14 **Abstract**

15 We use a series of chemical transport model and chemistry climate model simulations to
16 investigate the observed negative trends in MOPITT CO over several regions of the
17 world, and to examine the consistency of time-dependent emission inventories with
18 observations. We find that simulations driven by the MACCity inventory, used for the
19 Chemistry Climate Modeling Initiative (CCMI), reproduce the negative trends in the CO
20 column observed by MOPITT for 2000-2010 over the eastern United States and Europe.
21 However, the simulations have positive trends over eastern China, in contrast to the
22 negative trends observed by MOPITT. The model bias in CO, after applying MOPITT
23 averaging kernels, contributes to the model-observation discrepancy in the trend over
24 eastern China. This demonstrates that biases in a model's average concentrations can
25 influence the interpretation of the temporal trend compared to satellite observations. The
26 total ozone column plays a role in determining the simulated tropospheric CO trends. A
27 large positive anomaly in the simulated total ozone column in 2010 leads to a negative
28 anomaly in OH and hence a positive anomaly in CO, contributing to the positive trend in
29 simulated CO. These results demonstrate that accurately simulating variability in the
30 ozone column is important for simulating and interpreting trends in CO.

31 **1. Introduction**

32

33 Carbon monoxide (CO) is an air pollutant that contributes to ozone formation and
34 affects the oxidizing capacity of the troposphere (Thompson, 1992; Crutzen, 1973). Its
35 primary loss is through reaction with OH, which leads to a lifetime of 1-2 months (Bey et
36 al., 2001) and makes CO an excellent tracer of long-range transport. Both fossil fuel
37 combustion and biomass burning are major sources of CO. The biomass burning source
38 shows large interannual variability (van der Werf et al., 2010), while fossil fuel emissions
39 typically change more gradually. The time-dependent MACCity inventory (Granier et
40 al., 2011) shows decreases in CO emissions from the United States and Europe from
41 2000 to 2010 due to increasing pollution controls, but increases in emissions from China.
42 MACCity emissions for years after 2000 are based on the Representative Concentration
43 Pathway (RCP) 8.5 (Riahi et al., 2007). The REAS (Kurokawa et al., 2013) and
44 EDGAR4.2 (EC-JRC/PBL, 2011) inventories also show increasing CO emissions from
45 China. The bottom-up inventory of Zhang et al. (2009) shows an 18% increase in CO
46 emissions from China from 2001 to 2006, and Zhao et al. (2012) estimate a 6% increase
47 between 2005 and 2009. However, there is considerable uncertainty in bottom-up
48 inventories, and comparison of model hindcast simulations driven by bottom-up
49 inventories with observations provides an important test of the time-dependent emission
50 estimates.

51 Space-based observations of CO are now available for over a decade and show
52 trends at both hemispheric and regional scales. Warner et al. (2013) found significant
53 negative trends in both background CO and recently emitted CO at 500 hPa over southern
54 hemisphere oceans and northern hemisphere land and ocean in Atmospheric Infrared
55 Sounder (AIRS) data. Worden et al. (2013) calculated trends in the CO column from
56 several thermal infrared (TIR) instruments including MOPITT and AIRS. They found
57 statistically significant negative trends over Europe, the eastern United States, and China
58 for 2002-2012. He et al. (2013) also report a negative trend in MOPITT near-surface CO
59 over western Maryland.

60 Surface concentrations of CO show downward trends over the United States
61 driven by emission reductions (EPA, 2011), consistent with the space-based trends.
62 Decreases in the partial column of CO from FTIR stations in Europe also show decreases
63 from 1996 to 2006, consistent with emissions decreases (Angelbratt et al., 2011). Yoon

64 and Pozzer (2014) found that a model simulation of 2001 to 2010 reproduced negative
65 trends in surface CO over the eastern U.S. and western Europe, but showed a positive
66 trend in surface CO over southern Asia.

67 The cause of the negative trend over China seen in MOPITT and AIRS data is
68 uncertain. The trend is consistent with the results of Li and Liu (2011), who found
69 decreases in surface CO measurements in Beijing, and with decreases in CO emissions in
70 2008 inferred from the correlation of CO with CO₂ measured at Hateruma Island
71 (Tohjima et al., 2014) and at a rural site in China (Wang et al., 2010). Yumimoto et al.
72 (2014) used inverse modeling of MOPITT data to infer a decrease in CO emissions from
73 China after 2007. The 2008 Olympic Games and the 2009 global economic slowdown
74 led to reductions in CO (Li and Liu, 2011; Worden et al., 2012). However, the negative
75 trend in MOPITT CO is inconsistent with the rising CO emissions of the MACCity and
76 REAS inventories. Inverse modeling of MOPITT version 6 data yields a negative trend
77 in CO emissions from China and a larger global decline in CO emissions than that found
78 in the MACCity inventory (Yin et al., 2015).

79 This study examines whether global hindcast simulations can reproduce the trends
80 and variability in carbon monoxide seen in the MOPITT record. We examine the role of
81 averaging kernels and the contribution of trends at different altitudes to the trends
82 observed by MOPITT. We then examine the impact of OH variability on the simulated
83 trends in CO.

84 **2. Methods**

85 **2.1. MOPITT**

86 The MOPITT instrument onboard the Terra Satellite provides the longest satellite-
87 based record of atmospheric CO, with observations available from March 2000 to
88 present. It provides nearly global coverage every three days (Edwards et al., 2004). We
89 use the monthly Level 3 daytime column data from the Version 5 TIR product, which has
90 negligible drift in the bias over time (Deeter et al., 2013). The level 3 data is a gridded
91 product and includes the a priori and averaging kernel for each grid box. Supplemental
92 Figure S1 shows the MOPITT column averaging kernels averaged over four regions. The
93 column averaging kernels depend on the observed scene, and vary year to year as well as

94 seasonally. The dependence of the column averaging kernels on the CO mixing ratio
95 profile (Deeter, 2009) explains the high values in the lower troposphere over eastern
96 China in winter.

97 We calculate trends and de-seasonalized anomalies for the Eastern U.S., Europe, and
98 eastern China regions described by Worden et al. (2013). Trends that differ from zero by
99 more than the two-sigma uncertainty on the trend are considered statistically significant.
100 We account for autocorrelation of the data for a one-month lag when calculating the
101 uncertainty on the trends. We calculate the annual cycle by fitting the data with a series
102 of sines and cosines as well as the linear trend, and then remove the annual cycle to
103 obtain the de-seasonalized anomalies. Months with no MOPITT data or only a few days
104 of MOPITT data are excluded from the trend analysis. This includes May-August of
105 2001 and August-September of 2009. We report the MOPITT trends for 2000-2010 for
106 comparison with model simulations, and for 2000-2014 to give a longer-term view of the
107 observed trends.

108

109 **2.2. Model Simulations**

110 We use a suite of chemistry climate model (CCM) and chemical transport model
111 (CTM) simulations to interpret the observed trends. The Global Modeling Initiative
112 (GMI) CTM includes both tropospheric (Duncan et al., 2007) and stratospheric (Strahan
113 et al., 2007) chemistry, including over 400 reactions and 124 chemical species.
114 Meteorology for the GMI simulations comes from the Modern-Era Retrospective
115 Analysis for Research and Applications (MERRA) (Rienecker et al., 2011). The GEOS-
116 5 Chemistry Climate Model (GEOSCCM)(Oman et al., 2011) incorporates the GMI
117 chemical mechanism into the GEOS-5 atmospheric general circulation model (AGCM).
118 The GEOSCCM simulations are forced by observed sea surface temperatures (SSTs)
119 from (Reynolds et al., 2002).

120 The Community Earth System Model, CESM1 CAM4-chem, includes 191 chemical
121 tracers and over 400 reactions for both troposphere and stratosphere (Tilmes et al., 2016).
122 The model can be run fully coupled to a free-running ocean, with prescribed SSTs, or
123 with nudged meteorology from GEOS-5 or MERRA analysis. CESM1 CAM4-chem is

124 further coupled to the land model, providing biogenic emissions from the Model of
125 Emissions and Aerosols from Nature (MEGAN), version 2.1 (Guenther et al., 2012).

126 Several simulations were conducted as part of the Chemistry-Climate Model Initiative
127 (CCMI) project (Eyring et al., 2013). These include the Ref-C1 simulation of the
128 GEOSCCM and a Ref-C1 CESM1 CAM4-Chem simulation, hereafter called G-Ref-C1
129 and C-Ref-C1, respectively, and the Ref-C1-SD simulation of the GMI CTM. Both the
130 Ref-C1 and the Ref-C1-SD simulations use time-dependent anthropogenic and biomass
131 burning emissions from the MACCity inventory (Granier et al., 2011), but the Ref-C1-
132 SD simulations use specified meteorology while the Ref-C1 simulations run with
133 prescribed SSTs. The MACCity inventory linearly interpolates the decadal
134 anthropogenic emissions from the ACCMIP inventory (Lamarque et al., 2010) for 2000,
135 and the RCP8.5 emissions for 2005 and 2010, to each year in between. The MACCity
136 biomass burning emissions have year-to-year variability based on the GFED-v2 (van der
137 Werf et al., 2006) inventory. From 2000 to 2010, CO emissions in the MACCity
138 inventory decreased from 31 to 11 Tg yr⁻¹ over the eastern U.S., from 97 to 59 Tg yr⁻¹
139 over Europe, and increased from 56 Tg to 72 Tg yr⁻¹ over eastern China.

140 Given the uncertainty in CO emissions, we conduct a GMI CTM simulation using an
141 alternative time-dependent emissions scenario, called AltEmis. This simulation is
142 described in detail in (Strode et al., 2015b). Briefly, anthropogenic emissions include
143 time-dependence based on EPA (<http://www.epa.gov/ttn/chief/trends/index.html>), the
144 REAS inventory (Ohara et al., 2007), and EMEP
145 (http://www.ceip.at/ms/ceip_home1/ceip_home/webdab_emepdatabase/reported_emissiondata/),
146 and annual scalings from van Donkelaar et al. (2008). Biomass burning
147 emissions are based on the GFED3 inventory (van der Werf et al., 2010). While the
148 regional emission trends in this simulation are of the same sign as in the Ref-C1 case, the
149 magnitude of the negative trends over the U.S. and Europe are smaller and the positive
150 trend over China is larger, leading to a positive global trend (Fig. 1). We also conduct a
151 sensitivity study called EmFix with anthropogenic and biomass burning emissions held
152 constant at year 2000 levels. Table 1 summarizes the simulations used in this study.

153 We regrid the model output to the MOPITT grid and convolve the simulated CO with
154 the MOPITT averaging kernels and a priori in order to compare the simulated and

155 observed CO columns. The averaging kernels are space and time dependent. We use the
156 following equation from Deeter et al. (2013):

$$157 \quad C_{\text{sim}} = C_0 + \mathbf{a}(\mathbf{x}_{\text{mod}} - \mathbf{x}_0) \quad (1)$$

158 where C_{sim} and C_0 are the simulated and a priori CO total columns, respectively, \mathbf{a} is the
159 total column averaging kernel, and \mathbf{x}_{mod} and \mathbf{x}_0 are the modeled and a priori CO profiles,
160 respectively. The column averaging kernel is calculated from the standard averaging
161 kernel matrix, which is based on the log of the CO concentration profile, following the
162 method of Deeter (2009):

$$163 \quad a_j = (K / \log_{10}e) \sum \Delta p_i v_{\text{rtv},i} A_{ij} \quad (2)$$

164 where Δp_i and $v_{\text{rtv},i}$ are the pressure thickness and retrieved CO concentration,
165 respectively, of level i , \mathbf{A} is the standard averaging kernel matrix, and $K = 2.12 * 10^{13}$
166 molec cm⁻² hPa⁻¹ ppb⁻¹.

167 We deseasonalize the simulated CO columns and calculate their linear trend
168 following the same procedure that we applied to the MOPITT CO. Months that do not
169 have MOPITT data (June-July 2001 and August-September 2009) are excluded from the
170 analysis of the model trends as well.

171 The Ref-C1 and Ref-C1-SD simulations requested by CCMI extend until 2010.
172 However, the MACCity biomass burning emissions extend only until 2008. CAM4-
173 Chem therefore repeated the biomass burning emissions for 2008 for years 2009-2010.
174 In contrast, the GEOSCCM Ref-C1 and GMI Ref-C1-SD simulations used emissions
175 from GFED3 (van der Werf et al., 2010) for years after 2008. Some simulations were
176 available through 2011, while others ended in 2010. We therefore report results for
177 2000-2010, but note that extending the analysis through 2011 does not alter the
178 conclusions.

179 **3. Results**

180 **3.1. Trends over Europe, the United States, and the Northern Hemisphere**

181 The hindcast simulations driven by MACCity emissions (G-Ref-C1, Ref-C1-SD, and
182 C-Ref-C1) show negative trends in CO over the U.S. and Europe that agree with the
183 observed slope from MOPITT within the uncertainty (Fig. 2, Table 2). The MOPITT

184 trends for both regions are statistically significant for both regions, as shown by Worden
185 et al. (2013). These results are consistent with the findings of Yin et al. (2015), whose
186 inversion of MOPITT data showed a posteriori trends in CO emissions over the U.S. and
187 western Europe that were consistent with but slightly larger than the a priori trends. The
188 EmFix hindcast shows a positive, though non-significant, trend for both regions,
189 indicating that the decrease in CO emissions is necessary for reproducing the downward
190 trend in the CO column. The AltEmis simulation fails to produce the negative trends,
191 despite including negative trends in regional emissions for both the U.S. and Europe.
192 The impact of these negative regional trends is insufficient to overcome the positive
193 global emission trend in the AltEmis scenario (Fig. 1), leading to positive trends in CO.

194 Figure 2 also reveals a negative bias in the simulated CO column between the models
195 and MOPITT. A low bias in simulated CO at northern latitudes is often present in global
196 models (Naik et al., 2013), and may indicate a high bias in northern hemisphere OH
197 (Strode et al., 2015a) or CO dry deposition (Stein et al., 2014), as well as an
198 underestimate of CO emissions.

199 The deseasonalized anomalies in the MOPITT and simulated CO columns are shown
200 in Fig. 2b,d, and the correlation coefficient between the observed and simulated monthly
201 anomalies are presented in Table 2b. The highest correlations are for the AltEmis and
202 Ref-C1-SD simulations of the GMI CTM. This result is consistent with the use of year-
203 specific meteorology, which we expect to better match the transport of particular years.
204 The lowest correlations are for the EmFix simulation. This is expected since the EmFix
205 simulation does not include inter-annual variability (IAV) in biomass burning. The IAV
206 in biomass burning makes a large contribution to the IAV of CO (Voulgarakis et al.,
207 2015).

208 The role of biomass burning in driving the CO variability is even more evident at the
209 hemispheric scale. Figure 2g,h shows the anomalies in MOPITT and the simulations for
210 the northern hemisphere (0-60N). The EmFix simulation shows almost no correlation,
211 while the other simulations have correlation coefficients exceeding 0.6 (Table 2). The
212 role of changing anthropogenic emissions is also evident, as the Ref-C1-SD simulation
213 captures the 2008-2009 dip in the CO column while the EmFix simulation does not.
214 Gratz et al. (2015) found decreasing CO concentrations at Mount Bachelor Observatory

215 in Oregon during spring for 2004-2013, which they attribute to reductions in emissions
216 leading to a lower hemispheric background. We also note that Ref-C1-SD and G-Ref-
217 C1 have similar correlations with the observed variability for the northern hemisphere
218 (Table 2), indicating that transport differences are less important for variability at the
219 hemispheric scale.

220 **3.2. Trend over China**

221 Observations from MOPITT show a negative trend in the CO column over eastern
222 China for 2002-2012 (Worden et al., 2013). The negative trend for the years 2000-2014
223 exceeds that for 2000-2010 (Table 2), showing that it is not driven solely by temporary
224 emission reductions in 2008. Our simulations do not reproduce this trend, and instead
225 show increases in the CO column (Fig. 2e), which is expected given that CO emissions
226 from China increase in four of the five simulations. The anomalies (Fig. 2f) show that
227 the discrepancy in the simulated versus observed trends is driven largely by the failure of
228 the simulations to capture the 2008 dip in the CO column, leading to an overestimate that
229 continues through 2010. This suggests emission reductions in China during this time
230 period are not adequately captured by the emission inventories. However, the good
231 agreement between the observed and simulated decreases in CO for the northern
232 hemisphere as a whole (Fig. 2g,h) suggest that on a global scale, the emission time series
233 is reasonable. Consequently, we examine several other factors that may contribute to the
234 difference in sign between the MOPITT and simulated CO trends.

235 Regional trends in CO are expected to vary with altitude, with surface concentrations
236 most heavily influenced by local emissions. MOPITT TIR retrievals have higher
237 sensitivity to CO in the mid-troposphere than at the surface (Deeter et al., 2004), so the
238 trend in the MOPITT CO column will be weighted towards the trends in free tropospheric
239 CO rather than near-surface CO. We quantify this impact on our Ref-C1-SD CO column
240 trends by comparing the trend in the pure-model CO column with that of the simulated
241 column convolved with the MOPITT averaging kernels.

242 The simulated CO trend over eastern China for 2000-2010 is positive (but not
243 significant) both with and without the averaging kernels, but application of the MOPITT
244 kernels increases the positive trend from 1.3×10^{16} molec cm⁻² yr⁻¹ to 1.4×10^{16} molec cm⁻²
245 yr⁻¹. This result is initially surprising since we expect trends in the mid-troposphere to be

246 more strongly influenced by the decrease in the hemispheric CO background. Indeed, the
247 trends in CO concentration over eastern China simulated in Ref-C1-SD switch from
248 positive in the lower troposphere to negative in the middle and upper troposphere.
249 However, the application of the kernels results in more positive (or less negative) trends
250 in all regions.

251 Yoon et al. (2013) show that since the averaging kernels vary over time, a bias
252 between the true atmosphere and the a priori assumed by MOPITT can lead to an
253 artificial trend in the retrieved CO. Similarly, the bias between the average simulated CO
254 concentrations and the MOPITT a priori, evident in Figure 2, can lead to an artifact in the
255 simulated CO trend when the simulation is convolved with the MOPITT averaging
256 kernels. This is due to the changing contribution of the a priori when the vertical
257 sensitivity (averaging kernel) is varying in time. MOPITT vertical sensitivity varies with
258 time due to instrument degradation as well as the change in CO abundance. The bias in
259 CO varies with altitude, so if the vertical sensitivity described by the averaging kernel
260 changes, this will change the value of the convolved CO column even if there were no
261 changes in the CO profile. Furthermore, changes in the averaging kernel result in more
262 or less weight placed on the a priori versus the CO simulated by the model. Thus, a
263 difference between the a priori and the model means that placing more (or less) weight on
264 the a priori will change the resulting value of C_{sim} . Since the a priori profiles and
265 columns are constant in time, taking the time derivative of equation 1 yields:

$$266 \quad \partial C_{sim}/\partial t = \mathbf{a} (\partial \mathbf{x}_{mod}/\partial t) + \partial \mathbf{a}/\partial t (\mathbf{x}_{mod} - \mathbf{x}_0) \quad (3)$$

267 The second term on the right hand side shows that the larger the bias between the
268 modeled CO and the a priori, the larger the impact of the changing averaging kernel.

269 We quantify this effect by convolving the simulated CO for each year with the
270 MOPITT averaging kernels for the year 2008, thus removing the effect of the time-
271 dependence of the averaging kernels. The resulting trend, $0.56 \cdot 10^{16} \text{ molec cm}^{-2} \text{ yr}^{-1}$, is
272 less positive than the pure model trend or the original simulated trend. Thus, accounting
273 for the time-dependence of the averaging kernels convolved with model bias reduces but
274 does not eliminate the discrepancy with the observed trend. Other regions also show a
275 more negative trend when the same averaging kernel is applied to the model results for
276 all years. The large bias in CO at middle and high northern latitudes commonly seen in

277 modeling studies thus impacts the ability of models to reproduce and attribute observed
278 trends in satellite data.

279 Figure 2 and Table 2 also show a positive trend in the GMI EmFix simulation for
280 eastern China. This larger trend in the EmFix simulation than the Ref-C1-SD simulation
281 indicates that the net decrease in emissions contributes to decreasing CO over eastern
282 China, consistent with the observed negative trend, but other factors in the model cause
283 an increase in CO over eastern China even when all emissions are constant. The trend in
284 the EmFix simulation thus contributes to the erroneous sign of the trend in the GMI
285 simulations. The trends in the EmFix simulation for the northern hemisphere average and
286 the eastern U.S. and Europe are positive as well (Table 2). We examine their cause in the
287 next section.

288 **3.3. Contribution of OH Interannual Variability**

289

290 Since the EmFix simulation shows a positive trend in the northern hemisphere, we
291 next examine the variability in the CO sink, OH. We also examine variability in the total
292 ozone column, since overhead ozone is a major driver of OH variability (Duncan and
293 Logan, 2008). Figure 3 shows the variability in CO and OH in the EmFix simulation.
294 The positive and negative anomalies in CO correspond with the negative and positive
295 anomalies, respectively, in OH. The anomalies in OH are in turn inversely related to
296 anomalies in the total ozone column. The correlation coefficient between OH and
297 column ozone is -0.53 for the 15°S-15°N average, -0.72 for the 15°-25°N average, and -
298 0.75 for the 30°-60°N average. The large NH ozone anomaly in 2010, in particular, leads
299 to a large anomaly in OH and thus CO. This OH anomaly extends from the northern
300 tropics to the midlatitudes. The large CO anomaly near the end of the time series
301 contributes to the apparent 11-year trend. We note that since the lifetime of CO is several
302 months, CO anomalies are not expected to have a one-to-one correspondence with the
303 OH anomalies.

304 The large anomaly in the simulated total ozone column in 2010 is overestimated
305 compared to observations. Figure 4 shows the time-dependence of the total ozone
306 column from 30°-60°N in EmFix compared to SBUV data (Frith et al., 2014). While the
307 observations show an anomaly in 2010, the magnitude is smaller than that produced by

308 the simulation. Steinbrecht et al. (2011) attribute the 2010 anomaly in northern
309 midlatitude ozone observations to a combination of an unusually strong negative Arctic
310 Oscillation and North Atlantic Oscillation and the easterly phase of the quasi-biennial
311 oscillation.

312 While the impact of OH interannual variability on the apparent trend in CO is clear in
313 the EmFix simulation, this source of variability is partially masked by large interannual
314 variability in CO emissions in the other simulations. We examine the correlation
315 between the de-trended and deseasonalized CO anomalies from 10°S-10°N in the Ref-
316 C1-SD simulation and the CO emissions as well as the simulated OH and column ozone.
317 Since the CO emitted in a given month can influence concentrations for several
318 subsequent months, we use a 3-month smoothing of the emission time series. We find a
319 high correlation ($r=0.88$) between the CO anomalies and the CO emissions. This
320 correlation is also evident in the MOPITT data, as the MOPITT CO anomalies have a
321 correlation of $r=0.70$ with the emissions. Figure 5 shows the strong relationship between
322 the simulated CO anomalies and the CO emissions. However, the colors in Fig. 5
323 indicate that the scatter for a given level of emissions is often linked to the OH
324 anomalies, with low/high OH anomalies leading to CO that is higher/lower than would be
325 predicted just from the CO emissions. We find that the 10°S-10°N OH in the Ref-C1-SD
326 simulation is anticorrelated with CO ($r=-0.62$) and with the total ozone column ($r=-0.68$).
327 Consequently, the simulated ozone column plays a role in modulating tropical CO
328 variability even when variable CO emissions are included, although the emissions still
329 play the strongest role.

330 **4. Conclusions**

331 We conducted a series of multi-year simulations to analyze the causes of the negative
332 trends in MOPITT CO reported by Worden et al. (2013). Both CTM and CCM
333 simulations driven by the MACCity emissions reproduce the observed trends over the
334 eastern U.S. and Europe, providing confidence in the regional emission trends.

335 None of the simulations reproduce the observed negative trend over eastern China.
336 This negative trend persists even with the MOPITT data extended out to 2014. The
337 MOPITT averaging kernels are weighted towards the free troposphere, where the relative

338 importance of hemispheric versus local trends is greater. However, our simulations
339 indicate that this effect is insufficient to explain the negative trends over China. While
340 this likely indicates a too positive emission trend for China, several other factors play a
341 role in the model-observation mismatch. We find that the time-dependent MOPITT
342 averaging kernels, combined with the low bias in simulated CO, provides a positive
343 component to the simulated trends. Large anomalies in the simulated ozone column in
344 the GMI CTM simulations also contribute a positive component to the northern
345 hemisphere trends due to their impact on OH.

346 Variability in emissions is the primary driver of year-to-year variability in simulated
347 CO, but OH variability also plays a role. The simulated OH is anti-correlated with both
348 CO and the total ozone column, highlighting the importance of realistic overhead ozone
349 columns for accurately simulating CO variability and trends. In addition, further work is
350 needed to understand recent changes in CO emissions from China.

351

352 **Acknowledgements**

353 This work was supported by NASA's Modeling, Analysis, and Prediction program
354 and computing resources from the NASA High-End Computing Program. We thank
355 Bruce Van Aartsen for contributing to the GMI simulations. The CESM project is
356 supported by the National Science Foundation and the Office of Science (BER) of the US
357 Department of Energy. The MOPITT project is supported by the NASA Earth Observing
358 System (EOS) Program. The National Center for Atmospheric Research (NCAR) is
359 sponsored by the National Science Foundation.
