12 Abstract: The North China plain (NCP), which includes Beijing, is currently suffering from severe
13 haze events due to high pollution level of PM_{2.5}. To mitigate the serious pollution problem,
14 identification of the sources of PM_{2.5} is urgently needed for the effective control measures. Daily
15 samples of PM_{2.5} were collected in Beijing city and in a rural area in Baoding, Hebei Province
16 through the year of 2014, and the seasonal variation of water-soluble ions (WSIs) in PM_{2.5} were
17 comprehensively analyzed to determine their possible sources. The results indicated that the
18 periodic emissions from farmers' activities made a significant contribution to the atmospheric WSIs
19 in Beijing. The relatively high concentration of K⁺ in winter and autumn at the two sampling sites
20 confirmed that crop straw burning contributed to atmospheric K⁺ in Beijing. The remarkable
21 elevation of Cl⁻ at the two sampling sites as well as the evident increase of the Cl⁻/K⁺ ratio and the
22 Cl⁻ proportion in WSIs during the winter in Beijing could be ascribed to coal combustion for heating
23 by farmers. The unusually high ratio of Cl⁻ to Na⁺ in summer, the obviously high concentrations of
24 Cl⁻ in the rural sampling site and the elevation of Cl⁻ proportion in WSIs in Beijing during the maize
25 fertilization could be explained by the use of the prevailing fertilizer of NH₄Cl in the vast area of
26 NCP. The abnormally high concentrations of Ca²⁺ at the two sampling sites and the elevation of
27 Ca²⁺ proportion during the period of the maize harvest and soil ploughing in Beijing provided
28 convincing evidence that the intensive agricultural activities in autumn contributed to the regional
29 mineral dust. The most serious pollution episodes in autumn were coincident with significant
30 elevation of Ca²⁺, indicating that the mineral dust emission from the harvest and soil ploughing not
31 only increased the atmospheric concentrations of the primary pollutants, but also greatly accelerated
32 formation of sulfate and nitrate through heterogeneous reactions of NO₂ and SO₂ on the mineral
33 dust. The backward trajectories also indicated that the highest concentrations of WSIs usually
34 occurred in the air parcel from southwest/south regions, which have a high density of farmers. In
35 addition, the values of nitrogen oxidation ratio (NOR) and the sulfur oxidation ratio (SOR) were
36 found to be much higher under haze days than under non-haze days, implying that formation of
37 sulfate and nitrate was greatly accelerated through heterogeneous or multiphase reactions of NO₂
38 and SO₂ on PM_{2.5}.

39 **1. Introduction**

40 The North China plain (NCP) is frequently suffering from severe haze pollution in recent years
41 (Chan and Yao, 2008;Liang et al., 2016), which has aroused great attention from the general public
42 (Zhang et al., 2014;Guo et al., 2014;Huang et al., 2014a;Yang et al., 2015b;Zhang et al.,
43 2015b;Zheng et al., 2015b;Sun et al., 2006). The severe haze pollution is mainly ascribed to
44 elevation of fine particulate matter with dynamic diameter less than 2.5 μm ($\text{PM}_{2.5}$) (Huang et al.,
45 2014a). $\text{PM}_{2.5}$ can directly reduce atmospheric visibility by scattering or absorbing solar light
46 (Seinfeld and Pandis, 1998;Buseck and Posfai, 1999;Cheng et al., 2006) and is harmful to human
47 health (Finlayson-Pitts and Pitts, 2000;Nel, 2005;Poschl, 2005;Peplow, 2014).

48 To mitigate the serious pollution problem, identification of the sources of $\text{PM}_{2.5}$ is urgently needed
49 for the effective control measures. Based on field measurements, positive matrix factorization (PMF)
50 (Yu et al., 2013;Wu et al., 2014;Huang et al., 2014a), principal component analysis (PCA) (Wang et
51 al., 2015) and chemical mass balance (CMB) (Huang et al., 2014a;Guo et al., 2012) have been
52 widely used for identifying the sources of $\text{PM}_{2.5}$. However, the results of the source apportionment
53 are still not convincing because there are large uncertainties about the indicators, dominant factors
54 and emission inventories used for the identification. For example, some studies suggested traffic
55 emissions in Beijing contributed about 15~20% to the $\text{PM}_{2.5}$ (Yu et al., 2013;Wu et al., 2014), while
56 only 4% of the contribution was also reported (Zhang et al., 2013). Additionally, the current source
57 apportionment can only present gross contribution of each source classification, but there are
58 markedly different emissions from individual sources in the same classification. For example, due
59 to the strict control measures and highly efficient combustion, the emissions of pollutants from
60 power plants and big boilers fueled by coal must be totally different from the emissions of farmers'

61 coal stoves in both the emission intensity and composition of pollutants. Finally, most studies about
62 source apportionment mainly focused on emissions from traffic, industry, construction and
63 secondary formation, whereas the emissions from farmers' activities in the NCP were often
64 neglected.

65 There are about 300,000 km² of agricultural fields and 0.16 billion farmers in the NCP (Zhang et
66 al., 2011). The farmers' activities in the NCP are seasonal, e.g., the fertilization events and harvests
67 mainly occur in June-July and October-November and farmers' coal stoves are prevailingly used for
68 heating in winter. The seasonal activities of farmers in the NCP were suspected to make significant
69 contribution to deteriorate the regional air quality, e.g., the most serious pollution events (or haze
70 days) in the NCP were usually coincident with the three seasonal activities of farmers in recent years
71 (Yang et al., 2015b;Huang et al., 2012;Li et al., 2014;Li et al., 2011;Liu et al., 2013;Sun et al., 2013).

72 The serious pollution events during harvest seasons were widely ascribed to crop straw burning
73 (Huang et al., 2012;Li et al., 2014), but the influence of fertilization events and crop straw returning
74 to fields on the regional air quality during the harvest seasons periods was mostly neglected. Strong
75 ammonia (NH₃) emission from the vast agricultural fields in the NCP has been found during
76 fertilization events just after the wheat harvest (in June-July) (Zhang et al., 2011), which must
77 accelerate atmospheric ammonium formation. Although crop straws burning by stealth is still
78 prevalent, most residual crops are being returned into the agricultural fields under the advocacy of
79 government for protecting the air quality. Because crop leaves absorbed large quantities of
80 atmospheric particles during crop growing season (Bealey et al., 2007; Ji et al., 2013), the abrupt
81 release of the particles by smashing crop straw for returning in the vast area of the NCP must also
82 make a contribution to atmospheric particles in the region during the seasonal harvest seasons. In

83 winter, heavy smoke from the chimneys of the farmers' coal stoves can be seen everywhere in rural
84 areas of the NCP due to heating supply. Although residential coal consumption only accounts for a
85 small fraction of the total, e.g., ~11% in Beijing-Tianjin-Hebei area (<http://hbdczx.mep.gov.cn/pub/>),
86 the emission factors of typical pollutants such as PM_{2.5}, organic carbon (OC) and polycyclic
87 aromatic hydrocarbons (PAHs) from farmers' coal stoves (about 1054-12910 mg/kg for PM_{2.5}, 470-
88 7820 mg/kg for OC and 58.5-229.1 mg/kg for PAHs) are usually about 1-3 orders of magnitude
89 greater than those from coal power plants or industries boilers (about 16-100 mg/kg for PM_{2.5}, 0.3-
90 17.1 mg/kg for OC and 0.8-12.8 μg/kg for PAHs) (Zhang et al., 2008; Xu et al., 2006; Geng et al.,
91 2014; Chen et al., 2005; Revuelta et al., 1999; Yang et al., 2016), and the coal consumption by
92 farmers mainly concentrates on the four months in winter.

93 In this study, to understand the possible influence of farmers' activities on the regional air quality in
94 the NCP, filter samples of PM_{2.5} were collected daily in Beijing city as well as a rural area in Baoding,
95 Hebei Province for a whole year of 2014, and the seasonal variation characteristics of the water-
96 soluble ions (WSIs) in the PM_{2.5} samples were comprehensively investigated in relation to the
97 farmers' activities. The scientific evidence found in this study will be helpful for future control
98 measures in reducing pollutant emissions from rural areas in the NCP.

99 **2. Materials and methods**

100 **2.1. Sampling sites**

101 The sampling site in Beijing city was on a rooftop (about 25 m above ground) in the Research Center
102 for Eco-Environmental Sciences (here referred to as RCEES, 40°00'29.85"N, 116°20'29.71"E),
103 which is located between the north fourth-ring road and the north fifth-ring road of Beijing and
104 surrounded by some institutes, campuses, and residential areas (Pang and Mu, 2006). Another

105 sampling site in a rural area was selected on the rooftop of a field station (about 5 m above ground)
106 which is located in the agricultural field of Dongbaituo village (here referred to as DBT,
107 38°39'37.36"N, 115°15'16.05"E), Baoding, Hebei Province. The rural sampling site is far away
108 from industries, traffic and commercial emissions. The distance between the two sampling sites is
109 about 170 km and the detailed location of the two sampling sites is presented in Fig. 1.

110 **2.2. Sample collection**

111 PM_{2.5} samples at the two sites were both collected on Millipore PTFE filters (90 mm) by a PM_{2.5}
112 sampler (LaoYing-2034) and the sampling flow rate was set to 100 L min⁻¹. The duration of each
113 sampling was 24 hours, started at 3:00 p.m. every day and ended at 3:00 p.m. on the next day. All
114 the samples were put in dedicated filter storage containers (90 mm, Millipore) after sampling and
115 preserved in a refrigerator till analysis. For the sampling site of RCEES, a total of 235 PM_{2.5} samples
116 were collected from January to November of 2014, in winter (Jan 9- Mar 15), spring (Mar 16- May
117 31), summer (Jun 1- Jun 30, Aug 9- Aug 21) and autumn (Sep 19- Nov 14). To explore the possible
118 influence of farmers' activities, PM_{2.5} samples at DBT were mainly collected during the periods of
119 periodic farmers' activities: heating season in winter (Jan 9- Feb 25), harvest seasons in summer
120 (Jun 9- Jun 22, Aug 9- Aug 17) and autumn (Sep 19- Oct 18, Oct 28- Nov 14).

121 **2.3. Sample analysis**

122 Each sample filter was extracted ultrasonically with 10 mL ultrapure water for half an hour. The
123 solutions were filtered through a micro-porous membrane (pore size, 0.45 μm; diameter, 13 mm)
124 before analysis and the WSIs in the treated filtrates were analyzed by Ion Chromatography (IC,
125 WAYEE IC6200). Five anions (F⁻, HCOO⁻, Cl⁻, NO₃⁻ and SO₄²⁻) were separated by using an anion
126 column (IC SI-52 4E, 4 mmID*250 mm) with the eluent (3.6 mmol L⁻¹ Na₂CO₃) flow rate of 0.8

127 mL min⁻¹ and column temperature of 45 °C. Five cations (Na⁺, NH₄⁺, Mg²⁺, Ca²⁺ and K⁺) were
128 separated by using a cation column (TSKgelSuperIC-CR, 4.6 mmID*15 cm) with the eluent (2.2
129 mmol L⁻¹ MSA and 1 mmol L⁻¹ 18-crown-6) flow rate of 0.7 mL min⁻¹ and column temperature of
130 40 °C. The relative standard deviation (RSD) of each ion was less than 0.5% for the reproducibility
131 test. The detection limits (S/N=3) were less than 0.001 mg L⁻¹ for the anions and cations. At least
132 three filter blanks were analyzed for 60 filter samples, and the average blank values were about 0.03
133 mg L⁻¹ for Na⁺, Ca²⁺, F⁻, NO₃⁻ and SO₄²⁻, 0.02 mg L⁻¹ for NH₄⁺ and Cl⁻, 0.01 mg L⁻¹ for Mg²⁺, K⁺
134 and HCOO⁻. The concentrations of all the ions were corrected for blanks.

135 **2.4. Meteorology, trace gases and back trajectory**

136 The meteorological data, including temperature, wind speed, wind direction, relative humidity (RH),
137 visibility and Air Pollution Index of PM_{2.5}, SO₂, NO₂, O₃ at RCEES were from Beijing urban
138 ecosystem research station (<http://www.bjurban.rcees.cas.cn/>), which is about 20m away from our
139 sampling site of RCEES.

140 To identify the potential influence of air parcel transport, the air mass backward trajectories were
141 calculated for 72 h through the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT
142 4) Model of the Air Resources Laboratory of NOAA with NCEP Final analyses data. The backward
143 trajectories arriving at 500 m above sampling position were computed at 0:00 h, 6:00 h, 12:00 h and
144 18:00 h (UTC) in each sampling day, respectively. A total of 940 backward trajectories with 72
145 hourly trajectory endpoints in four seasons were used as input for further analysis.

146 **3. Results and discussion**

147 The ratios of total cation concentration (defined as [Na⁺] + [NH₄⁺] + 2 × [Mg²⁺] + 2 × [Ca²⁺] + [K⁺])
148 to total anion concentration (defined as [F⁻] + [HCOO⁻] + [Cl⁻] + [NO₃⁻] + 2 × [SO₄²⁻]) in different

149 seasons are illustrated in Fig. 2a. The near unity of the ratios indicated excellent charge balance in
150 $PM_{2.5}$ and high quality of the data. The mass concentrations of WSIs and $PM_{2.5}$ at the sampling site
151 of RCEES during the period of Jan 1- Jan 24, 2015 were also simultaneously measured by the filter
152 sampling method and the TEOM 1405 Monitor, respectively. As shown in Fig. 2b, the variation
153 trends of the WSIs and $PM_{2.5}$ were almost the same with a correlation coefficient (R^2) of 0.91,
154 implying that the concentration of WSIs measured could be used as an indicator of the pollution
155 level. The average mass concentration of WSIs contributed about 80% to the mass of $PM_{2.5}$
156 measured by the TEOM 1405 Monitor, which was much greater than the values of 50-60% reported
157 by previous studies in the NCP (Shen et al., 2009; Li et al., 2013). It was possible that the mass
158 concentration of $PM_{2.5}$ measured by the TEOM 1405 Monitor was underestimated because the
159 volatile even semi-volatile component in $PM_{2.5}$ can be easily lost at 50 °C which is designed in the
160 TEOM 1405 Monitor for avoiding water condensation on the filter (Charron et al., 2004; Grover et
161 al., 2005; Liu et al., 2014). It is well documented that temperature is a key factor affecting the
162 distribution of NH_4NO_3 on particle phase due to its thermal decomposition, e.g., at temperature
163 greater than 35 °C, little NH_4NO_3 is expected under typical ambient conditions (Finlayson-Pitts et
164 al., 1986). The total mass proportions of NO_3^- and NH_4^+ in WSIs usually account for about 50% in
165 Beijing city (Yang et al., 2015a), whereas they were found to only account for about 20% in the
166 filters of the TEOM 1405 Monitor in this study, confirming the serious loss of NH_4NO_3 under the
167 high temperature adopted by the TEOM 1405 Monitor.

168 **3.1. Daily variations of WSIs in Beijing city**

169 The daily variation of WSIs at RCEES in each season is illustrated in Fig. 3 and the average mass
170 concentrations of the WSIs at RCEES are summarized in Table 1. It is evident that the concentration

171 of the WSIs varied greatly on timescale of days, indicating meteorological conditions played a
172 pivotal role in accumulation and dissipation of atmospheric pollutants. For example, the highest
173 frequency pollution levels of the WSIs in winter were mainly ascribed to the relatively stable
174 meteorological conditions with the low height of boundary layer which favored pollutants'
175 accumulation (Wang et al., 2013;Quan et al., 2014;Tian et al., 2014;Wang et al., 2014;Zhang et al.,
176 2015a). Besides meteorological conditions, the extremely high levels of the WSIs during the
177 pollution episodes revealed strong sources of the pollutants around Beijing.

178 The mean concentrations ($\mu\text{g m}^{-3}$) of WSIs at RCEES in spring, summer, autumn and winter were
179 50.5 ± 37.3 , 44.2 ± 28.9 , 78.3 ± 92.6 , and 78.7 ± 61.2 , respectively. NO_3^- , SO_4^{2-} and NH_4^+ were
180 found to be the principal ions, accounted for about 80% to the total WSIs in each season, which
181 were in line with previous studies (Hu et al., 2014;Yang et al., 2015a;Huang et al., 2016;Yang et al.,
182 2015b). The three principal ions were mainly ascribed to secondary formation as discussed in the
183 following section. Although the most intensive photochemical reactivity in summer favors sulfate
184 and nitrate formation, the relatively low SO_2 concentration, the reduced gas-to-particle partitioning
185 of ammonium nitrate and the frequent scavenging by rain events must greatly counteract the
186 contribution of the secondary formation, resulting in the lowest pollution levels of the WSIs in
187 summer. In comparison with other seasons, the large elevation of atmospheric SO_2 and NO_x (see
188 section 3.2.3) in winter would result in large sulfate and nitrate formation rates despite the lower
189 concentrations of oxidizing species and cause the highest mean concentration of WSIs. Although
190 the atmospheric concentrations of SO_2 and NO_x in autumn were much smaller than in winter and in
191 spring (see section 3.2.3), the mean concentration of WSIs in autumn was almost the same as that
192 in winter and nearly twice as those in spring and summer, indicating that special mechanisms

193 dominated the secondary formation of the atmospheric principal ions (see section 3.2.3).

194 **3.2. The possible sources for the WSIs**

195 To explore the possible contribution of the periodic emissions from farmers' activities to the WSIs
196 in Beijing, the concentrations of typical WSIs at the urban and rural sites are compared in Fig. 4. It
197 is evident that the seasonal variation of the typical WSIs at the two sites exhibited the similar trend,
198 indicating the similar regional meteorological conditions. The concentrations of the typical WSIs at
199 DBT were generally higher than those at RCEES during the periods of farmers' activities (heating
200 in winter, fertilization in summer and maize harvest in autumn). To reveal the air mass transport
201 influence on the WSIs in Beijing, three-day backward trajectories for clusters and the corresponding
202 mass concentrations of WSIs during the four seasons in Beijing were analyzed, and the results are
203 illustrated in Fig. 5. It could be seen that the highest concentrations of the typical WSIs were usually
204 observed in the air parcels from southwest/south regions with high density of population.
205 Considering the large fraction (~30%) of air parcels from the southwest/south regions in each season,
206 the human activities in the southwest/south regions contributed to the atmospheric WSIs in Beijing.
207 Besides the industries, the emissions from the high density of farmers in the southwest/south regions
208 of Beijing was also suspected to affect to the atmospheric WSIs in Beijing.

209 **3.2.1. The sources of K^+ and Cl^-**

210 With the exception of the extremely high concentrations of K^+ on 1 February and 16 February (Fig.
211 4) due to firework for celebrating Spring Festival and Lantern Festival (Jiang et al., 2015;Kong et
212 al., 2015), the concentrations of Cl^- and K^+ were much higher in winter and autumn than in spring
213 and summer at the two sites (Fig. 4). The molar ratio of Cl^- to Na^+ at the two sites measured by this
214 study (Fig. 6) in each season was above 1.30 which was greater than the value of 1.18 in fresh sea-

215 salt particles (Brewer, 1975), indicating sources other than sea-salt dominated atmospheric Cl^- . The
216 pronounced correlation coefficients ($r > 0.6$, $p < 0.01$) between K^+ (the indicator for biomass burning,
217 Gao et al., 2011) and Cl^- in winter and autumn indicated that crop straw burning was a common
218 source for K^+ and Cl^- (Li et al., 2014). However, only crop straw burning couldn't explain the
219 relatively high concentrations of Cl^- in winter (Fig. 4), because the average molar Cl^-/K^+ ratio of 7.8
220 (except for firework event during the Spring Festival) in winter was about a factor of 2 greater than
221 the value of 4.2 in autumn when straw burning was prevailing in the region. Besides straw burning
222 and sea-salt, coal combustion (Yu et al., 2013; Wu et al., 2014) and biofuel burning (Christian et al.,
223 2010) have been also recognized as the sources for atmospheric Cl^- . Coal have almost been replaced
224 with natural gas and electricity for heating during the winter before 2013 in Beijing city (Ma et al.,
225 2015). Considering the relatively stable Cl^- emissions from coal combustion of industries and power
226 plants as well as biofuel burning during the whole year, the obviously higher Cl^- concentrations
227 measured in winter than in other seasons (Fig. 4) should be ascribed to the additional coal
228 combustion by farmers because of the large amount of residential coal consumption (about 42
229 Tg/year) in Beijing-Tianjin-Hebei region and extremely high emission factors of Cl^- (80-300 mg/kg
230 coal) from the coal combustion (Huang et al., 2014b). The obviously higher Cl^- proportion in winter
231 than in early spring (Fig. 7) provided further evidence for the above conclusion, because the
232 proportion largely counteracted the influence of meteorological factors.

233 It is interesting to note that the remarkably higher Cl^-/Na^+ ratio was observed in summer than in
234 other seasons at RCEES (Fig. 6), which couldn't be explained by the Cl^- sources mentioned above.
235 Fertilization events in the vast agricultural fields of the NCP were suspected to contribute to
236 atmospheric Cl^- in Beijing because volatile NH_4Cl fertilizer are prevailingly used as the basal

237 fertilization for maize in summer. Based on yearbook of China fertilizer industry (2012), national
238 production of NH_4Cl fertilizers was about 1.174 Tg in 2011, which was mainly used as the basal
239 fertilization for maize in summer. The obviously high concentrations of Cl^- at DBT (Fig. 4) were
240 indeed observed during the basal fertilization period for maize in June. Compared with the periods
241 before and after maize fertilization, the proportion of Cl^- during maize fertilization in summer
242 increased about 3%-4% (Fig. 7), confirming the influence of maize fertilization on atmospheric Cl^-
243 in Beijing. The extremely high concentration (about 2 ppbv) of Nitryl chloride (ClNO_2) observed
244 by Tham et al. (2016) at the same rural site in June indirectly indicated the high concentrations of
245 Cl^- during the period of basal fertilization for maize. Because fertilization is an important source for
246 atmospheric NH_3 , the elevation of Cl^- (as a tracer for fertilization) revealed that fertilization in the
247 rural areas around Beijing could also make obvious contribution to atmospheric NH_4^+ in Beijing.

248 3.2.2. The sources of Ca^{2+}

249 The remarkably high concentrations of Ca^{2+} occurred in both spring and autumn at RCEES (Fig. 3
250 and Fig. 4), which were in good agreement with previous studies (Fig. 8). The evident elevation of
251 Ca^{2+} concentrations in spring has been usually ascribed to the frequent dust storms (Zhao et al.,
252 2013b), but there was still no explanation about the extremely high Ca^{2+} concentrations in autumn
253 (Zhao et al., 2013b; Zhang et al., 2013). The intensive maize harvest and soil ploughing in autumn
254 in the vast agricultural fields of the NCP were suspected to contribute to atmospheric Ca^{2+} in Beijing.
255 Because abundant atmospheric mineral particles were absorbed by crop leaves (Bealey et al., 2007;
256 Ji et al., 2013) during crop growing season, especially in the North China where atmospheric mineral
257 dust is always at high level (Zhang et al., 2013; Zhao et al., 2013b), a large fraction of the mineral
258 dust absorbed on the leaves of crop could be released into the atmosphere during harvest with crop

259 straw being crushed into pieces for returning to fields which is a prevailing method under the
260 advocacy of governments for reducing the influence of crop straw burning on the air quality.
261 Additionally, the soil ploughing can also cause the suspension of particles (Fang et al., 2006; Chen
262 et al., 2015). The remarkably high concentrations of Ca^{2+} during the autumn at DBT (Fig. 4) should
263 be ascribed to the above agricultural activities because there are few construction activities in the
264 rural area. Compared with the periods before and after maize harvest and soil ploughing, the
265 proportion of Ca^{2+} during maize harvest and soil ploughing in autumn increased about 5%-7% (Fig.
266 7), confirming the influence of maize harvest and soil ploughing on atmospheric Ca^{2+} in Beijing.
267 The back trajectory cluster analysis also supported the above conclusion: (1) the extremely high
268 concentrations of Ca^{2+} in Beijing occurred during the period of 6-25 October (Fig. 3 and Fig. 4)
269 when the air parcels were mainly from the southwest/south regions (Fig. 5) where the vast areas of
270 agricultural field were being under intensive maize harvest and soil ploughing. (2) Although the
271 concentrations of Ca^{2+} in the rural area remained at high levels during the period of 2-14 November
272 (Fig.3 and Fig. 4), the relatively low concentrations of Ca^{2+} in Beijing were observed during the
273 period when the air parcels were mainly from the northwest region (Fig. 5) where agricultural
274 activities are relatively sparse.

275 3.2.3. The sources of NH_4^+ , SO_4^{2-} and NO_3^-

276 The remarkably high concentrations of NH_4^+ , SO_4^{2-} and NO_3^- also appeared in both winter and
277 autumn at the two sites (Fig. 4). NH_4^+ was mainly from the reactions of NH_3 with acid gases (such
278 as HNO_3) and acid particles, and hence its variation trend was the same as those of SO_4^{2-} and NO_3^- .
279 Although atmospheric NH_3 has long been considered to be mainly from agricultural activities, their
280 emissions mainly concentrate on warmer seasons (Krupa, 2003), which cannot explain the frequent

281 high concentrations of NH_4^+ observed in winter. Besides the increased gas-to-particle partitioning
282 of ammonium nitrate at lower temperatures, strong NH_3 emission sources other than agricultural
283 activities were suspected to be responsible for the frequent high concentrations of NH_4^+ in the cold
284 winter. Besides NH_3 emission from vehicles (Liu et al., 2014), strong emission of NH_3 from farmers'
285 coal stoves (the NH_3 emission factor was 0.62-1.10 g/kg coal) was indeed found by our preliminary
286 measurements, which was in line with the latest study (Li et al., 2016). During the serious pollution
287 episodes, the concentrations of SO_2 at RCEES in autumn were almost the same as those in summer
288 and about one order of magnitude lower than in winter (Fig. 9), but the peak concentrations of SO_4^{2-}
289 in autumn were about a factor of 2 greater than those in summer and at almost the same level as
290 those in winter. The gaseous phase reaction with OH (Zhao et al., 2013c; Quan et al., 2014), the
291 heterogeneous reaction on mineral dust (He et al., 2014; Nie et al., 2014), and multiphase reactions
292 in the aerosol water (Zheng et al., 2015a) of SO_2 have been recognized to be responsible for
293 atmospheric SO_4^{2-} formation. The significant elevation of both Ca^{2+} and SO_4^{2-} in autumn implied
294 that the heterogeneous reaction of SO_2 on the mineral dust might greatly accelerate the conversion
295 of SO_2 to SO_4^{2-} . Although evidently high concentrations of Ca^{2+} occurred (Fig. 3 and Fig. 4) in
296 spring and SO_2 concentrations were much greater in spring than in autumn (Fig. 9), the SO_4^{2-}
297 concentrations were about a factor of 2 less in spring than in autumn. Atmospheric humidity was
298 suspected to play an important role in the heterogeneous reaction, e.g., the relative humidity was
299 much higher in autumn than in spring during the serious pollution events (Fig. 9). Similar to SO_4^{2-} ,
300 the relatively high concentrations of NO_3^- during the serious pollution events in autumn were also
301 ascribed to the heterogeneous reaction of NO_2 on the mineral dust. Therefore, the emission of
302 mineral dust from maize harvest and soil ploughing in autumn also played important roles in

303 secondary formation of nitrate and sulfate in Beijing.

304 The nitrogen oxidation ratio $NOR = nNO_3^- / (nNO_3^- + nNO_x)$ (n refers to molar concentration) and

305 the sulfur oxidation ratio $SOR = nSO_4^{2-} / (nSO_4^{2-} + nSO_2)$ have been used to estimate the degree of

306 secondary formation of NO_3^- and SO_4^{2-} , which can counteract the interference of meteorological

307 factors (Chan and Yao, 2008; Yu et al., 2013; Guo et al., 2014; Huang et al., 2014a; Yang et al.,

308 2015b; Zheng et al., 2015b). The values of NOR and SOR during haze days and non-haze days in

309 four seasons are listed in Table 2. Both the values of NOR and SOR on non-haze days were found

310 to be the highest in summer and the lowest in winter, reflecting the seasonal variation of

311 photochemical intensity. Although sunlight intensity greatly reduced at ground level during haze

312 days, the values of NOR and SOR were about a factor of 2 greater during haze days than during

313 non-haze days in the four seasons, implying again that the heterogeneous or multiphase reactions of

314 SO_2 and NO_2 on atmospheric particles made significant contribution to atmospheric sulfate and

315 nitrate.

316 3.2.4. The variation characteristics of NO_3^- and SO_4^{2-} during serious pollution episodes

317 As shown in Fig. 9, the serious pollution episodes with noticeable elevation of various pollutants

318 usually occurred under slow wind speed (less than 2 m s^{-1}) and high relative humidity. In comparison

319 with their precursors of SO_2 and NO_x , the detailed variation trends of SO_4^{2-} and NO_3^- were different,

320 indicating that the elevation of SO_4^{2-} and NO_3^- was not simply ascribed to the physical process of

321 accumulation. It is interesting to note that the increasing rates of SO_4^{2-} during some serious pollution

322 events especially with elevation of Ca^{2+} (such as in spring and autumn) were much slower than those

323 of NO_3^- (Fig. 10), implying that the atmospheric heterogeneous reaction of NO_2 on the mineral dust

324 was faster than that of SO_2 . Compared with summer and winter, the relatively high ratios of NO_3^-

325 /SO₄²⁻ in spring and autumn (Fig. 6) also supported the above conclusion.

326 **3.3. Comparison with previous studies**

327 The mean concentrations of the three principal ions and some related indicators in Beijing over the
328 past decade are summarized in Table 3. The seasonal variations of the three principal ions reported
329 were quite different, e.g., Huang et al. (2016) found the maximal mean concentrations of SO₄²⁻ and
330 NH₄⁺ in the summer and of NO₃⁻ in the autumn of 2014, whereas in this study all the maximal mean
331 concentrations of the three principal ions appeared in autumn. The mean concentrations of the three
332 ions in autumn in this study were in good agreement with the values reported by Yang et al. (2015).
333 For the molar concentration ratios of NO₃⁻/SO₄²⁻ (denoted as N/S), all the investigations exhibited
334 relatively high values in autumn and spring, further confirming that the heterogeneous reaction of
335 NO₂ on mineral dust favored nitrate formation (as discussed above). For NOR and SOR, all
336 investigations were in good agreement, with the highest values in summer, the lowest in winter and
337 higher values during haze days than during clean days. Compared with the investigations of 2003,
338 the evident increase of both the concentration of NO₃⁻ and the ratio of N/S in recent years revealed
339 the fast increase of vehicle numbers in the decade made significant contribution to atmospheric
340 nitrate.

341 **4. Conclusions**

342 The large daily fluctuation of the WSIs in each season confirmed that meteorological factors played
343 an important role in governing the accumulation and dispersion of the pollutants. The extremely
344 high concentrations of the WSIs during the serious pollution episodes indicated there were strong
345 sources of the pollutants in Beijing. Based on the comprehensive analysis of the data of the WSIs,
346 the farmers' activities, such as crop harvest, crop straw burning, and coal combustion for heating,

347 were found to contribute to the atmospheric WSIs in Beijing. To mitigate the currently serious
348 pollution status in the NCP including Beijing, the strong emissions of pollutants from the periodic
349 activities of farmers should be paid greater attention.

350 **Author contribution**

351 **Y. J. Mu** designed the experiments and prepared the manuscript. **P. F. Liu** carried out the
352 experiments and prepared the manuscript. **C. L. Zhang** carried out the experiments. **C. T. Liu, C.**
353 **Y. Xue, C. Ye, J. F. Liu** and **Y. Y. Zhang** were involved in part of the work. **H. X. Zhang** provided
354 the meteorological data and trace gases.

355 **Acknowledgements**
