust aerosol types are given in Section 4 and followed by the  
160 Summary in Section 5.

## 161 **2. Site Description and Measurement**

### 162 **2.1. Site Description**

163 In this article, we select 13 AERONET sites located in arid or semi-arid Asian  
164 regions (see Fig. 1), which are recognized as the primarily active centre of dust storms.  
165 These drylands are very sensitive to climate change and human activities and would  
166 accelerate drought expansion by the end of twenty-first century (Zheng et al., 2009;  
167 Huang et al., 2016). Eight sites over East Asian region are labeled with red colors, and  
168 five sites over Central Asian area are labeled with blue colors. The major Great  
169 deserts or Gobi deserts along with plateaus are marked with black font (e.g., Great  
170 Gobi desert in Mongolia, Taklimakan Desert, Thar Desert, Karakum Desert, Tibetan  
171 Plateau, Loess Plateau, and Iranian Plateau). In order to quantitatively explore  
172 detailed spectral absorptive characteristics of dust aerosols over East and Central Asia,  
173 we choose four East Asian sites (SACOL, Dalanzadgad, Beijing, and Yulin) and four  
174 Central Asian sites (Dushanbe, Karachi, Kandahar, and IASBS). They consist of:  
175 SACOL located over Loess Plateau of northwest China (Huang et al., 2008b; Guan et  
176 al., 2009; Huang et al., 2010b; Wang et al., 2010a), Dalanzadgad in the Great Gobi of

177 southern Mongolia (Eck et al., 2005), Beijing in the downwind of Inner Mongolia  
178 (Xia et al., 2007), Yulin on the southwestern fringe of the Mu Us desert in northwest  
179 China (Xu et al., 2004; Che et al., 2009b, 2015), Dushanbe in Tadjikistan situated at  
180 the transport corridor of Central Asian desert dust (i.e. Karakum Desert; Golitsyn and  
181 Gillette, 1993), Karachi located in the southern margin of Thar Desert in Pakistan and  
182 about 20 km from the east coast of Arabian Sea (Alam et al., 2011), Kandahar in the  
183 arid area of southern Afghanistan, IASBS on the Iranian Plateau of northwest Iran.

## 184 **2.2. Sun Photometer Measurements**

185 AERONET is an internationally federated global ground-based aerosol monitoring  
186 network utilizing Cimel sun photometer, which comprises more than 500 sites all over  
187 the world (Holben et al., 1998). The Cimel Electronique sun photometer (CE-318)  
188 takes measurements of sun direct irradiances at multiple discrete channels within the  
189 spectral range of 340-1640 nm, which can be calculated aerosol optical depth (AOD)  
190 and columnar water vapor content (WVC) in centimeter. Furthermore, the instrument  
191 can perform angular distribution of sky radiances at 440, 675, 870, and 1020 nm  
192 (nominal wavelengths), which can be simultaneously retrieved aerosol volume size  
193 distribution, complex refractive index, single-scattering albedo, and asymmetry factor  
194 under cloudless condition (Dubovik and King, 2000; Dubovik et al., 2002a, 2006).  
195 The total accuracy in AOD for a newly calibrated field instrument is about  
196 0.010-0.021 (Eck et al., 1999). The retrieval errors of SSA, ASY, Ri, and Re are  
197 anticipated to be 0.03-0.05, 0.04, 30%-50%, and 0.025-0.04, respectively, relying on  
198 aerosol types and loading (Dubovik et al., 2000). It should be borne in mind that these  
199 uncertainties are **valid for**  $AOD_{440} \geq 0.4$  and for solar zenith angle  $>50^\circ$  (Level 2.0  
200 product), and the retrieval errors will become much greater when  $AOD_{440} < 0.4$ . The  
201 datasets of selected 13 AERONET sites in this study come from the Level2.0 product,  
202 which are pre- and post-field calibrated, automatically cloud screened, and  
203 quality-assured (Smirnov et al., 2000). In addition, a mixture of randomly oriented  
204 polydisperse spheroid particle shape assumption with a fixed aspect ratio distribution  
205 is applied to retrieve key optical properties of Asian dust (Dubovik, et al., 2002a,  
206 2006). Fu et al. (2009) have concluded that Mie-based single-scattering properties of

207 spheroidal dust aerosols are well suited in radiative flux calculations.

### 208 **3. Asian Dust Optical Properties**

209 A great amount of publications have verified that mineral dust aerosols are  
210 commonly predominant by large particles with coarse mode ( $\text{radii} > 0.6 \mu\text{m}$ ), which are  
211 the essential feature differentiating the dust from fine-mode dominated biomass  
212 burning and urban-industrial aerosols (Dubovik et al., 2002b; Eck et al., 2005; Bi et  
213 al., 2011, 2014; Kim et al., 2011; Che et al., 2013). In other word, the values of  
214 Ångström exponent at 440-870 nm ( $\alpha$ ) for dust aerosols usually range between -0.1 to  
215 0.6. As pointed out by Smirnov et al. (2002) and Dubovik et al. (2002b), sea salt  
216 aerosol is also dominant by coarse mode and has small Ångström exponent ( $\sim 0.3-0.7$ )  
217 but with low  $\text{AOD}_{440}$  ( $\sim 0.15-0.2$ ) compared with dust aerosol. Moreover, the selected  
218 desert locations in this study are mostly not affected by sea salt. By virtue of these  
219 differences, we can distinguish Asian dust aerosols from other fine-mode dominated  
220 non-dust particles. The criteria of two thresholds are put forward. (I) The particles  
221 with high aerosol optical depth at 440 nm ( $\text{AOD}_{440} \geq 0.4$ ) and low Ångström  
222 wavelength exponent at 440-870 nm ( $\alpha < 0.2$ ) are defined as Pure Dust (PDU) that  
223 keep high accuracy of pure Asian dust and eliminate most fine mode aerosols. (II) The  
224 particles with  $\text{AOD}_{440} \geq 0.4$  and  $0.2 < \alpha < 0.6$  are designated as Transported  
225 Anthropogenic Dust (TDU), which are mainly dominated by dust and might mix with  
226 other anthropogenic aerosol types during transportation. The definition of  
227 anthropogenic dust in this study is different from earlier literature (Tegen and Fung,  
228 1995; Prospero et al., 2002; Huang et al., 2015), which define that anthropogenic dust  
229 is primarily produced by various human activities on disturbed soils (e.g., agricultural  
230 practices, industrial activity, transportation, desertification and deforestation). It is still  
231 a huge challenge to discriminate between natural and anthropogenic components of  
232 dust aerosols by using current technology, AERONET products or in-situ  
233 measurements. Recently, Ginoux et al. (2012) first estimated that anthropogenic  
234 sources globally account for 25% based on Moderate Resolution Imaging  
235 Spectroradiometer (MODIS) Deep Blue dust optical depth in conjunction with other

236 land use data sets. Huang et al. (2015) proposed a new algorithm for distinguishing  
237 anthropogenic dust from natural dust by using Cloud-Aerosol Lidar and Infrared  
238 Pathfinder Satellite Observation (CALIPSO) and planetary boundary layer (PBL)  
239 height retrievals along with MODIS land cover data set. They revealed that  
240 anthropogenic dust produced by human activities mainly comes from semi-arid and  
241 semi-humid regions and is generally mixed with other types of aerosols within the  
242 PBL that is more spherical than natural dust. Thereby, we assume that anthropogenic  
243 dust aerosol originated from Asian arid or semi-arid areas has got smaller size  
244 distribution (thus larger Ångström exponent) than that of pure natural dust.

245 Before insight into dust aerosol optical characteristics, we first analyze the  
246 occurrence frequency of Asian dust over the study region that significantly affects the  
247 intensity and distribution of mineral dust loading. Figure 2 depicts the total number  
248 days of each month for Pure Dust ( $\alpha < 0.2$ ) and transported Anthropogenic Dust  
249 ( $0.2 < \alpha < 0.6$ ) at selected four East Asian sites and four Central Asian sites. The dust  
250 events at four East Asian sites primarily concentrate on springtime and corresponding  
251 peak days for PDU and TDU both appear in April. This is greatly attributed to the  
252 intrusion of dust particles during spring when dust storms are prevalent over these  
253 regions (Wang et al., 2008). For SACOL and Beijing sites, both the PDU and TDU  
254 days also occur in whole year except for autumn when is the rainy season, which is  
255 [linked with](#) long-range transport of dust particulates from desert source areas and  
256 locally anthropogenic dust (e.g., agricultural cultivation, overgrazing, desertification,  
257 industrial and constructed dust in urbanization). Shen et al. (2016) have demonstrated  
258 that urban fugitive dust generated by road transport and urban construction  
259 contributes to more than 70% of particulate matter (PM<sub>2.5</sub>) in northern China. The  
260 dust episodes in Dushanbe of Tadjikistan mostly happen from July to October,  
261 which are the peak seasons of dust storms (Golitsyn and Gillette, 1993). For Karachi  
262 site in Pakistan, the dust activities take place in spring and summer seasons. This is  
263 because the region is not affected by the summer monsoon, leaving the land surface  
264 sufficiently dry, and hence susceptible to wind erosion by strong winds and  
265 meso-scale thunderstorm events typical of this time of year (Alizadeh Choobari et al.,

266 2014). In addition, the transport of summer dust plumes from the Arabian Peninsula  
267 can partially contribute dust particles to Karachi site. Note that the occurred months of  
268 PDU cases are nearly different from TDU cases at Dalanzadgad, Kandahar, and  
269 IASBS sites, suggesting that dust aerosols over these areas are rarely affected by  
270 anthropogenic pollutants. For Kandahar site in Afghanistan, the limited sampling days  
271 to some extent may affect the statistical results. Generally, the aforementioned  
272 occurrence frequency of dust storms over diverse sites are principally dependent on  
273 different climatic regime and synoptic pattern, for instance, geographical location,  
274 atmospheric circulation, wet season and dry season.

275 Table 1 summarizes the site information, sampling period, overall average optical  
276 properties at 550 nm (e.g., SSA, ASY, Re, Ri, and Ångström exponent at 440-870 nm)  
277 for Asian PDU ( $\alpha < 0.2$ ), and total number of PDU and TDU ( $0.2 < \alpha < 0.6$ ) days. Note  
278 that dust optical feature at a common 550 nm wavelength is utilized here, which can  
279 be derived from logarithmic interpolation between 440 and 675 nm. It is worth  
280 pointing out that the absorption and optical properties of dust aerosols at two  
281 Dunhuang sites exhibit consistent features despite of different sampling periods,  
282 which indicate that the chemical composition of dust aerosol at Dunhuang area  
283 remains relatively stable.

284 The SSA or Ri of complex refractive index can characterize the absorptive  
285 capability of dust aerosols, and determine the sign (cooling or heating, depending on  
286 the planetary albedo) of the radiative forcing (Hansen et al., 1997). Both two  
287 quantities are mainly relied on the ferric oxide content in mineral dust (Sokolik and  
288 Toon, 1999). Figure 3 illustrates the overall average spectral behavior of key optical  
289 properties for PDU ( $\alpha < 0.2$ ) and TDU ( $0.2 < \alpha < 0.6$ ) at selected four East Asian sites.  
290 The SSA, ASY, Re and Ri of complex refractive index as a function of wavelength  
291 (440, 675, 870, and 1020 nm) are presented. For all cases, the spectral behaviors of  
292 aerosol optical parameters exhibit similar features, which can be representative of  
293 typical patterns of Asian dust. The SSA values systematically increase with  
294 wavelength at 440-675 nm and keep almost neutral or slight increase for the  
295 wavelengths greater than 675 nm, which is consistent with the previous results of dust

296 aerosols (Dubovik et al., 2002b; Eck et al., 2005; Bi et al., 2011). In contrast, an  
297 opposite pattern is displayed by imaginary part of refractive index, namely, Ri values  
298 dramatically decrease from 440 nm to 675 nm, and preserve invariant from 675 nm to  
299 1020 nm. These variations indicate that Asian dust aerosols have got much stronger  
300 absorptive ability at shorter wavelength. Alfaro et al. (2004) implied that the  
301 absorption capacity of soil dust increase linearly with iron oxide content, and  
302 estimated SSA at 325 nm (~0.80) is much lower than that at 660 nm (~0.95). Sokolik  
303 and Toon (1999) revealed that ferric iron oxides (e.g., hematite and goethite) are often  
304 internally mixed with clay minerals and result in significant dust absorption in the  
305 UV/visible wavelengths. Hence, the spectral variations of SSA and Ri with  
306 wavelengths are attributable to the domination of coarse-mode dust particles that have  
307 larger light absorption in the blue spectral band as mentioned above. It is worth noting  
308 that spectral ASY values remarkably reduce from 440 nm to 675 nm, and are almost  
309 constant at 675-1020 nm range. This suggests that Asian dust aerosols have much  
310 stronger scattering at 440 nm than other longer visible wavebands, due to the  
311 contribution of coarse mode particles. By contrast, the spectral behavior of Re is not  
312 obvious for PDU and TDU at all sites, and the mean Re values at 440 nm vary  
313 between 1.50 and 1.56. Although there are 18 years continuous AERONET datasets at  
314 Dalanzadgad site, the effective days of PDU and TDU are only 8 and 6 days,  
315 respectively, almost appearing in springtime period. There are no identifiable  
316 differences for dust absorption properties between PDU and TDU cases for  
317 Dalanzadgad, which indicates again that the site is hardly influenced by  
318 anthropogenic pollutants. The spectral discrepancies of optical characteristics between  
319 PDU and TDU at other three sites show much more apparent than Dalanzadgad,  
320 which is ascribed to these regions are not only affected by dust aerosols, but also  
321 including local anthropogenic emissions, for instance, urban-industry, coal fuel  
322 combustion, biomass burning, mobile source emissions, and agricultural dust (Xu et  
323 al., 2004; Xia et al., 2007; Che et al., 2015; Bi et al., 2011; Wang et al., 2015).

324 Figure 4 is the same as Figure 3, but for selected four Central Asian sites. The  
325 wavelength dependencies of PDU and TDU cases at Central Asian sites are consonant

326 with that of East Asian sites, despite of somewhat different variations of magnitude  
327 and amplitude. This is expected, because the East Asian desert sites are very close to  
328 the Central Asian desert locations and remain similar chemical compositions of dust  
329 aerosols (Wang et al., 2004). The spectral behaviors of dust optical properties for  
330 PDU at Kandahar and IASBS sites are nearly the same as TDU cases, which agrees  
331 well with the consistent variability of occurrence of dust storms. The wavelength  
332 dependency of dust characteristics for PDU at Dushanbe and Karachi presents large  
333 differences with TDU case, which is also likely due to the influence of local  
334 anthropogenic pollutions. Furthermore, the standard deviation of PDU is far less than  
335 that of TDU at all wavelengths, suggesting that the robustness of PDU recognition  
336 method.

337 Particle size distribution is another critical agent for deciding the optical and  
338 radiative properties of dust aerosol. Nakajima et al. (1996) and Dubovik and King  
339 (2000) uncovered that based on the spherical Mie theory, the retrieval errors of  
340 volume size distribution do not exceed 10% for intermediate particle size ( $0.1 \leq r \leq 7$   
341  $\mu\text{m}$ ) and may greatly increase to 35-100% at the edges of size range ( $r < 0.1 \mu\text{m}$  or  $r > 7$   
342  $\mu\text{m}$ ). As mentioned above, a polydisperse, randomly oriented spheroid method is  
343 utilized in this study, which is demonstrated to remove the artificially increased size  
344 distribution of fine particle mode with  $\text{AOD}_{440} \geq 0.4$  and for solar zenith angle  $> 50^\circ$ .  
345 Additionally, the large errors at the edges do not significantly affect the derivation of  
346 the main features of the particle size distribution (concentration, median and effective  
347 radii, etc.), because typical dust aerosol size distributions have low values at the edges  
348 of retrieval size interval (Dubovik et al., 2002a). Figure 5 delineates the overall  
349 average columnar aerosol volume size distributions ( $dV/d\ln r$ ,  $0.05 \mu\text{m} \leq r \leq 15 \mu\text{m}$ ) for  
350 Pure Dust ( $\alpha < 0.2$ ) and Transported Anthropogenic Dust ( $0.2 < \alpha < 0.6$ ) at selected 13  
351 AERONET sites. Corresponding  $\text{AOD}_{440}$  and effective radius of coarse mode ( $r_{\text{coarse}}$ )  
352 in  $\mu\text{m}$  are also shown. It is apparent that the  $dV/d\ln r$  exhibits a typical bimodal  
353 structure and is dominant by coarse mode for PDU and TDU at all sites. The  $dV/d\ln r$   
354 peak of coarse mode particle varies dramatically and appears at a radius  $r_{Vc} \sim 2.24 \mu\text{m}$   
355 for all PDU cases and  $r_{Vc} \sim 2.0-3.0 \mu\text{m}$  for TDU cases, while the corresponding peak of

356 fine mode particle arises at a radius  $r_{vf} \sim 0.09\text{-}0.12 \mu\text{m}$ . The  $dV/d\ln r$  peak and  
 357 effective radius ( $r_{coarse}$ ) of coarse mode particles strikingly increase with the increase  
 358 of AOD ascribed to the intrusion of dust particles. For instance, the  $AOD_{440}$ ,  $dV/d\ln r$   
 359 peak values of coarse mode, and  $r_{coarse}$  for PDU at Minqin site are 0.48,  $0.31 \mu\text{m}^3/\mu\text{m}^2$ ,  
 360 and  $1.74 \mu\text{m}$ , respectively, and corresponding values are 1.13,  $0.77 \mu\text{m}^3/\mu\text{m}^2$ , and  $1.93$   
 361  $\mu\text{m}$  at Lahore site, as shown in Fig. 5(a). The average volume median radii of  
 362 fine-mode and coarse-mode particles for PDU are  $0.159 \mu\text{m}$  and  $2.157 \mu\text{m}$ ,  
 363 respectively, and  $0.140 \mu\text{m}$  and  $2.267 \mu\text{m}$  for TDU (see Table. 2). The mean volume  
 364 concentration ratio of coarse mode to fine mode particles ( $C_{vc}/C_{vf}$ ) for Pure Dust is  
 365 about 18 (varying between 11~31) over East and Central Asia, which is close to the  
 366 average of  $\sim 20$  at Dunhuang\_LZU during the spring of 2012 (Bi et al., 2014), and  
 367 much less than that over Saharan pure desert domain ( $\sim 50$ ) (Dubovik et al., 2002b).  
 368 The  $dV/d\ln r$  peak of coarse mode for TDU is clearly smaller than that for PDU, and  
 369 corresponding mean  $C_{vc}/C_{vf}$  value is 9 ( $\sim 5\text{-}11$ ). We attribute the high fractions of  
 370 coarse-mode particles to high AOD and low Ångström exponent values.

371 In this paper, we postulate that Asian dust particles only possess scattering and  
 372 absorption characteristics. And the absorption AOD value (AAOD) at a specific  
 373 wavelength can be obtained from SSA and AOD, namely,  $AAOD_{\lambda} = (1 - SSA_{\lambda}) \times AOD_{\lambda}$ ,  
 374 where  $\lambda$  is the wavelength. Thereby, the corresponding absorption Ångström exponent  
 375 at 440-870 nm (AAE) is calculated from spectral AAOD values by using a log-linear  
 376 fitting algorithm. Figure 6 outlines the total average Ångström exponent ( $\alpha$ ) and  
 377 absorption Ångström exponent at 440-870 nm, volume concentration of coarse mode  
 378 in  $\mu\text{m}^3/\mu\text{m}^2$ , and volume median radius of coarse mode in  $\mu\text{m}$  for TDU ( $0.2 < \alpha < 0.6$ )  
 379 and PDU ( $\alpha < 0.2$ ) at selected AERONET sites. There are very big differences of all  
 380 quantities between PDU and TDU cases, except for some sites (e.g., Dunhuang and  
 381 Minqin). The primary reason is that we only acquire limited datasets of dust days  
 382 during spring time at Dunhuang and Minqin sites, which are hardly affected by other  
 383 anthropogenic pollutants. The AE values of TDU show remarkable changes among  
 384 each site, ranging from 0.24 to 0.44, whereas corresponding values of PDU keep  
 385 comparatively slight variations for selected 13 sites ( $\sim 0.04\text{-}0.15$ ). Furthermore, all the

386 AAE values of PDU are greater than 1.5, ranging between 1.65 and 2.36, and the  
387 AAE of TDU vary from 1.2 to 2.3. We can conclude that the Asian pure dust aerosols  
388 have got AE values smaller than 0.2 and corresponding AAE larger than 1.50, which  
389 is another typical feature distinguishing with other non-dust aerosols. Yang et al.  
390 (2009) attributed the high AAE values of dust aerosol in China to the presence of  
391 ferric oxides. It is evident that volume concentrations of coarse mode for PDU are  
392 significantly higher than TDU case, which is expected for the more coarse-mode  
393 particles in PDU. While the volume median radius of coarse mode for TDU is greater  
394 than PDU case, although there are some smaller values for TDU at Dalanzadgad and  
395 Yulin sites. This is owing to dust particles at these sites usually mix with other  
396 anthropogenic aerosol species and substantially enhance their median radii.

397 Figure 7 characterizes the overall mean optical properties (e.g., SSA, ASY, Re,  
398 and Ri) at 440 nm for selected 13 sites. In general, the absorption capacity of PDU is  
399 less than that for TDU. That is, higher SSA and smaller Ri values for PDU, except for  
400 Dalanzadgad site. A reasonable interpretation is that threshold criterion method for  
401 PDU in this study has effectively eliminated the fine mode aerosols, which are mostly  
402 the much stronger absorbing aerosols (e.g., soot and biomass burning aerosol) over  
403 East and Central Asia but weaker absorbing pollution aerosols (i.e., sulfate and nitrate)  
404 over Dalanzadgad. Wu et al. (2012, 2014) have documented that sulfate and nitrate in  
405 background atmosphere most likely originated directly from surface soil at the north  
406 and south edges of Taklimakan desert and comprised steadily about 4% of dust  
407 particulate matters, which could partially explain our results. Additionally, the overall  
408 mean ASY and Re of PDU are greater than that of TDU, which again verifies that the  
409 Asian pure dust has got much stronger forward scattering ability than the mixture of  
410 Asian dust. Note that the standard deviation of SSA and Ri for PDU is a factor of two  
411 to four lower than those from TDU. And the total average values of SSA, ASY, Re,  
412 and Ri at 550 nm wavelength for Asian PDU are  $0.935\pm 0.014$ ,  $0.742\pm 0.008$ ,  
413  $1.526\pm 0.029$ , and  $0.00226\pm 0.00056$ , respectively, while corresponding values are  
414  $0.921\pm 0.021$ ,  $0.723\pm 0.009$ ,  $1.521\pm 0.025$ ,  $0.00364\pm 0.0014$  for TDU. Yang et al. (2009)  
415 took advantage of various in situ aerosol optical and chemical measurements at

416 Xianghe, China during the EAST-AIRC campaign, and deduced a refractive index of  
417  $1.53-0.0023i$  at 550 nm of dust aerosol, which is close to the result of PDU in this  
418 study. Nevertheless, the TDU case should be much closer to actual airborne dust  
419 aerosol in the real world. When the elevated dusts over desert source regions are  
420 transported eastward, they generally mix with other chemical species and react  
421 heterogeneously with anthropogenic pollutants, and thus may significantly modify  
422 their chemical composition and microphysical properties (Arimoto et al., 2004).  
423 Recently, Kim et al. (2011) presented that the annual mean SSA, ASY, Re, and Ri of  
424 complex refractive index for nearly pure Saharan dust are  $0.944\pm 0.005$ ,  $0.752\pm 0.014$ ,  
425  $1.498\pm 0.032$ , and  $0.0024\pm 0.0034$  at 550 nm, respectively, which are close to our  
426 results of pure Asian dust but exist some differences of quantitative values and  
427 spectral behaviors.

428 Average spectral optical properties (at 440, 675, 870, and 1020 nm) for PDU and  
429 TDU over East and Central Asian regions are tabulated in Table 2. To our knowledge,  
430 this is the first built on Asian dust optical characteristics utilizing multiyear and  
431 multi-site AERONET measurements, which will hopefully improve uncertainties of  
432 Asian dust shortwave radiative forcing in current regional and global climate models.

#### 433 **4. Discussion**

434 Figure 8 describes the mean spectral behaviors of Re, RI, and SSA for Asian Pure  
435 Dust ( $\alpha < 0.2$ ) in this study along with published dust results over various geographical  
436 locations (Carlson and Caverly, 1977 or C77; Patterson et al., 1977 or P77; WMO,  
437 1983; Hess et al., 1998 or OPAC; Dubovik et al., 2002b or Persian Gulf; Alfaro et al.,  
438 2004 or Ulan Buh Desert; Wang et al., 2004 or ADEC; Todd et al., 2007 or T07). It is  
439 well known that a lot of present-day dust models commonly take advantage of the  
440 Optical Properties of Aerosols and Clouds (OPAC, Hess et al., 1998) or World  
441 Meteorological Organization (WMO, 1983) databases. Curves C77 and P77 show the  
442 complex refractive index of Saharan dust in Cape Verde Islands, Barbados West  
443 Indies, Tenerife Canary Islands obtained from laboratory analysis by Carlson and  
444 Caverly (1977) and Patterson et al. (1977), respectively. Curve P77 gives one of the

445 most widely used datasets of  $R_i$  value in the range 300-700 nm. Curve Persian  
446 Gulf(98-00) displays the refractive index and SSA of dust over Bahrain-Persian Gulf  
447 Desert during period of 1998-2000 derived from Dubovik et al. (2002b). Curve T07  
448 shows the optical properties of mineral dust over Bodélé Depression of northern Chad  
449 during 2005 retrieved from Cimel sun photometer by Todd et al. (2007). And the  
450 curves ADEC and Ulan Buh exhibit the dust absorptive properties over  
451 aforementioned Taklimakan Desert and Ulan Buh Desert of northwest China by Wang  
452 et al. (2004) and Alfaro et al. (2004). Figure 8(a) presents that the spectral behaviors  
453 of  $R_e$  have relatively slight variations with values ranging from 1.50-1.56 apart from  
454 T07 that shows lower  $R_e$  values of 1.44-1.47. Todd et al. (2007) utilized Scanning  
455 Electron Microscope (SEM) analysis of airborne dust material and confirmed that the  
456 mineral dust is dominated by fragmented fossil diatoms from the dry lake bed of the  
457 Bodélé Depression, which is to some extent different from the typical desert soil. As  
458 shown in Figure 8(b), wavelength dependences of  $R_i$  exhibit comparably greater  
459 differences in UV wavebands. In mid-visible and near infrared, our results are slightly  
460 larger than Persian Gulf (98-00) and T07 that are retrieved from Cimel sun  
461 photometer, but still comparable. It is very distinct that the absorbing ability of Asian  
462 pure dust ( $\alpha < 0.2$ ) in the whole spectrum range is about a factor of 4 smaller than  
463 current dust models (WMO, 1983; Hess et al., 1998), and is a factor of 2 to 3 lower  
464 than the results from in situ measurements combined with laboratory analysis or  
465 model calculations (Carlson and Caverly, 1977; Patterson et al., 1977; Wang et al.,  
466 2004). Meanwhile, the wavelength dependences of SSA agree well with Persian Gulf  
467 (98-00) and Ulan Buh Desert, but are much higher than OPAC. The discrepancy  
468 increases dramatically with decreasing wavelength. Such big differences of dust  
469 absorption capacity for diverse dust models (OPAC and WMO) and researches will  
470 certainly lead to different radiative impacts on regional or global climate change.

471 Figure 9 draws the aerosol shortwave direct radiative effects (ARF) at the top of  
472 atmosphere (TOA), at the surface (SFC), and in the atmospheric layer (ATM) for  
473 Asian Pure Dust ( $\alpha < 0.2$ ) and Transported Anthropogenic Dust ( $0.2 < \alpha < 0.6$ ) acquired  
474 in this study, and corresponding ARF values for OPAC Mineral accumulated (Mineral

475 acc.) and transported (Mineral tran.) modes are also presented for comparison. We  
476 make use of the Santa Barbara Discrete-ordinate Atmospheric Radiative Transfer  
477 model (SBDART, Ricchiazzi et al., 1998) to calculate the ARF, which has been  
478 proved to be a reliable software code and widely used for simulating plane-parallel  
479 radiative fluxes in the Earth's atmosphere (Halthore et al., 2005; Bi et al., 2013). The  
480 main input parameters of spectral AOD, surface albedo, WVC, and columnar ozone  
481 amount are prescribed to same values (e.g., 0.72, 0.30, 1.0 cm, and 300 DU for input  
482 AOD<sub>440</sub>, surface albedo, WVC, and ozone amount), and the spectral SSA, ASY, Re,  
483 and Ri values are obtained from aforementioned various dust models. It is evident that  
484 Earth's energy budget is modulated and redistributed by different absorbing properties  
485 of mineral dusts. The results indicate that the cooling rate at SFC (negative radiative  
486 forcing) gradually increases with PDU ( $\alpha < 0.2$ ), TDU ( $0.2 < \alpha < 0.6$ ), OPAC Mineral  
487 accumulated and transported dust modes. By contrast, the cooling intensity at TOA  
488 gradually decreases with diverse dust cases, and even becomes positive radiative  
489 forcing for OPAC transported dust mode, with ARF varying from -15.6, -13.8, -6.9,  
490 and +0.24 Wm<sup>-2</sup>, respectively. Therefore, the heating intensity in the atmospheric  
491 layer sharply increases from +22.7, +29.5, +46.6, and +58.3 Wm<sup>-2</sup>. The heating rate in  
492 ATM for OPAC Mineral (acc. and tran.) modes is about two-fold greater than Asian  
493 dust cases (PDU and TDU). Such large diabatic heating rates might warm the dust  
494 layer, suppress the development of convection under the lower atmosphere, thus exert  
495 profound impacts on the atmospheric dynamical and thermodynamic structures and  
496 cloud formation together with the strength and occurrence frequency of precipitation  
497 (Rosenfeld et al., 2001; Huang et al., 2010a; Creamean et al., 2013). Hence, accurate  
498 and reliable absorbing characteristics of Asian dust should be considered in  
499 present-day regional climate models.

## 500 **5. Summary**

501 In this study, we have proposed two threshold criteria to discriminate two types of  
502 Asian dust: Pure Dust (PDU,  $\alpha < 0.2$ ) and Transported Anthropogenic Dust (TDU,  
503  $0.2 < \alpha < 0.6$ ). PDU can represent nearly "pure" dust in desert source regions and

504 decrease disturbance of other non-dust aerosols, which would also exclude some fine  
505 mode of dust particles. The spectral behaviors of TDU exhibit similar variations with  
506 PDU, but show much stronger absorption and weaker scattering than PDU cases.  
507 There are two markedly identifiable characteristics for Asian PDU. (I) spectral SSA  
508 values systematically increase with wavelength from 440 nm to 675 nm and remain  
509 almost neutral or slight increase for the wavelength greater than 675 nm, whereas an  
510 opposite pattern is shown for imaginary part of refractive index. (II) Asian pure dust  
511 aerosols have got AE values smaller than 0.2 and AAE larger than 1.50. Compared  
512 with current common dust models (e.g., OPAC and WMO), Asian dust aerosol has  
513 relatively weak absorption for wavelengths greater than 550 nm ( $SSA \sim 0.96-0.99$ ), but  
514 presents a moderate absorption in the blue spectral range ( $SSA_{440} \sim 0.92-0.93$ ). The  
515 overall average values of SSA, ASY, Re, and Ri at 550 nm wavelength for Asian PDU  
516 are  $0.935 \pm 0.014$ ,  $0.742 \pm 0.008$ ,  $1.526 \pm 0.029$ , and  $0.00226 \pm 0.00056$ , respectively,  
517 while corresponding values are  $0.921 \pm 0.021$ ,  $0.723 \pm 0.009$ ,  $1.521 \pm 0.025$ ,  
518  $0.00364 \pm 0.0014$  for TDU.

519 It should be noted that the definition of anthropogenic dust in this paper is  
520 ambiguous, and TDU here represents more accurately dominant dust mixing with  
521 other anthropogenic aerosols. [It is very difficult to quantify the anthropogenic  
522 contribution due to large uncertainties in defining](#) the anthropogenic fraction of  
523 ambient dust burden (Sokolik et al., 2001; Huang et al., 2015). Diverse human  
524 activities (e.g., agricultural cultivation, desertification, industrial activity,  
525 transportation, and construction in urbanization) in vulnerable environments might  
526 modify the land use and Earth's surface cover, and would affect the occurred  
527 frequency and intensity of anthropogenic dust. Hence, the optical features of  
528 anthropogenic dust aerosols are dependent on the source regions and chemical  
529 compositions. However, as concluded by Huang et al. (2015), anthropogenic dust  
530 generated by human activities mainly comes from semi-arid and semi-humid regions  
531 (Guan et al., 2016) and is generally mixed with other types of aerosols within the PBL.  
532 And we primarily investigated dust aerosols in arid or semi-arid regions over East and  
533 Central Asia, where are somewhat disturbed by human activities. Therefore, the key

534 optical properties of TDU derived from this study should to some extent contain the  
535 anthropogenic fraction. To fully elucidate exact optical properties of anthropogenic  
536 dust, we need to explore detailed morphology, mineralogy, and chemical  
537 compositions by means of in situ measurements, laboratory analysis, active and  
538 passive remote sensing methods (e.g., multi-wavelength lidar, AEROENT, MODIS)  
539 as well as model calculations.

866 **Table 1.** Overall average and standard deviation of key optical properties at 550 nm (e.g.,  
867 single-scattering albedo, asymmetry factor, real part and imaginary part of complex refractive  
868 index) for Asian pure Dust (PDU). Ångström wavelength exponent ( $\alpha$ ) is in the range of 440-870  
869 nm. Minimum and maximum values of the optical properties are in parenthesis for each  
870 corresponding column. Measuring period and the total number of PDU ( $\alpha < 0.2$ ) and Transported  
871 Anthropogenic Dust (TDU,  $0.2 < \alpha < 0.6$ ) days are in the parenthesis for the first and last column,  
872 respectively.

Site (sampled period)	SSA (min, max)	ASY (min, max)	Re (min, max)	Ri ( $\times 10^{-3}$ )	Ångström (440-870 nm)	PDU/days (TDU)

875

876

877 **Table 2.** Spectral optical properties of Pure Dust ( $\alpha < 0.2$ ) and Transported Anthropogenic Dust

878 ( $0.2 < \alpha < 0.6$ ) averaged for 13 sites over East and Central Asia areas.

Asian Dust	Pure Dust ( $\alpha < 0.2$ )	Transported Anthropogenic Dust ( $0.2 < \alpha < 0.6$ )
$\omega_0(440/675/870/1020)$	0.906/0.962/0.971/0.975 $\pm 0.009$	0.897/0.943/0.954/0.959 $\pm 0.019$
$Re(440/675/870/1020)$	1.520/1.533/1.517/1.503 $\pm 0.026$	1.509/1.533/1.532/1.525 $\pm 0.027$
$Ri(440/675/870/1020) \times 10^{-3}$	3.413/1.574/1.449/1.449 $\pm 0.450$	5.064/2.737/2.510/2.486 $\pm 1.300$
$ASY(440/675/870/1020)$	0.758/0.727/0.724/0.726 $\pm 0.008$	0.736/0.711/0.710/0.712 $\pm 0.009$
$r_{Vf} (\mu m); \sigma_f$	0.159 $\pm 0.029$	0.140 $\pm 0.011$
$r_{Vc} (\mu m); \sigma_c$	2.157 $\pm 0.112$	2.267 $\pm 0.214$
$C_{vf} (\mu m^3/\mu m^2)$	0.037 $\pm 0.011$ ; 0.06 $\times \tau(1020)$ -0.001	0.038 $\pm 0.011$ ; 0.12 $\times \tau(1020)$ -0.014
$C_{vc} (\mu m^3/\mu m^2)$	0.632 $\pm 0.167$ ; 0.88 $\times \tau(1020)$ -0.07	0.343 $\pm 0.084$ ; 0.90 $\times \tau(1020)$ -0.06
$C_{vc}/C_{vf}$	17.9 (11~31)	9.1 (5~11)

879 Each variable is accompanied by a standard deviation (e.g.,  $\pm 0.01$ ).  $r_{Vf}$  and  $r_{Vc}$  are the volume

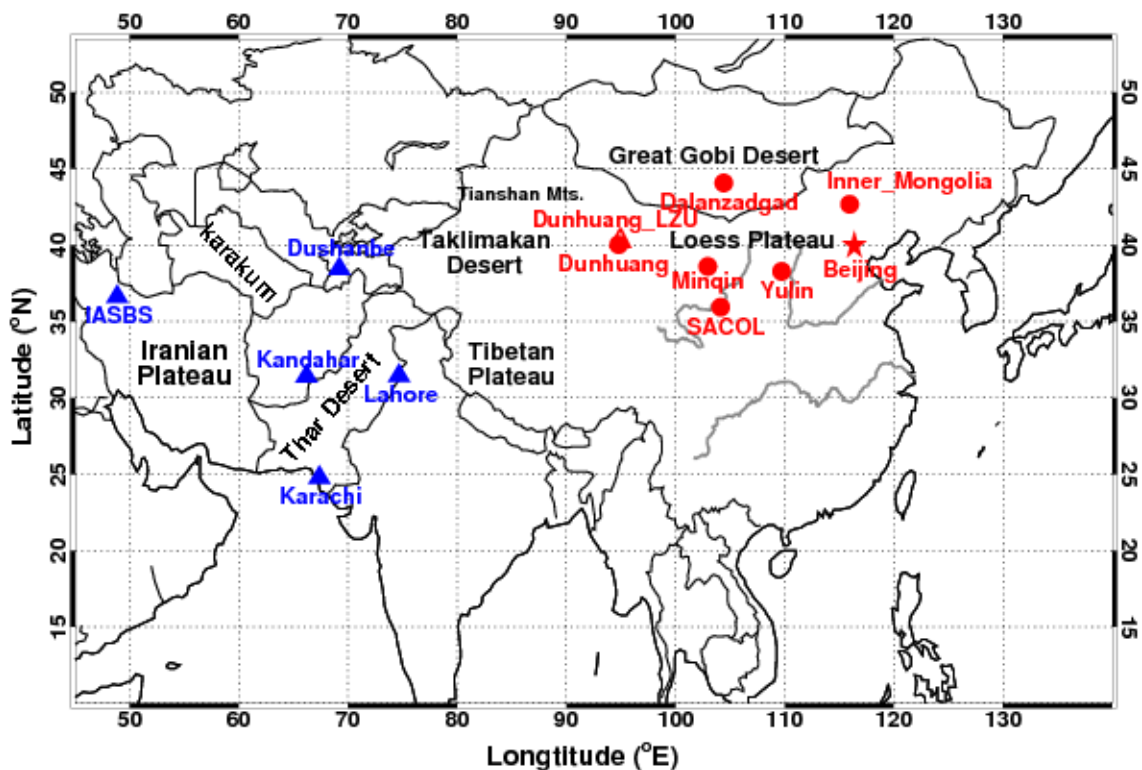

880 median radii of fine-mode and coarse-mode particles in  $\mu m$ ;  $C_{vf}$  and  $C_{vc}$  denote the volume

881 concentrations of fine-mode and coarse-mode particles in  $\mu m^3/\mu m^2$ , respectively. The dynamic

882 dependencies of dust optical properties are exhibited as functions of  $AOD_{1020}$ , with correlation

883 coefficients greater than 0.93 for all cases.

884

885

886 **Figure 1.** Geographical location of selected 13 AERONET sites in this study. Eight sites over East

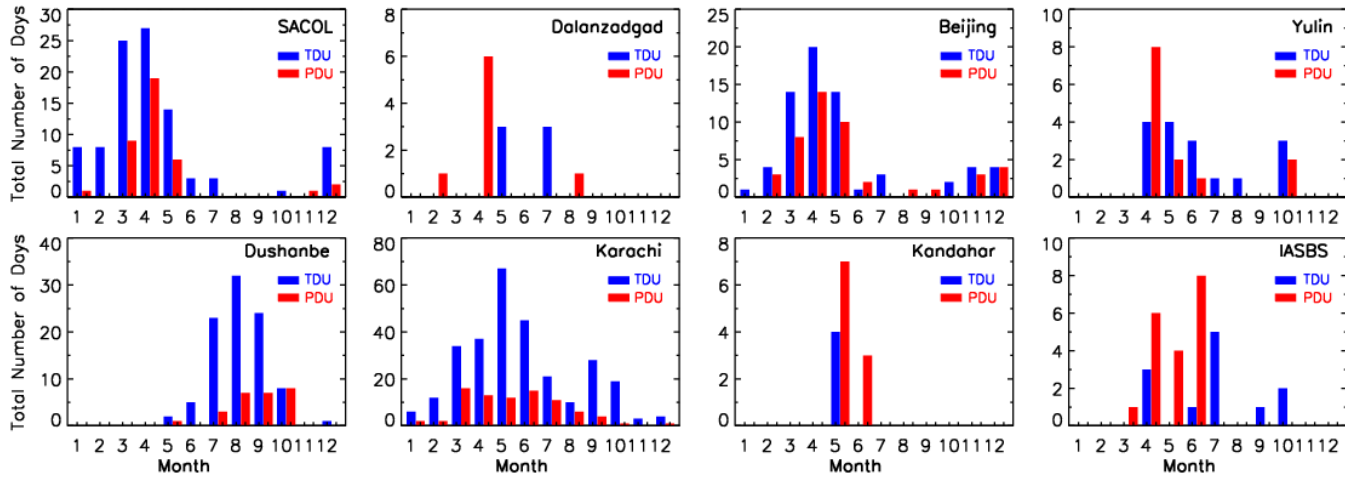

887 Asian region are labeled with red colors, and five sites over Central Asian region are labeled with

888 blue colors. The major Great deserts or Gobi deserts along with plateaus are marked with black

889 font.

890

**Figure 9.** Aerosol shortwave direct radiative effects at the top of the atmosphere (TOA, red color), at the surface (SFC, blue color), and in the atmospheric layer (ATM, green color) for Asian Pure Dust ( $\alpha < 0.2$ ) and Transported Anthropogenic Dust ( $0.2 < \alpha < 0.6$ ) computed in this study, and corresponding values for OPAC Mineral accumulated (Mineral acc.) and transported (Mineral tran.) modes are also presented for comparison.
