## Abstract

China suffers from frequent haze pollution episodes that alter the surface solar radiation and influence regional carbon uptake by the land biosphere. Here, we apply combined vegetation and radiation modeling and multiple observational datasets to assess the radiative effects of aerosol pollution in China on the regional land carbon uptake for the 2009-2011 period. First, we assess the inherent sensitivity of China's land biosphere to aerosol pollution by defining and calculating two aerosol optical depth (AOD) at 550 nm thresholds (i)  $AOD_{t1}$ , resulting in the maximum net primary productivity (NPP), and (ii)  $AOD_{t2}$ , such that if local  $AOD < AOD_{t2}$ , the aerosol diffuse fertilization effect (DFE) always promotes local NPP compared with aerosol-free conditions. Then, we apply the thresholds, satellite data, and interactive vegetation modeling to estimate current impacts of aerosol pollution on land ecosystems. In the Northeast, observed AOD is 55% lower than  $AOD_{t1}$ , indicating strong aerosol DFE on local NPP. In the southeastern coastal regions, observed AOD is close to  $AOD_{t1}$ , suggesting that regional NPP is promoted by the current level of aerosol loading but that further increases in AOD in this region will weaken the fertilization effects. The North China Plain experiences limited enhancement of NPP by aerosols because observed AOD is 77% higher than  $AOD_{t1}$  but 14% lower than  $AOD_{t2}$ . Aerosols always inhibit regional NPP in the Southwest because of the persistent high cloud coverage that already substantially reduces the total light availability there. Under clear-sky conditions, simulated NPP shows widespread increases of 20-60% ( $35.0 \pm 0.9$  % on average) by aerosols. Under all-sky conditions, aerosol pollution has spatially contrasting opposite sign effects on NPP from -3% to +6% ( $1.6 \pm 0.5$ % on average), depending on the local AOD relative to the regional thresholds. Stringent aerosol pollution reductions motivated by public health concerns, especially in the North China Plain and the Southwest, will help protect land ecosystem functioning in China and mitigate long-term global warming.

## 43 **1 Introduction**

44

45 Atmospheric aerosols scatter and absorb solar radiation, while plants rely on sunlight for  
46 photosynthesis. Thus, aerosols affect land carbon uptake through radiative perturbations. In  
47 particular, observations have demonstrated that aerosols can enhance canopy photosynthesis  
48 and light-use efficiency ( $LUE = GPP/PAR$ , GPP is gross primary productivity and PAR is  
49 photosynthetically active radiation) by increasing diffuse radiation in the lower canopy (Gu et  
50 al., 2003; Rap et al., 2015; Strada et al., 2015). This aerosol diffuse fertilization effect (DFE)  
51 is subject to the aerosol loading and sky conditions (Cohan et al., 2002; Oliphant et al., 2011)  
52 because the potential benefit of increased diffuse radiation in the lower canopy can be offset  
53 or even reversed by the concomitant reductions in direct sunlight. China is the world largest  
54 anthropogenic emitter of carbon dioxide reaching  $2.5 \text{ Pg C yr}^{-1}$  (Liu et al., 2015), while the  
55 land ecosystems mitigate only around  $0.2 \text{ Pg C yr}^{-1}$  with large uncertainties (Piao et al., 2009).  
56 At the same time, China encounters frequent haze pollution events due to large emissions of  
57 anthropogenic aerosols and precursors (Guo et al., 2014; Wang and Chen, 2016). It is  
58 critically important to understand how this haze pollution affects the land carbon sink in  
59 China.

60 Leaf photosynthesis increases with the solar irradiance before reaching saturation  
61 (Farquhar et al., 1980). For a canopy with complex composition and vertical distribution,  
62 only sunlit leaves receive both direct and diffuse sunlight. Typically, irradiance is abundant  
63 for these leaves and photosynthesis is light saturated. In contrast, shaded leaves receive only  
64 diffuse radiation and their photosynthesis is usually light-limited (He et al., 2013). Existence  
65 of aerosol pollution and/or a cloud layer simultaneously increases diffuse radiation but  
66 decreases direct radiation. The enhancement of diffuse radiation helps increase  
67 photosynthesis by the shaded leaves but the response of the sunlit leaves depends on the level  
68 of aerosol/cloud loading. Moderate reductions of direct sunlight will not decrease  
69 photosynthesis of sunlit leaves because the light availability is still saturated. Consequently,  
70 the GPP of the whole canopy (sunlit plus shaded portions) increases due to the improved  
71 LUE (Knobl and Baldocchi, 2008). Large reductions of direct sunlight may convert the light-  
72 saturated regime to light-limited regime for the sunlit leaves, leading to reduced LUE and  
73 dampened canopy GPP (Alton, 2008). Photosynthetic response to diffuse light is also  
74 dependent on plant functional type (PFT). C4 plants are less sensitive to the enhanced diffuse  
75 radiation compared to C3 plants because C4 plants do not become light saturated under high  
76 irradiance. As a result C4 plants are more sensitive to the reductions in direct light than C3

77 plants (Kanniah et al., 2012). Thus, the net effect of aerosol pollution on canopy carbon  
78 uptake depends on the aerosol loading, cloud amount, geographic location, and the plant  
79 species.

80 Previous observation-based studies of cloud and aerosol DFE are summarized in Table 1.  
81 Most observational studies have detected DFE using long-term ground-based measurements  
82 (Niyogi et al., 2004; Cirino et al., 2014). Currently, direct measurements of DFE on  
83 photosynthesis in China are limited (Li et al., 2014). Observations suggest that both clouds  
84 and aerosols exert similar impacts on land carbon uptake (Kanniah et al., 2012). Many  
85 observational studies have found that canopy GPP of trees maximizes with diffuse fraction  
86 (DF) of 0.4-0.7 (Rocha et al., 2004; Alton, 2008). For grass and savanna, the optimal DF is as  
87 low as 0.2-0.3, above which the carbon uptake will decrease (Alton, 2008; Kanniah et al.,  
88 2013). The appearance of thin cloud may enhance net ecosystem productivity (NEP) of trees  
89 by 7-11% (Monson et al., 2002; Misson et al., 2005), while thick cloud reduces carbon  
90 uptake due to large irradiance attenuation (Rocha et al., 2004; Cheng et al., 2016). Aerosol  
91 light scattering in clear sky may increase NEP of trees by 8-29% (Misson et al., 2005; Cirino  
92 et al., 2014), but decreases the carbon uptake of grassland (Niyogi et al., 2004). Previous  
93 vegetation modeling results are generally consistent with observations (Table 1). For example,  
94 Knohl and Baldocchi (2008) predicted maximum GPP with DF of 0.45 for a deciduous forest.

95 In this study, we apply the **Yale Interactive terrestrial Biosphere (YIBs)** model (Yue and  
96 Unger, 2015) combined with the **Column Radiation Model (CRM)** to analyze the impacts of  
97 aerosol DFE on net primary productivity (NPP) in China in the present day world. The main  
98 objective is to explore the responses of NPP to current aerosol pollution with and without the  
99 appearance of clouds. First, we perform multiple sensitivity experiments to derive the NPP  
100 sensitivity to aerosol optical depth (AOD) at 550 nm and compare it with available  
101 observations (Table 1). Second, we calculate the aerosol-induced DFE ‘tolerance’ of China’s  
102 land biosphere by defining and computing two thresholds of AOD: (i)  $AOD_{t1}$ , resulting in the  
103 maximum NPP, and (ii)  $AOD_{t2}$ , such that if local  $AOD < AOD_{t2}$ , the aerosol DFE always  
104 promotes local NPP compared with aerosol-free conditions. Third, we estimate changes in  
105 NPP between simulations with and without aerosol DFE, and relate these changes to the  
106 derived AOD thresholds so as to understand the causes of NPP responses to aerosol radiative  
107 effects. Our model approach offers a large regional scale assessment, and is not limited by  
108 spatiotemporal and species-specific sampling issues (Table 1). We consider aerosol-induced  
109 perturbations to diffuse, direct, and total PAR under both clear and cloudy sky conditions, but  
110 ignore the meteorological and hydrological feedbacks from those perturbations. Section 2

111 describes the measurement data, vegetation and radiation models, and the full group of  
112 simulations. Section 3 presents the model evaluation, the sensitivity of GPP to aerosol  
113 pollution in China, the derived AOD thresholds, and the simulated NPP responses to current  
114 levels of aerosol pollution. Section 4 summarizes and discusses the main results.

115

116

## 117 **2 Methods**

118

### 119 **2.1 The Yale Interactive Terrestrial Biosphere Model (YIBs)**

120 The YIBs is a process-based vegetation model that simulates global terrestrial carbon cycle  
121 with dynamic predictions of leaf area index (LAI) and tree growth (Yue and Unger, 2015).  
122 Plant photosynthesis is simulated using the well-established Farquhar scheme (Farquhar et al.,  
123 1980) and is coupled to stomatal conductance with the Ball-Berry scheme (Ball et al., 1987).  
124 The canopy radiative transfer scheme separates diffuse and direct PAR for sunlit and shaded  
125 leaves (Spitters, 1986), depending on solar zenith angle and canopy LAI (section 2.3).  
126 Autotrophic respiration ( $R_a$ ) is split into maintenance and growth components, and is  
127 dependent on leaf temperature and nitrogen content (Clark et al., 2011). The model includes 9  
128 PFTs, including evergreen needleleaf forest (ENF), deciduous broadleaf forest (DBF),  
129 evergreen broadleaf forest (EBF), shrubland, tundra, C3/C4 grassland, and C3/C4 cropland  
130 (Fig. S1). This land cover is derived based on retrievals from both MODIS (Hansen et al.,  
131 2003) and the Advanced Very High Resolution Radiometer (AVHRR) (Defries et al., 2000).  
132 The fraction of C4 cropland is derived based on the total crop fraction and the ratio of C4  
133 species (Monfreda et al., 2008).

134 The YIBs can be used in three different configurations: site-level, global/regional offline,  
135 and online within a climate model. For this study, we use the regional offline version driven  
136 with hourly  $1^\circ \times 1^\circ$  meteorological forcings from the NASA Modern Era Retrospective-  
137 analysis for Research and Applications (MERRA). On the global scale, simulated LAI, tree  
138 height, phenology, GPP, and NPP show reasonable spatial distribution and long-term trends  
139 compared with both *in situ* measurements and satellite retrievals (Yue and Unger, 2015; Yue  
140 et al., 2015a; Yue et al., 2015b). Other carbon fluxes such as NEP, autotrophic respiration,  
141 and heterotrophic respiration are also reasonably simulated relative to multiple model  
142 ensembles (Yue et al., 2015b).

143

### 144 **2.2 The Column Radiation Model (CRM)**

145 The CRM is the standalone version of the radiation model used by the NCAR  
146 Community Climate Model, which has been updated to the Community Earth System Model  
147 (<http://www.cesm.ucar.edu/models/>). Using temporal-varying aerosol profiles (types and  
148 concentrations) and meteorological reanalyses, the CRM model calculates reflectivity and  
149 transmission of atmospheric layers, emissivity and absorptivity of greenhouse gases (GHGs),  
150 and Mie scattering and absorption of aerosols. Aerosol optical parameters associated with  
151 each aerosol species, including specific extinction coefficients, single scattering albedo, and  
152 asymmetric parameters, are adopted from Yue et al. (2010) for mineral dust, Yue and Liao  
153 (2012) for sea salt, and RegCM4 model for other species (Giorgi et al., 2012). These  
154 parameters vary with changes in both wavelength and relative humidity (Fig. S2). Sulfate and  
155 nitrate aerosols share the same parameters. For carbonaceous aerosols (black carbon (BC)  
156 and organic carbon (OC)), half are considered hydrophobic and half are hydrophilic.

157 The CRM is driven with hourly  $1^{\circ}\times 1^{\circ}$  fields of temperature, humidity, and [O<sub>3</sub>] at 20  
158 sigma levels interpolated from the MERRA data. Vertical profiles of cloud cover and liquid  
159 water path are adopted from the CERES SYN1deg (<http://ceres.larc.nasa.gov>), which are  
160 determined using remote sensing from MODIS and the Visible and Infrared Sounder (VIRS).  
161 Surface albedo, temperature, and pressure are also adopted from MERRA. The CRM model  
162 utilizes aerosol profile of all species simulated by the ModelE2-YIBs, a fully coupled  
163 chemistry-carbon-climate model (Schmidt et al., 2014). Aerosol components include sulfate,  
164 nitrate, BC, OC, dust (clay and silt), and sea salt (accumulation and coarse modes).  
165 Concentrations of these pollution species are predicted based on emission inventories of the  
166 year 2010 from the Greenhouse Gas and Air Pollution Interactions and Synergies (GAINS)  
167 integrated assessment model (Amann et al., 2011). We compare the GAINS v4a inventory  
168 with the HTAP inventory adopted from the Emissions Database for Global Atmospheric  
169 Research (EDGAR, <http://edgar.jrc.ec.europa.eu>) and RCP8.5 inventory from the  
170 Intergovernmental Panel on Climate Change (IPCC, <http://www.ipcc.ch/>) (Fig. S3). The  
171 inter-comparison shows that the GAINS has similar magnitude (differences within  $\pm 10\%$ ) of  
172 emissions for major pollutants over China as HTAP and RCP8.5, except for ammonia, which  
173 is higher by 50-80% in GAINS. Simulated summertime surface PM<sub>2.5</sub> concentrations show  
174 high correlations ( $R=0.76$ ) and low biases (NMB=1.6%) with *in situ* measurements at 188  
175 sites (not shown).

176

### 177 **2.3 Canopy radiative transfer and carbon uptake**

178 We use the multilayer canopy radiative transfer scheme proposed by Spitters (1986) to  
 179 separate diffuse and direct PAR for sunlit and shaded leaves. The canopy is divided into an  
 180 adaptive number of layers (typically 2-16) for light stratification. Light intensity decreases  
 181 exponentially with LAI when penetrating in the canopy:

$$182 \quad I = (1 - \rho) \cdot I_t \cdot e^{-kL} \quad (1)$$

183 where  $I_t$  is the total PAR at the top of canopy,  $L$  is the LAI from the top of canopy to layer  $n$ ,  
 184  $I$  is the total PAR available for absorption at the depth  $L$ , and  $k$  is the extinction coefficient.  
 185 Here,  $\rho$  is the reflection coefficient calculated as follows:

$$186 \quad \rho = \left( \frac{1 - (1 - \sigma)^{1/2}}{1 + (1 - \sigma)^{1/2}} \right) \left( \frac{2}{1 + 1.6 \cos \alpha} \right) \quad (2)$$

187 where  $\alpha$  is the solar zenith,  $\sigma = 0.2$  is the scattering coefficient of single leaves. Light  
 188 absorption at the depth  $L$  is estimated as follows:

$$189 \quad I_a = -dI / dL = (1 - \rho) \cdot I_t \cdot k \cdot e^{-kL} \quad (3)$$

190 where  $I_a$  is the flux absorbed per unit leaf area. The total PAR at the top of canopy is consist  
 191 of diffuse ( $I_{df}$ ) and direct ( $I_{dr}$ ) components, both of which are simulated with CRM model:

$$192 \quad I_t = I_{df} + I_{dr} \quad (4)$$

193 According to equation (3), absorption of the diffuse flux is calculated as:

$$194 \quad I_{fa} = (1 - \rho) \cdot I_{df} \cdot k_f \cdot e^{-k_f L} \quad (5)$$

195 where  $k_f = 0.8(1 - \sigma)^{1/2}$  is the extinction coefficient of the diffuse flux. For the direct flux, it is  
 196 segregated into diffuse and direct components on its way through the canopy. The total  
 197 absorption of direct flux is calculated as:

$$198 \quad I_{ra} = (1 - \rho) \cdot I_{dr} \cdot (1 - \sigma)^{1/2} \cdot k_r \cdot e^{-(1 - \sigma)^{1/2} k_r L} \quad (6)$$

199 where  $k_r = 0.5 / \cos \alpha$  is the extinction coefficient of direct component of the direct flux. Here  
 200 the function  $(1 - \sigma)^{1/2}$  is applied to account for the scattering effects of leaves for direct light.  
 201 The absorption of the direct component of direct flux is calculated as:

$$202 \quad I_{rra} = (1 - \sigma) \cdot I_{dr} \cdot k_r \cdot e^{-(1 - \sigma)^{1/2} k_r L} \quad (7)$$

203 We distinguish light absorption for shaded and sunlit leaves. Shaded leaves absorb diffuse  
 204 flux and the diffuse component of direct flux:

$$205 \quad I_{sha} = I_{fa} + (I_{ra} - I_{rra}) \quad (8)$$

206 Sunlit leaves absorb both diffuse and direct radiation:

$$207 \quad I_{sla} = I_{sha} + (1 - \sigma) \cdot k_r \cdot I_{dr} \quad (9)$$

208 Photosynthesis is calculated separately for shaded and sunlit leaves based on the different  
209 light absorption. Canopy photosynthesis ( $\mu\text{mol C s}^{-1}$  per unit leaf area) is the sum of these  
210 two parts of leaves:

$$211 \quad A = f_{sl} \cdot A_{sl} + (1 - f_{sl}) \cdot A_{sh} \quad (10)$$

212 where  $A_{sl}$  and  $A_{sh}$  are photosynthesis of sunlit and shaded leaves, respectively. The fraction of  
213 sunlit leaf area  $f_{sl}$  is calculated as:

$$214 \quad f_{sl} = e^{-k \cdot L} \quad (11)$$

215 Finally, the total carbon uptake GPP ( $\mu\text{mol C s}^{-1}$  per unit ground area) is estimated as follows:

$$216 \quad GPP = \int_0^{LAI} A \cdot dL \quad (12)$$

217

## 218 **2.4 Simulations**

219 We conduct simulations combining the offline YIBs vegetation model and the CRM radiation  
220 model. Diffuse and direct PAR at the top of canopy is predicted with CRM model. These  
221 radiative fluxes are then used as input for the YIBs model, which further separates diffuse  
222 and direct fluxes absorbed by sunlit and shaded leaves using Spitters (1986) canopy scheme.  
223 We perform two groups of YIBs-CRM sensitivity simulations, 30 for clear-sky conditions  
224 and 30 for all-sky conditions, to derive the AOD thresholds for aerosol DFE (Table 2). The  
225 YIBs model is driven with meteorological forcings from MERRA, except for direct and  
226 diffuse PAR, which is predicted with the CRM model. We set up baseline simulations  
227 (CLR010 and ALL010) with the aerosol profile from ModelE2-YIBs and validated optical  
228 parameters. In other simulations, specific scaling factors ranging from 0.0 to 30 are applied to  
229 aerosol concentrations to represent variations of AOD. Due to the disk storage limit for  
230 hourly meteorological profiles, we perform CRM simulations for 2009-2011. The simulated  
231 PAR is alternately applied as input for the YIBs model, which uses additional meteorological  
232 forcings from MERRA for 2000-2011. In this case, predicted PAR at 2009-2011 is recycled  
233 as input for periods of 2000-2002, 2003-2005, 2006-2008, and 2009-2011 in the YIBs  
234 simulations. The last 3 years of YIBs output, including GPP and NPP, are used for analyses.  
235 We focus our analyses for the summer (June-July-August) season, when both AOD and  
236 carbon fluxes are high.

237

## 238 **2.5 Benchmark and evaluation observational datasets**

239 To evaluate GPP simulated with the YIBs model, we use global benchmark product upscaled  
240 from the FLUXNET eddy covariance data for 2009-2011 (Jung et al., 2009). For NPP, we  
241 use the satellite product of 2009-2011 retrieved by the Moderate Resolution Imaging  
242 Spectroradiometer (MODIS) (Zhao et al., 2005). The MODIS dataset provides indirect  
243 estimates of global NPP using an empirical light-use function between GPP and meteorology,  
244 as well as the modeled plant respiration. The actual values of MODIS NPP may exhibit  
245 certain biases at the regional scale compared with site-level observations (Pan et al., 2006).  
246 However, the spatial pattern of the product is in general reasonable and has been widely used  
247 for model evaluations (e.g., Collins et al., 2011; Pavlick et al., 2013). To evaluate surface  
248 radiative fluxes simulated with the CRM model, we use ground-based radiation data for  
249 2008-2012 from 106 pyranometer sites in China, provided by the Climate Data Center,  
250 Chinese Meteorological Administration (Xia, 2010). For each site and each month, we derive  
251 the monthly mean radiative fluxes based on daily data if <30% days are missing. We then  
252 select sites where all months are available for 2008-2012, leaving a total of 95 sites for the  
253 evaluation of total shortwave radiation. Diffuse radiation is not observed at all sites, and only  
254 a total of 17 sites meet the criteria for the continuous measurements. For aerosol radiative  
255 effects, we use assimilation data of surface radiative fluxes adopted from the SYN1deg  
256 product of NASA Clouds and the Earth's Radiant Energy System (CERES) (Wielicki et al.,  
257 1996; Rutan et al., 2015). Aerosol effect in CERES is calculated with the Langley Fu-Liou  
258 radiative transfer model (Fu and Liou, 1993), using aerosol profiles simulated by the Model  
259 for Atmospheric Transport and Chemistry (Rasch et al., 1997). We also use satellite-based  
260 AOD data of MOD08\_M3 for 2008-2012 retrieved by MODIS onboard the Terra platform  
261 (Remer et al., 2005). All gridded data are interpolated onto  $1^{\circ}\times 1^{\circ}$  grids, matching the  
262 resolution of both CRM and YIBs models.

263

264

## 265 **3 Results**

266

### 267 **3.1 Model evaluation**

268 The YIBs model predicts reasonable spatial distribution of carbon fluxes compared with  
269 other data products (Fig. 1). For the summer, high GPP and NPP is simulated in the Northeast,  
270 Southwest, and southeastern coastal regions, where DBF and ENF trees dominate (Fig. S1).  
271 The correlation coefficients between simulations and proxy data are as high as 0.8 for both  
272 GPP and NPP. Predicted GPP is -24% lower on average than benchmark product, mainly

273 because the model shows smaller values over North China Plain. The normalized mean bias  
274 (NMB) of NPP is close to 0, because of the regional offsetting. On the annual mean basis,  
275 simulations show higher correlations ( $R = 0.84$  for GPP and  $0.86$  for NPP) and similar NMB  
276 ( $-21\%$  for GPP and  $-16\%$  for NPP) compared with data products.

277 The CRM predicts opposite spatial distribution for total solar radiation and the  
278 corresponding DF (Fig. 2). For radiation, high values are found in the North and West, while  
279 low values in the East and Southwest. Such pattern is related to cloud cover, which is lower  
280 in the north but higher in the south, especially the Southwest where cloud cover is usually  
281 higher than  $80\%$  (Fig. S4). Due to the cloud scattering, those regions with low insolation  
282 have high DF. Compared with *in situ* measurements, the simulated total radiation exhibits  
283 reasonable spatial characteristics and the correlation coefficient is as high as  $0.88$ . The  
284 evaluation of DF shows certain biases but is reasonable over the East (blue points of Fig. 2f),  
285 which is the major domain for this study.

286 The CRM also predicts reasonable AOD and aerosol radiative effects (Fig. 3). Using  
287 aerosol concentrations from the climate model ModelE2-YIBs, the CRM simulates high  
288 regional AOD centered in the North China Plain. Previous sensitivity tests with ModelE2-  
289 YIBs shows that such high loading of aerosols is mainly ( $>80\%$ ) contributed by  
290 anthropogenic emissions. The AOD is generally high over the vast domain of eastern China  
291 but low in the western part. Compared with AOD from CERES, which is derived using  
292 aerosol concentrations from a chemical transport model, the AOD in CRM presents  
293 reasonable spatial distribution with high correlation coefficient of  $0.7$  and low NMB of  $-1\%$ .  
294 However, compared with MODIS AOD, which is derived based on satellite retrievals, the  
295 predicted AOD is on average overestimated by  $30\%$  in eastern China. For the following  
296 analyses, we use the predicted AOD as the benchmark but discuss the influence of its  
297 overestimation on the predicted aerosol DFE. We further assess aerosol radiative efficiency  
298 (ARE), defined as radiative forcing per unit AOD, over China. Higher magnitude of ARE is  
299 predicted in the North and West, because lower cloud coverage there allows larger radiative  
300 perturbations by the same level of aerosols. The comparison of ARE between CRM and  
301 CERES shows high correlation coefficient of  $0.87$ . However, ARE in CRM is smaller by  $21\%$   
302 in magnitude than that in CERES.

303

### 304 **3.2 Sensitivity of GPP to DF and AOD in China**

305 Appearance of cloud and/or aerosols increases DF but decreases total insolation. We  
306 examine PFT-specific GPP responses to DF for clear and all-sky conditions (Fig. 4). Under

307 clear-sky conditions, at  $DF < 0.55$ , all PFTs show increased GPP in response to increasing  
308 DF. At low DF ( $DF < 0.55$ ), shaded leaves experience low light availability because diffuse  
309 radiation is limited. Meanwhile, photosynthesis of sunlit leaves is light-saturated because  
310 direct radiation is abundant. Introduction of aerosol pollution, which increases DF, to this  
311 system redistributes sunlight to the shaded light-limited leaves (without compromising the  
312 total light availability to sunlit leaves), thus increasing the LUE and GPP of the whole canopy.  
313 The derived GPP-diffuse sensitivity ( $\Delta GPP/\Delta DF$ , units:  $g\ C\ m^{-2}\ day^{-1}$  per unit change of DF  
314 with  $\pm 95\%$  confidence interval) is  $5.4 \pm 1.2$  for ENF,  $6.8 \pm 2.1$  for DBF,  $5.6 \pm 1.7$  for shrub  
315 (tundra plus arid shrub),  $2.8 \pm 0.7$  for C3 herbs (C3 grassland and cropland), and  $2.2 \pm 2.3$  for  
316 C4 herbs (C4 grassland and cropland) when  $DF < 0.55$ . However, at high DF ( $DF > 0.55$ ),  
317 light is no longer saturated for sunlit leaves because of the large attenuation of direct light.  
318 Further introduction of aerosols decreases photosynthesis of sunlit leaves, which may offset  
319 the carbon gains from enhanced diffuse light by shaded leaves, resulting in a net carbon loss  
320 for the whole canopy. Although large variations in GPP, denoted as error bars, exist within  
321 each bin, they do not affect the significance of the GPP-diffuse responses. We select the  
322 GPP-diffuse sensitivity at clear-sky conditions averaged for all PFTs as an example. The  
323 largest bin-to-bin difference in GPP is calculated as  $1.9\ g\ C\ m^{-2}\ day^{-1}$  between  $DF = 0.58$  and  
324  $DF = 0.12$ . Such GPP difference is significant at  $p < 0.001$  level based on a Student T test,  
325 suggesting that GPP varies significantly when the DF change is pronounced.

326 Under all-sky conditions, which includes both clear and cloudy skies, DF is always  
327 higher than 0.55, because existing cloud cover has already increased the diffuse light fraction  
328 in the system. Any further increase of DF by aerosol scattering has limited or even  
329 detrimental impacts on whole canopy GPP because the associated aerosol-induced reductions  
330 in direct radiation impact photosynthesis by the sunlit leaves. GPP decreases almost linearly  
331 for all PFTs in response to increasing  $DF > 0.55$ , with GPP-diffuse sensitivity of  $-6.9 \pm 1.4$   
332 for ENF,  $-10.8 \pm 2.3$  for DBF,  $-3.8 \pm 1.7$  for shrubland,  $-3.8 \pm 0.8$  for C3 herbs, and  $-10.1 \pm$   
333  $1.6$  for C4 herbs. The GPP response to increases in  $DF > 0.55$  is almost identical under clear-  
334 sky and all-sky conditions.

335 The PFT-specific GPP responses to idealized perturbations in AOD depend strongly on  
336 the sky conditions (Fig. 5). Under clear sky conditions, aerosol promotes GPP for most PFTs  
337 if  $AOD < 2$ . The maximum possible enhancement of GPP is  $\sim 40\%$  for DBF, ENF, and C3  
338 herbs, and can be as high as 60% for shrub. Most shrub species (especially tundra) are  
339 located in the Southwest (Fig. S1). Over that region, solar irradiance is abundant at clear days

340 (not shown), allowing more efficient scattering for a given AOD. For a given AOD, the DFE  
341 of C4 herbs is the weakest amongst PFTs with a maximum possible GPP enhancement of  
342 only ~10%. C4 plants usually have lower LUE than C3 plants, and as a result more easily  
343 become light-limited when aerosol attenuates total irradiance (Still et al., 2009; Kanniah et al.,  
344 2012). A clear turning point is found for all species. For C3 plants, aerosol scattering  
345 weakens GPP when  $AOD > 2$ , because photosynthesis of the sunlit leaves starts to become  
346 light-limited due to reductions in direct insolation. For C4 plants, this turning point appears  
347 earlier when  $AOD > 1$ . Under all-sky conditions, atmospheric aerosol shows neutral effects  
348 on GPP when  $AOD < 1$  and detrimental negative effects when  $AOD > 1$  for all PFTs except  
349 C4 (Fig. 4). For C4 plants, any addition of aerosol to the atmospheric column decreases GPP.

350 Our estimates of GPP sensitivity to DF and AOD are reasonable compared with previous  
351 studies (Table 1) as summarized below: (1) the maximum enhancement of GPP is 40% at  
352 clear-sky conditions for most PFTs (Gu et al., 2003); (2) the GPP enhancement of C4 plants  
353 is the least due to the lowest LUE compared with other PFTs (Still et al., 2009; Kanniah et al.,  
354 2012); (3) the aerosol DFE is much stronger at clear-sky than that at all-sky conditions  
355 (Cohan et al., 2002); (4) both clouds and aerosols exert similar DFE on land carbon uptake  
356 (Kanniah et al., 2012; Cirino et al., 2014); and (5) the maximum GPP enhancement appears  
357 when  $DF = 0.4-0.8$  (Rocha et al., 2004; Alton, 2008; Zhang et al., 2010). Most results listed  
358 in Table 1 are based on NEP, however, we evaluate the sensitivity of GPP because it is the  
359 direct carbon metric affected by DFE.

360

### 361 **3.3 Aerosol pollution DFE in China 2009-2011**

362 We apply the idealized GPP responses in Section 3.2 to estimate the current magnitude  
363 of aerosol pollution DFE under realistic background conditions by defining 2 summertime  
364 AOD thresholds across China (Fig. 6). The AOD thresholds are derived based on NPP (=  $GPP - Ra$ ),  
365 assuming no impacts of aerosol DFE on the autotrophic respiration  $Ra$  (Knohl  
366 and Baldocchi, 2008). Now, we consider NPP responses, instead of GPP, because the former  
367 represents the net carbon uptake by plants after subtracting autotrophic respiration for  
368 maintenance and growth. The first threshold,  $AOD_{t1}$  is defined as the AOD value with the  
369 maximum  $\Delta NPP$  (the uppermost point of the response curve in Fig. 5), representing the  
370 saturation of DFE. The second threshold,  $AOD_{t2}$  is the cross point of the response curve at  
371 zero  $\Delta NPP$ . For each model grid cell, if AOD is close or equal to  $AOD_{t1}$ , the peak NPP is

372 expected. If  $AOD < AOD_{t2}$ , aerosol DFE always promotes local NPP relative to aerosol-free  
373 conditions ( $AOD=0$ ).

374 We find relatively high  $AOD_{t1}$  in the Northeast and low values in the Southwest ( $23^\circ$ -  
375  $35^\circ N$ ,  $100^\circ$ - $105^\circ E$ , box d in Fig. 6a), where average cloud cover is 80% in the summer (Fig.  
376 S4). The pattern of  $AOD_{t2}$  is similar to that of  $AOD_{t1}$  (Fig. 6b), except for high values in the  
377 North ( $42^\circ$ - $48^\circ N$ ,  $105^\circ$ - $118^\circ E$ ), where insolation is high while average cloud fraction is less  
378 than 50%. The values of the AOD thresholds are much higher for clear days; for example, the  
379 average clear-sky  $AOD_{t1}$  is six times the all-sky values over the East (Fig. S5). Observed  
380 summer AOD in the North China Plain ( $32^\circ$ - $40^\circ N$ ,  $113^\circ$ - $120^\circ E$ ) exceeds  $AOD_{t1}$  by 77% but  
381 is 14% lower than  $AOD_{t2}$  (Fig. 6c), suggesting limited aerosol DFE in this region. A  
382 reduction of 44% in local AOD (so that  $AOD = AOD_{t1}$ ) leads to the largest benefit for  
383 regional carbon uptake. Both  $AOD_{t1}$  and  $AOD_{t2}$  in the Southwest are close to 0 (Fig. 6d),  
384 indicating that appearance of aerosol always inhibits regional carbon uptake there. Observed  
385 AOD in the Southeastern Coast ( $22^\circ$ - $^\circ N$ ,  $110^\circ$ - $122^\circ E$ ) is approximately equal to  $AOD_{t1}$  (Fig.  
386 6e) and that in the Northeast ( $40^\circ$ - $47^\circ N$ ,  $122^\circ$ - $132^\circ E$ ) is 55% lower than  $AOD_{t1}$  (Fig. 6f),  
387 indicating amplified carbon uptake by aerosol enhancements there.

388 To understand the relationship between the current AOD level and DFE, we calculate  
389 differences between MODIS AOD and the thresholds (Fig. 7). The pattern is quite similar for  
390 annual and summer differences, except that the former is less positive than the latter. The  
391 stronger dampening effect by aerosols in summer is related to the higher seasonal AOD  
392 (summer mean of 0.43 versus annual mean of 0.38) and cloud amount (summer mean of 65%  
393 versus annual mean of 58%). Over the Southwest, current AOD level is larger than both  
394  $AOD_{t1}$  and  $AOD_{t2}$ , suggesting that aerosols there on average inhibit NPP and further  
395 increases in AOD lead to stronger inhibition. In North China Plain, AOD exceeds  $AOD_{t1}$  and  
396 is close to  $AOD_{t2}$ , indicating that aerosol pollution there has almost neutralized impacts on  
397 local NPP. For the Southeast, current AOD is lower than  $AOD_{t1}$  and  $AOD_{t2}$  at confined  
398 regions along the coast, but is higher than  $AOD_{t1}$  in the inner domain. On average, observed  
399 AOD of the box domain e (Fig. 6a) is lower than  $AOD_{t2}$  but close to  $AOD_{t1}$  (Fig. 6e),  
400 suggesting that aerosols there generally promote NPP relative to aerosol-free conditions.  
401 However, the potential for stronger DFE is limited as further increases of AOD will dampen  
402 NPP. For the North and Northeast, current AOD is far below  $AOD_{t1}$ , suggesting that  
403 appearance of aerosols there boosts carbon uptake, and increases in AOD continue to  
404 increase NPP.

405 We calculate perturbations in NPP for different sky conditions (Fig. 8), resulting from  
406 the aerosol-induced perturbations in both direct and diffuse radiation (Fig. S6). Under clear  
407 sky conditions, aerosol DFE causes widespread enhancement of NPP (Fig. 8a), ranging from  
408 20% to 60% over the East (Fig. S7). The absolute changes in NPP are small over North China  
409 Plain (Fig. 8a), where high AOD is observed (Fig. 3). In contrast, fractional changes in NPP  
410 exhibit a high center of >60% in North China Plain, consistent with the conclusion of  
411 sensitivity tests that aerosols usually promote carbon uptake at clear sky (Fig. 5). Such  
412 discrepancy originates from the low background (aerosol-free) NPP in North China Plain,  
413 because the YIBs model applies satellite-based land cover (Fig. S1), which shows high  
414 fraction of C3 cropland but almost zero tree (including ENF and DBF) coverage in North  
415 China Plain. On average, aerosols increase NPP by  $1.14 \pm 0.01 \text{ Pg C yr}^{-1}$  ( $35.0 \pm 0.9 \%$ ) for  
416 the whole China domain at the clear sky conditions (Fig. S7).

417 Under the all-sky conditions, aerosols drive weak patchy NPP responses (Fig. 8b),  
418 mainly because of the high DF from existing cloud cover. The spatial pattern of percentage  
419 NPP changes (Fig. S7b) highly resembles the AOD differences shown in Fig. 7d but with  
420 opposite signs. Over the Southwest and part of North China Plain, current high level of AOD  
421 exceeds  $\text{AOD}_{t2}$  and as a result inhibits local NPP by 1-2%. In the southeastern coastal regions,  
422 aerosol DFE is limited, though regional AOD is below  $\text{AOD}_{t2}$ . The largest NPP enhancement  
423 is predicted over the Northeast, where current AOD is far smaller than  $\text{AOD}_{t1}$  (Fig. 7c) and  
424 cloud amount is moderate (Fig. S4). Regional changes of NPP range from -3% to 6% and the  
425 total change is  $0.07 \pm 0.02 \text{ Pg C yr}^{-1}$  ( $1.6 \pm 0.5\%$ ) over China.

426

#### 427 **4 Discussion and conclusions**

428

429 We provide the first assessment of aerosol pollution radiative effects on land carbon uptake  
430 in China today based on regional simulations that combine the CRM radiation model and the  
431 YIBs vegetation model. The confidence level of our estimate is dependent on the capability  
432 of these models to reproduce observed radiative and carbon fluxes, aerosol-induced radiative  
433 perturbations, and GPP responses to these perturbations. For the first two aspects, we  
434 evaluate CRM and YIBs models using *in situ*, satellite, and assimilation data (Figs. 1-3). The  
435 simulated GPP-AOD relationship (Figs. 4-5) is reasonable compared with available  
436 measurements and modeling results in the literature (Table 1).

437 Our estimate is subject to limitations and uncertainties. First, calculated aerosol DFE is  
438 sensitive to the canopy radiative transfer scheme. We apply the widely used Spitters (1986)  
439 scheme to separate diffuse and direct light for sunlit and shaded leaves (2-leaf mode). This  
440 scheme invokes Beer's law that assumes light decays exponentially from the top to bottom of  
441 canopy. The predicted maximum GPP enhancement of 40% is at the high end of the range of  
442 previous modeling estimates (Table 1). A similar magnitude of GPP change was predicted by  
443 Gu et al. (2003) using different parameterizations of light partitioning and leaf photosynthesis  
444 (1-leaf mode). Mercado et al. (2009) predicted maximum GPP enhancement of only 18% for  
445 deciduous trees, considering Beer's law for light extinction and a 2-leaf model for light  
446 partitioning. Cohan et al. (2002) showed a maximum NPP enhancement of 17-30%  
447 depending on the choice of canopy scheme. These discrepancies reveal large uncertainties  
448 due to differences in the treatment of the canopy geometry (sphere or non-sphere), canopy  
449 properties (e.g., leaf clumping factor, leaf inclination angle, and leaf optical properties), light  
450 partitioning (diffuse or non-diffuse), and the upscaling of leaf photosynthesis (1-leaf or 2-  
451 leaf). More observations are required to evaluate the different parameterizations and their use  
452 in large-scale vegetation models.

453 Second, uncertainties in simulated AOD and aerosol radiative effects may affect the  
454 derived aerosol DFE. For this study, simulated AOD is calculated based on the three  
455 dimensional aerosol concentrations from ModelE2-YIBs climate model. Simulation shows  
456 similar spatial pattern and magnitude compared with CERES product (Figs 3a-c), which also  
457 uses aerosol profile from a chemical transport model. However, evaluations with MODIS  
458 data show that the predicted AOD is on average overestimated by 30% in eastern China (not  
459 shown). Considering that aerosol radiative efficiency from the CRM model is 21% lower  
460 than that from Fu-Liou model (Figs 3d-f), our estimate of aerosol radiative perturbations in  
461 China might be reasonable due to the offsetting biases in AOD and aerosol radiative  
462 efficiency. On the other hand, even if we ignore the uncertainties from radiative transfer  
463 scheme, the 30% overestimation in AOD does not cause large differences in the derived  
464 aerosol DFE. As a check, we calculate  $\Delta\text{NPP}$  in sensitivity experiments CLR007 and  
465 ALL007 (Table 2), which employ AOD level lower by 30% than CLR010 and ALL010. We  
466 find that clear-sky  $\Delta\text{NPP}$  by aerosols is  $0.91 \text{ Pg C yr}^{-1}$  (27.7%) in CLR007, lower than the  
467 enhancement of 35.0% in CLR010 (Fig. 8a). The all-sky  $\Delta\text{NPP}$  by aerosols is  $0.07 \text{ Pg C yr}^{-1}$   
468 (1.6%) in ALL007, equal to the values derived from ALL010. The reason for such similarity  
469 between ALL007 and ALL010 can be explained by the GPP-AOD relationship, which shows

470 that all-sky GPP is almost invariant when AOD<1 (Fig. 5). The results suggest that cloud  
471 plays a dominant role in regulating diffuse radiation in China, and the aerosol DFE might be  
472 secondary compared with cloud DFE.

473 Third, calculated aerosol DFE does not account for biotic feedbacks. Photosynthesis is  
474 connected to plant physiological processes, such as stomatal conductance and respiration.  
475 Observations have shown that aerosol DFE may increase water use efficiency (Rocha et al.,  
476 2004; Knohl and Baldocchi, 2008), promoting plant growth and LAI that may further  
477 increase canopy photosynthesis. We have assumed no responses in autotrophic respiration so  
478 that the derived GPP-AOD relationship can be applied directly to NPP-AOD. Yet,  
479 observations suggest that plant respiration decreases due to the aerosol-induced cooling  
480 (Alton, 2008). Ignoring these biotic feedbacks indicates that NPP sensitivity to AOD  
481 employed in our estimate may be underestimated.

482 Fourth, we omit the associated climatic responses to aerosol radiative effects. The  
483 aerosol-induced radiative perturbations decrease surface temperature but increase relative  
484 humidity (because of decreased saturation water vapor pressure) (Jing et al., 2010; Cirino et  
485 al., 2014). Increases in air humidity will help enhance plant water use efficiency, leading to  
486 increased photosynthesis. The impact of cooling is uncertain depending on the relationship  
487 between the local background temperature and the optimal temperature of photosynthesis,  
488 which is about 25°C for most species (Farquhar et al., 1980). If leaf temperature is >25°C,  
489 aerosol-induced cooling is beneficial for photosynthesis. On the contrary, if leaf temperature  
490 is <25°C, the cooling will act to inhibit carbon uptake. Furthermore, cloud modification,  
491 caused by both aerosol direct and indirect effects, may exert complex influences on land  
492 ecosystems through perturbations in diffuse radiation, surface temperature, and precipitation.  
493 Resolving these concomitant biotic, meteorological, and hydrological feedbacks requires  
494 earth-system models that fully couple the land biosphere, atmospheric chemistry, radiation,  
495 and climate.

496 Finally, the biogeochemical response to aerosol pollution-related reactive nitrogen (N)  
497 deposition is not included. Simulations with the ModelE2-YIBs climate model show that  
498 anthropogenic emissions contribute 90% of the total reactive inorganic and organic N  
499 deposition in China, indicating potentially large impacts of anthropogenic aerosols on  
500 regional carbon uptake through the coupled C-N cycle. Using a terrestrial ecosystem model,  
501 Tian et al. (2011) proposed that anthropogenic N deposition and fertilizer applications  
502 together account for 61 percent of the net carbon storage in China for the 1961-2005 period.

503 The carbon sequestered per gram of deposited nitrogen decreases gradually after the year  
504 1985, suggesting that most areas have reached nitrogen saturation. Similarly, based on  
505 satellite retrievals, Xiao et al. (2015) revealed that anthropogenic N deposition makes no  
506 significant contributions to the increases of vegetation productivity during 1982-2006.  
507 Therefore, additional fertilization from aerosol N deposition may be limited because many  
508 areas have been N saturated for decades such that our estimate of  $\Delta$ NPP due to aerosol effects  
509 based on radiative changes (Fig. 8b) may be realistic.

510 Despite these uncertainties, our study reveals strong impacts of aerosol DFE on land  
511 carbon uptake in China. Although aerosol DFE widely promotes NPP during clear days, NPP  
512 shows strongly spatially contrasting responses under all-sky conditions. Aerosol pollution  
513 increases NPP by 2-6% in the Northeast where both cloud coverage and particle loading is  
514 moderate. Aerosol decreases NPP by 2-4% in both the North China Plain and the Southwest.  
515 For the North China Plain, the NPP inhibition is related to the high local pollution level that  
516 is above the  $AOD_{12}$  threshold for carbon uptake. Our estimates show that a 44% reduction in  
517 local aerosol AOD would help achieve the maximum benefits for plant productivity in this  
518 region. In the Southwest, existing cloud cover is already dense and pollution aerosols inhibit  
519 NPP in this region. Reductions of pollution aerosol loading will increase carbon uptake in  
520 this region.

CLR300	30.0	Clear sky	ALL300	30.0	All sky

<sup>a</sup> We amplify or diminish base AOD by a certain ratio for each simulation. The base AOD (Fig. 3a) is derived with the aerosol profiles from ModelE2-YIBs climate model and optical parameters from multiple data sources (Fig. S2).

<sup>b</sup> For clear-sky simulations, cloud cover and liquid water path are set to zero.

<sup>c</sup> For all-sky simulations, cloud cover and liquid water path are adopted from the Clouds and the Earth's Radiant Energy System (CERES) SYN1deg Product.

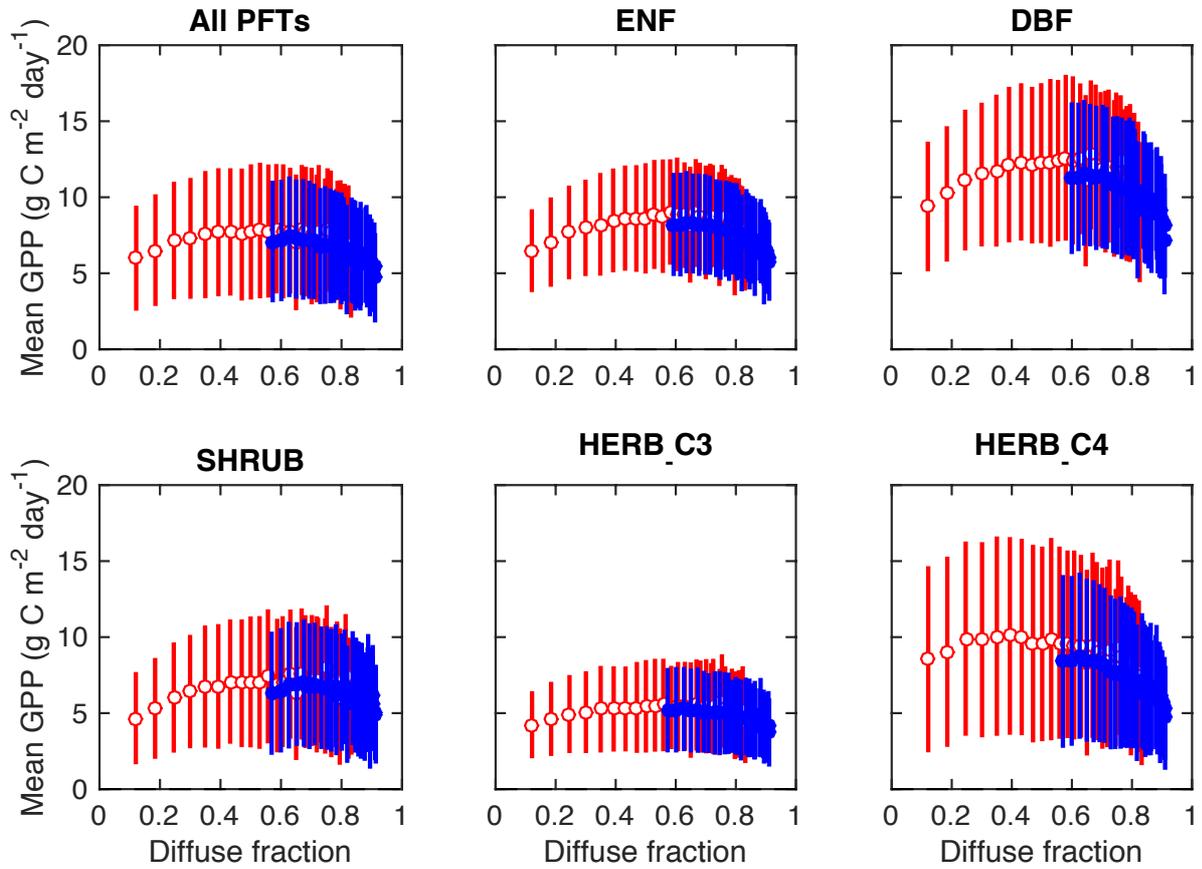

**Figure 1.** Evaluation of summertime carbon fluxes simulated with the YIBs model. Simulations are (a) GPP and (d) NPP from ALL010. Derived carbon fluxes are averaged for 2009-2011, with (b) GPP from the benchmark upscaling of flux tower data and (e) NPP from MODIS. The aerosol DFE is included in the simulation. The correlation coefficients ( $r$ ), relative biases ( $b$ ), and number of  $1^\circ \times 1^\circ$  grid cells ( $n$ ) for the comparisons are listed on the scatter plots (c and f). The dashed line represents the 1:1 ratio. The red line is the linear regression between simulations (predictand) and data products (predictor). Units of GPP and NPP is  $\text{g C m}^{-2} \text{ day}^{-1}$ .

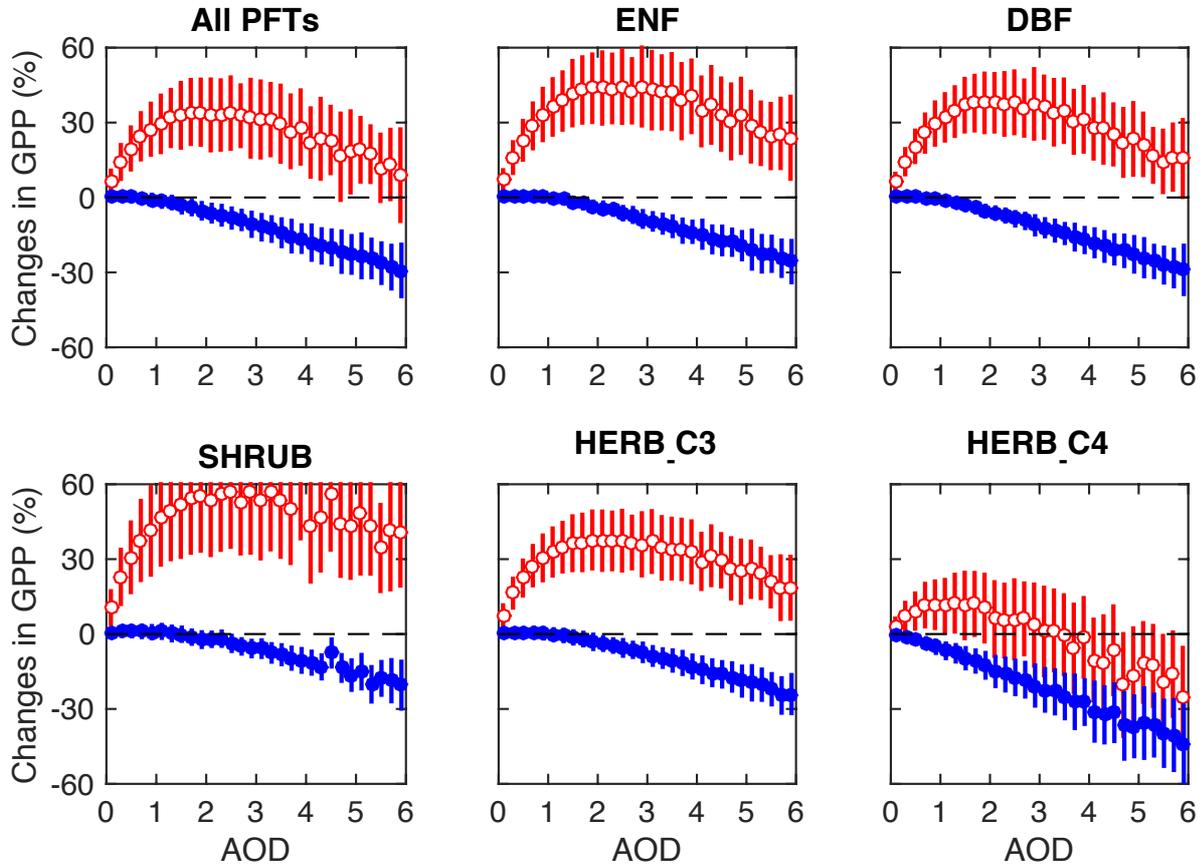

**Figure 2.** Evaluation of summertime radiation fluxes simulated with the CRM model. Simulations are (a) surface total shortwave radiation ( $\text{W m}^{-2}$ ) and (d) diffuse radiation fraction from ALL010 with  $1^\circ \times 1^\circ$  resolution. Observations (b and e) are the average during 2008-2012 from 106 sites operated by the Climate Data Center, Chinese Meteorological Administration. The correlation coefficients ( $r$ ), relative biases ( $b$ ), and number of sites ( $n$ ) are shown in the scatter plots (c and f). The blue points in the scatter plots represent sites located within the box regions in eastern China as shown in (a). The dashed line represents the 1:1 ratio. The red line is the linear regression between simulations and observations.

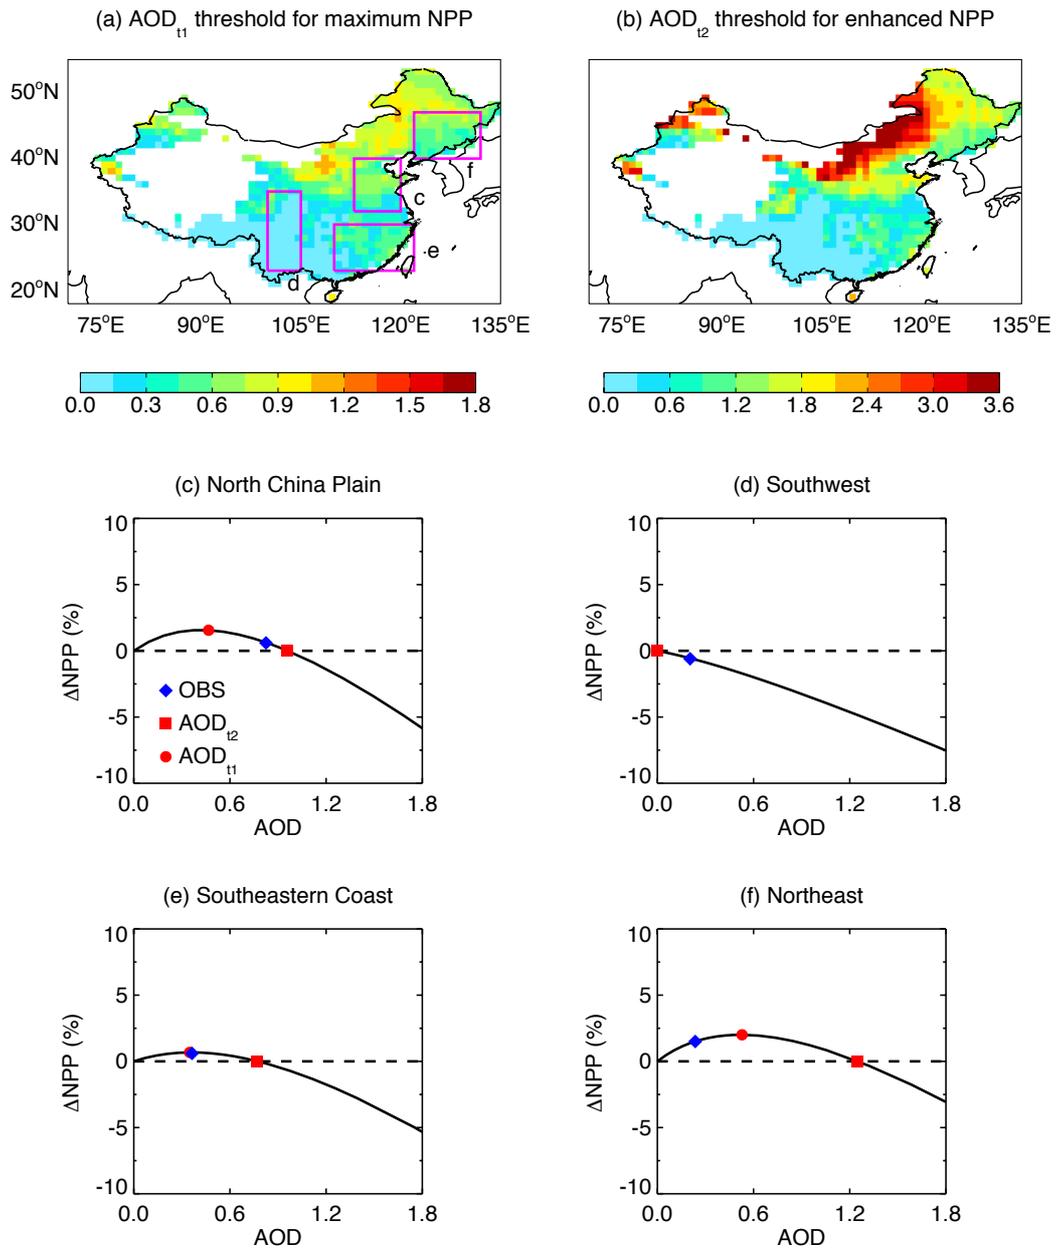

**Figure 3.** Evaluation of aerosol radiative effects simulated with the CRM model. Panels show the simulated (a) AOD at 550 nm and (d) all-sky aerosol radiative efficiency (ARE,  $W m^{-2}$  per unit AOD) with that from the CERES SYN1deg product (b, e). The correlation coefficients ( $r$ ), relative biases ( $b$ ), and number of  $1^\circ \times 1^\circ$  grid cells ( $n$ ) for the comparisons over the box domain in figure (a) are listed on the scatter plots (c, f). The dashed line represents the 1:1 ratio. The red line is the linear regression between simulations and data products.

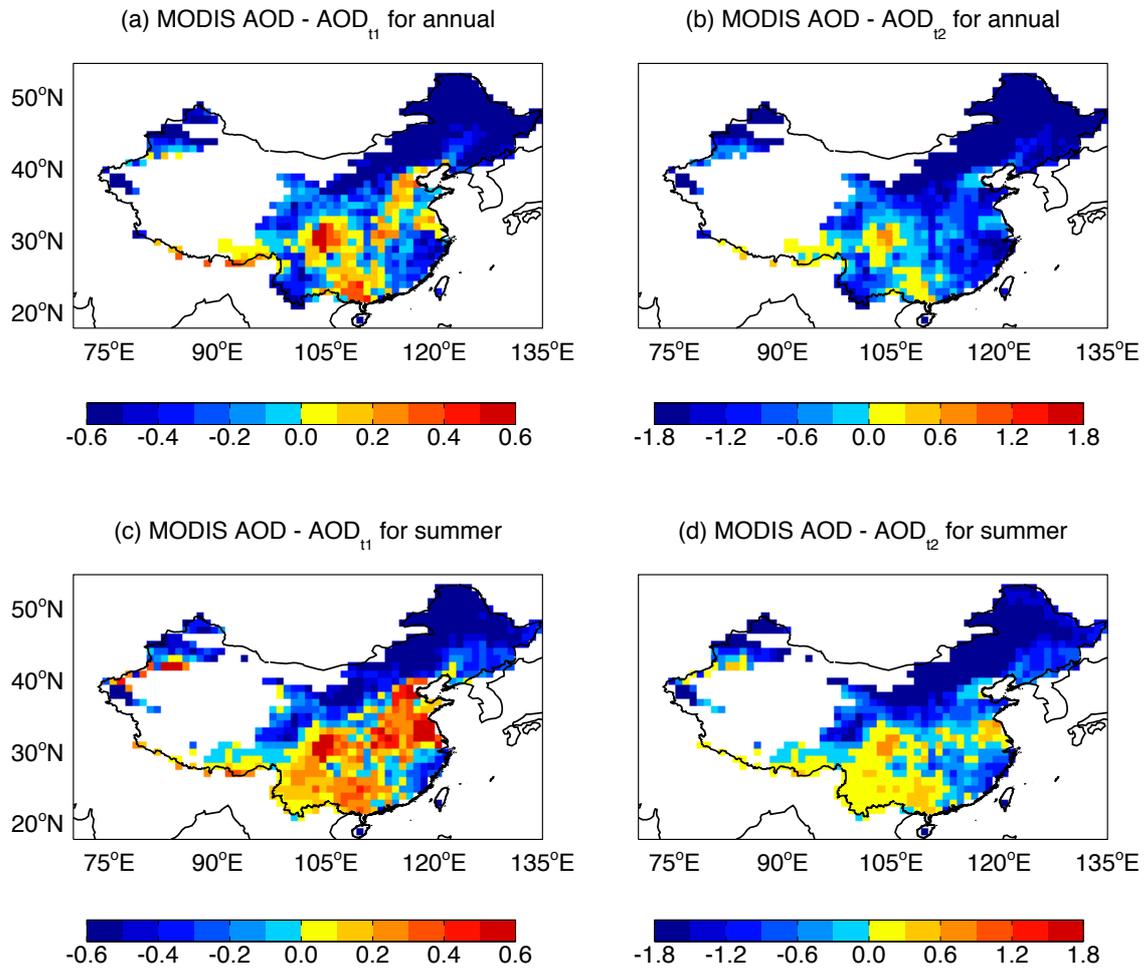

**Figure 4.** Mean summer GPP for different diffuse fractions. Results shown are for clear-sky (red empty points) and all-sky (blue solid points) conditions. Separately for clear-sky and all-sky conditions, we first collect all grid cells in eastern China (box region in Fig. 2a) for all 30 sensitivity simulations. We then aggregate all grid cells with non-zero fraction of a specific PFT into 30 AOD bins ranging from 0 to 6 at an interval of 0.2. In each bin, we calculate average diffuse fraction and corresponding GPP, with an error bar indicating one standard deviation.

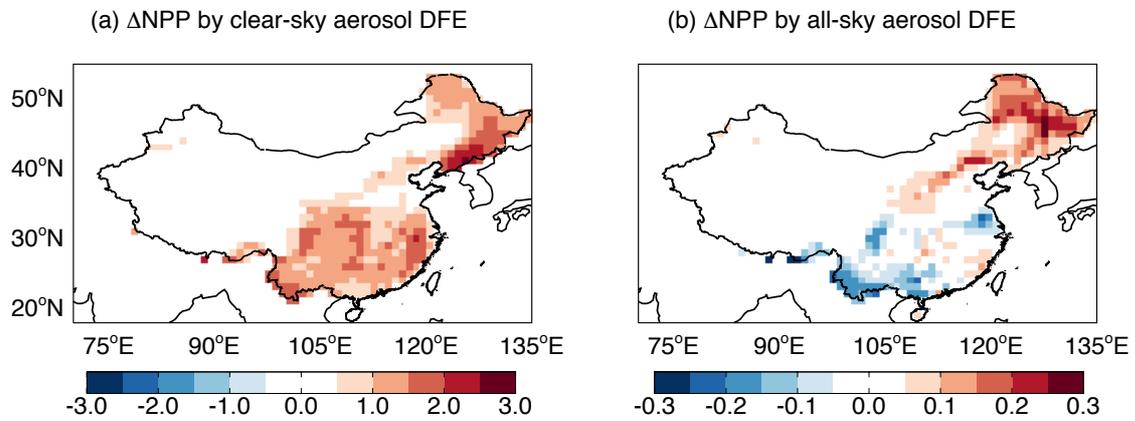

**Figure 5.** Sensitivity of summer GPP to changes of AOD. Results shown are different for clear-sky (red empty points) and all-sky (blue solid points) conditions in summer (June-August). Separately for clear-sky and all-sky conditions, we first collect all grid cells in eastern China (box region in Fig. 2a) for all 30 sensitivity simulations (Table 2). We then aggregate all grid cells with non-zero fraction of the specific PFT into 30 AOD bins ranging from 0 to 6 at an interval of 0.2. In each bin, we calculate average GPP change relative to aerosol-free conditions, with an error bar indicating one standard deviation.

**Figure 6.** Thresholds of AOD at 550 nm for aerosol DFE. (a)  $AOD_{t1}$  threshold leading to maximum NPP in summer (June-August). (b)  $AOD_{t2}$  threshold leading to enhanced summer NPP. Aerosol indirect effects and climatic feedback are not included for these thresholds. The average AOD-NPP response curves at four box domains in (a) are shown in (c-f), with red symbols indicating two AOD thresholds and blue symbols indicating observed AOD from MODIS. Chinese regions with low aerosol-free NPP ( $<0.05 \text{ g C m}^{-2} \text{ day}^{-1}$ ) are blanked in (a-b). Color scales for (a) and (b) are different.

**Figure 7.** Differences between MODIS AOD and two derived AOD thresholds. Left panel shows  $\Delta$ AOD between MODIS and AOD<sub>t1</sub> for the average of (a) whole year and (c) summer months. Right panel shows  $\Delta$ AOD between MODIS and AOD<sub>t2</sub> for the average of (b) whole year and (d) summer months. For the left panel, regions with positive values indicate that increase (decrease) of local AOD leads to reductions (enhancement) in NPP, while regions with negative values denote that decrease (increase) of local AOD results in reductions (enhancement) in NPP. For the right panel, regions with negative (positive) values indicate that current level of AOD always promotes (inhibits) NPP, compared with the aerosol-free conditions. The color scales among panels are different.

**Figure 8.** Changes in summer NPP caused by aerosol DFE in China for (a) clear-sky (CLR010 – CLR000) and (b) all-sky (ALL010 – ALL000) conditions. The percentage changes of NPP are shown in Figure S7. The color scales between panels are different. Units:  $\text{g C m}^{-2} \text{ day}^{-1}$ .
