13 **Abstract**

14 Biomass-burning aerosols have a significant effect on global and regional aerosol climate forcings. To
15 model the magnitude of these effects accurately requires knowledge of the size distribution of the
16 emitted and evolving aerosol particles. Current biomass-burning inventories do not include size
17 distributions, and global and regional models generally assume a fixed size distribution from all
18 biomass-burning emissions. However, biomass-burning size distributions evolve in the plume due to
19 coagulation and net organic aerosol (OA) evaporation or formation, and the plume processes occur on
20 spacial scales smaller than global/regional-model grid boxes. The extent of this size-distribution
21 evolution is dependent on a variety of factors relating to the emission source and atmospheric
22 conditions. Therefore, to account for biomass-burning aerosol size in global models accurately requires
23 an *effective* aerosol size distribution that accounts for this sub-grid evolution and can be derived from
24 available emissions-inventory and meteorological parameters.

25 In this paper, we perform a detailed investigation of the effects of coagulation on the aerosol size
26 distribution in biomass-burning plumes. We compare the effect of coagulation to that of OA
27 evaporation and formation. We develop coagulation-only parameterizations for effective
28 biomass-burning size distributions using the SAM-TOMAS large-eddy simulation plume model. For
29 the most-sophisticated parameterization, we use the Gaussian Emulation Machine for Sensitivity

30 Analysis (GEM-SA) to build a parameterization of the aged size distribution based on the
31 SAM-TOMAS output and seven inputs: emission median dry diameter, emission distribution modal
32 width, mass emissions flux, fire area, mean boundary-layer wind speed, plume mixing depth, and
33 time/distance since emission. This parameterization was tested against an independent set of
34 SAM-TOMAS simulations, and yields R^2 values of 0.83 and 0.89 for D_{pm} and modal width,
35 respectively. The aged size distribution is particularly sensitive to the mass emissions flux, fire area,
36 wind speed, and time, and we provide simplified fits of the aged size distribution to just these input
37 variables. These fits may be used in global and regional aerosol models. Finally, we show that
38 variability in coagulation may lead to greater variability in the particle size distribution than does OA
39 evaporation/formation using estimates of OA production/loss from the literature.

40 **1. Introduction**

41 *1.1 Biomass-burning aerosols*

42 Biomass burning (including wildfires, prescribed fires, and agricultural fires) releases significant
43 amounts of gas- and particle-phase species to the atmosphere (Andreae and Merlet, 2001; Reid et al.,
44 2005). The particle-phase emissions are composed primarily of a mixture of organic aerosol (OA) and
45 black carbon (BC) with some inorganic species (e.g. potassium), and the ratios of these species depend
46 on the source fire conditions (Capes et al., 2008; Carrico et al., 2010; Cubison et al., 2011; Hecobian et
47 al., 2011; Hennigan et al., 2011; Reid et al., 2005). These aerosols affect the global radiation budget
48 through the indirect and direct aerosol effects (Boucher et al., 2013). The smoke particles themselves
49 are able to act as cloud condensation nuclei (CCN) and increase cloud albedo and lifetime (indirect
50 aerosol effect; Lee et al., 2013; Pierce et al., 2007; Spracklen et al., 2011) as well as
51 scattering/absorbing incoming solar-radiation directly (direct aerosol effect; Alonso-Blanco et al.,
52 2014; Boucher et al., 2013; Haywood and Boucher, 2000; Jacobson, 2001).

53 Particle size has a significant effect on the magnitude of both the direct and indirect aerosol
54 effects (Lee et al., 2013; Seinfeld and Pandis, 2006; Spracklen et al., 2011). The composition and
55 diameter of the particles affect their absorption/scattering efficiencies, which dictate the amount of
56 solar radiation absorbed/scattered per emitted mass of particles (Seinfeld and Pandis, 2006). Particle
57 diameter and hygroscopicity determine the particles' ability to act as a CCN and influence cloud
58 processes, and the total number of emitted particles increases with decreased particle size if total mass

59 emissions are fixed. Spracklen et al., (2011) found that a reduction by a factor of two in particle size for
60 all carbonaceous aerosols (for a fixed total aerosol mass) resulted in a ~300% increase in the cloud
61 albedo indirect effect globally, as more particles were available to act as CCN. Lee et al., (2013)
62 determined that CCN concentrations in the GLOMAP model were very sensitive to uncertainties in
63 biomass-burning emission diameter on both the regional and global scale (its attributable CCN
64 uncertainty ranked third of 28 factors tested globally). Therefore, to ascertain the role of
65 biomass-burning aerosols in climate forcings accurately, biomass-burning size distributions must be
66 well represented in aerosol-climate models.

67 Size distributions are subject to physical and chemical processing in the plume. The formation of
68 secondary organic aerosol (SOA) has been observed in lab studies of biomass-burning aerosol
69 (Cubison et al., 2011; Grieshop et al., 2009; Hennigan et al., 2011; Heringa et al., 2011; Ortega et al.,
70 2013) and in field campaigns (DeCarlo et al., 2010; Lee et al., 2008; Reid et al., 1998; Yokelson et al.,
71 2009). This SOA condenses onto existing particles causing growth of the aerosol size distribution.
72 Conversely, recent lab and field studies have characterized primary organic aerosol (POA) as
73 semi-volatile, with plume dilution allowing the evaporation of organic aerosol from particles (Huffman
74 et al., 2009; Cubison et al., 2011; May et al., 2013,). The cumulative net effects of OA production/loss
75 within biomass-burning plumes has been found to be highly variable from fire to fire (Hennigan et. al,
76 2011). Coagulation is also important for size-distribution evolution as it reduces particle number and
77 shifts the distribution to larger sizes. Coagulation rates are proportional to the square of the particle
78 number concentration (all else remaining fixed), so the high number concentrations in biomass-burning
79 plumes relative to background can lead to rapid coagulation growth of the size distribution. The rate
80 and magnitude of the aerosol growth caused by these combined processes is a function of aging time,
81 emission source characteristics, aerosol properties at emission, and atmospheric conditions.

82 These condensation/evaporation and coagulation aging processes affect both the composition and
83 size of the aerosol size distribution – both properties that influence the extent to which smoke particles
84 affect climate. While fresh smoke is generally composed of fine particles between 20-60 nm in
85 diameter (Levin et al., 2010), condensation and coagulation cause rapid aerosol growth to larger sizes
86 (over 100 nm) on timescales of often less than 24 hrs (Janhäll et al., 2010). However, Janhäll et al.,
87 (2010) found the observed geometric mean diameter of aged biomass-burning particles varied between
88 170-300 nm, with geometric standard deviations (hereafter referred to as “modal width”) between
89 1.3-1.7 with significant dependence on fuel type and modified combustion efficiency. It is currently

90 unclear to what extent these factors and others drive the variability in aged size distributions.

91 As stated earlier, an accurate representation of aged biomass-burning aerosol size is necessary for
92 predictions of aerosol climate effects in regional and global models (Lee et al., 2013). Current wildfire
93 inventories are mass-based (neglecting aerosol size data), and thus regional and global models used for
94 aerosol-climate effects generally specify fixed, “aged” size distributions that do not account for
95 sub-grid processing of the emitted particles (Reid et al., 2009; van der Werf et al., 2010; Wiedinmyer et
96 al., 2011). Any variability in the biomass-burning size distribution due to fire or emissions
97 characteristics and meteorology are not accounted for, nor is it clear what the best “aged” size
98 distribution to use is in these models.

99 In this paper, we perform a detailed investigation of coagulation in biomass-burning plumes and
100 compare to the effects of OA evaporation and formation. We investigate the factors that influence
101 coagulation growth of the particles in the plume. These factors include fire area, particle-emissions
102 mass flux, particle-emissions size, and meteorological conditions. We create parameterizations of
103 varying degrees of complexity for median dry diameter (D_{pm}) and lognormal modal width (σ) of the
104 aged biomass-burning size distributions as a function of these input parameters, based on detailed
105 numerical simulations using a large-eddy model with embedded aerosol microphysics (SAM-TOMAS).
106 Finally, we compare the effect of coagulation on the aerosol size distribution to that of OA
107 production/evaporation.

108 We describe the parameterization building process, including the use of a Gaussian emulator, in
109 Sect. 2. A discussion of input and output ranges, processing, and constraints of the parameters we have
110 chosen is provided in Sect. 2.1. We discuss the SAM-TOMAS model and the emulation process in Sect.
111 2.2-2.3. Sections 3.1-3.2 contain the results of the SAM-TOMAS model and the emulator. We discuss
112 emulator sensitivities to the inputs in Sect. 3.3 and present a series of simplified fit equations for the
113 effective size distributions in Sect. 3.4. We discuss the effects of potential OA production/loss on our
114 size distribution estimates in Sect. 3.5. Finally, we conclude in Sect. 4, including future plans for testing
115 the parameterization and known existing limitations.

116

117

118 2. Methods

119 Figure 1 provides an overview of our methods that will be described in detail in the subsections below.
120 In short, we used a Large-Eddy Simulation model, the System for Atmospheric Modelling (SAM;
121 Khairoutdinov and Randall, 2003), with the online aerosol microphysics module, TwO Moment
122 Aerosol Sectional (TOMAS, Adams and Seinfeld, 2002; Stevens et al., 2012) to simulate the evolution
123 of the biomass-burning aerosol size distribution by coagulation across a wide range of emission and
124 meteorological conditions. We used the SAM-TOMAS size distributions to build parameterizations to
125 predict aged D_{pm} and σ using: (1) a statistical emulator of the SAM-TOMAS model itself and (2)
126 simplified fits to the SAM-TOMAS output data. The statistical emulator was built by the Gaussian
127 Emulation Machine for Sensitivity Analysis (GEM-SA), and we used the emulator and SAM-TOMAS
128 data to determine the relative importance of various inputs to shaping the aged size distribution.

129 *2.1 Investigated factors that may lead to variability in aged size distributions*

130 We investigated seven parameters that may affect the aging of the biomass-burning aerosol size
131 distribution. These can be divided into those representing the initial lognormal-mode size parameters
132 (D_{pm0} , σ_0), fire conditions (mass flux, fire area), atmospheric conditions (wind speed, plume mixing
133 depth), and time. Each of these parameters is generally available in large-scale aerosol models, which
134 means a parameterization for aged biomass-burning size distributions based on these parameters may
135 be used in these models. Table 1 lists these input parameters and the ranges of values tested in this
136 work.

137 We assumed that the initial size distributions were a single lognormal mode (described by dry
138 median diameter, D_{pm} , and modal width, σ), which is sufficient when representing both fresh and aged
139 observed biomass-burning size distributions (Capes et al., 2008; Janhäll et al., 2010; Levin et al., 2010;
140 Sakamoto et al., 2015). The initial size-distribution parameters specify the median dry diameter (D_{pm0})
141 and modal width (σ_0) of the freshly emitted aerosol distribution. We varied these parameters between
142 20-100 nm for D_{pm0} and 1.2-2.4 for σ_0 . The large ranges are due to variability in combustion efficiency
143 and fuel-type factors as seen in lab and observational studies (Janhäll et al., 2010; Levin et al., 2010).

144 Fire area, mass flux, wind speed and mixing depth (the vertical extent of the aerosol plume) all
145 affect the aerosol number concentration (N) within the plume, which in turn affects the coagulation rate

146 (proportional to N^2). In our simulations, we constrained mass flux to $2 \times 10^{-8} - 5 \times 10^{-6} \text{ kg m}^{-2} \text{ s}^{-1}$ using
147 approximate maximum and minimum values of summed black carbon and organic carbon flux
148 (BC+OC) found in the Global Fire Emissions Database ver. 3 (GFED3; van der Werf et al., 2010;
149 available from <http://www.globalfiredata.org>). Fire area ranged from 1 - 49 km^2 (simulated as a square),
150 which was found to represent the range of fire sizes in GFED3. Boundary layer wind speed varied
151 between 2 m s^{-1} and 20 m s^{-1} and was based on ranges in the National Center for Environmental
152 Prediction (NCEP) North American Regional Reanalysis (NARR) meteorology (Mesinger et al., 2006)
153 during the fire season (specifically, July, 2010). Mixing depth had a range of 150-2500 m (based on
154 SAM-TOMAS output; see Sect. 2.2).

155 The aging time was the final input parameter, and we used 5 hr (300 min) as an upper time
156 bound due to this being a typical timescale for transport across large global model gridboxes.

157 **2.2 The SAM-TOMAS model**

158 We used the SAM-TOMAS model to simulate the evolution of biomass-burning aerosol size
159 distributions due to coagulation across the range of input parameters described above. SAM
160 (Khairoutdinov and Randall, 2003) is a dynamical large-eddy simulation (LES) model, which has
161 previously been used to model emissions plumes (Lonsdale et al., 2012; Stevens et al., 2012; Stevens
162 and Pierce, 2013). We ran the model in Lagrangian 2D mode (Stevens and Pierce, 2013), in which a
163 wall oriented normal to the mean boundary layer wind moves at the mean boundary-layer wind speed.
164 This moving wall tracks the radial dispersion of a plume as it travels downwind (Fig. 2). This 2D mode
165 is computationally efficient compared to the full 3D model with minor differences due to axial plume
166 symmetry (Stevens and Pierce, 2013).

167 The size distributions of the aerosol particles in SAM were simulated using the Two Moment
168 Aerosol Sectional (TOMAS; Adams and Seinfeld, 2002) microphysical scheme embedded into SAM.
169 The algorithm simulated the size distribution across 15 logarithmically-spaced size bins spanning 3
170 nm-10 μm . The aerosol size distribution was tracked via two independent moments for each bin of the
171 size distribution (mass and number). TOMAS calculated coagulation explicitly in each grid cell
172 assuming a Brownian diffusion kernel (Seinfeld and Pandis, 2006). Our SAM-TOMAS simulations
173 included only coagulation, and particles were assumed to be a single species (no differentiating
174 between BC and OA). The SAM-TOMAS model had previously been tested against observations in

175 Stevens et al. (2012) and Lonsdale et al. (2012) for power plant plumes.

176 We set background aerosol concentrations to zero as the biomass-burning aerosol
177 concentrations emitted into SAM-TOMAS were orders of magnitude larger than those present in a
178 remote background location, and as such the lack of background aerosol would have had an
179 insignificant effect on the rate of in-plume coagulation processing. The biomass-burning aerosol was
180 assumed to have a constant density of 1400 kg m^{-3} as primarily a mix of organic compounds, thus we
181 do not consider how changes in BC/OA composition may affect density and coagulation rates. The
182 hygroscopicity of the aerosol particles was set to zero, allowing no water uptake. This assumption is
183 not true of real world biomass-burning aerosol and has been characterized in other works finding
184 hygroscopicities of fresh ($\kappa=0.02-0.8$; Petters et al., 2009) and aged smoke ($\kappa=0.1-0.3$; Engelhart et al.,
185 2012) with a strong dependence on fuel type. In terms of their effect on the size distribution, a constant
186 κ across all particle sizes has the simple effect of increasing the effective diameter of the particles via
187 water uptake by a scalar factor. This initial increase should only have a relatively minor effect on the
188 final dry D_{pm} or σ of the plume after coagulation processing as the mean coagulation rates are
189 relatively insensitive to the size shifting of a particle population (Seinfeld and Pandis, 2006; Stuart et
190 al., 2013).

191 We ran 100 SAM-TOMAS simulations at $500 \text{ m} \times 500 \text{ m}$ horizontal resolution (total horizontal
192 extent = 100 km), and constant 40 m vertical resolution (total vertical extent = 4 km). This resolution
193 accommodated the chosen plume parameters (see Sect. 2.1). The model was run with a master timestep
194 of 2 seconds (varied internally for accuracy in the coagulation calculation) for a duration of 5 model
195 hours (300 minutes). The output from each SAM-TOMAS simulation was recorded at four different
196 times (400 total time slices across 100 simulations).

197 The seven inputs to the SAM-TOMAS model were constrained to capture a range of
198 biomass-burning characteristics in realistic scenarios and are summarized in Table 2. The ranges of
199 values used for $D_{\text{pm}0}$, σ_0 , fire area and mass flux are the same as those listed in Table 1. The
200 meteorological fields were supplied by NCEP reanalysis meteorology from over North America (land
201 only, lat: $30^\circ - 70^\circ \text{ N}$, lon: $70^\circ - 135^\circ \text{ W}$) during the July 2010 fire season. The SAM-TOMAS wall speed
202 was set equal to the mean boundary layer wind speed from NCEP. We filtered these inputs by requiring
203 wind speed $> 2 \text{ m s}^{-1}$ to eliminate stagnation situations over the source. The injection height (lower
204 bound) and injection depth of the aerosol were specified at between 50-1500 m and 500-2000 m
205 respectively. No emission injection parameterization (e.g. Freitas et al., 2007) was used as we were

206 only trying to capture a range of mixing depths for our aging calculation, and the absolute height was
207 relatively unimportant. All the SAM-TOMAS simulation inputs were chosen using semi-random Latin
208 hypercube sampling across the ranges listed above (Lee et al., 2012). The results of the full
209 SAM-TOMAS simulation set are summarized in Sect. 3.1.

210 We calculated the time-dependent mixing depth of the plume from vertical profiles averaged
211 horizontally across the entire simulation wall at each time slice. Figure 3 shows a sample of six vertical
212 profiles from different SAM-TOMAS simulations. The mixing depth was defined as the range of
213 altitudes where the aerosol mass was greater than half of the peak aerosol mass:

$$214 \quad \text{mixing depth} = \Delta_{\text{alt } 50\% \text{ peak aerosol mass}}$$

215 In cases where the plume mixed down to the ground, the lower altitude bound was defined as 0
216 m. Runs with mixing depths greater than 2500 m were excluded to ensure that the plume did not reach
217 the model top. In addition to mixing depth, D_{pm} and σ were calculated for each of the SAM-TOMAS
218 time slices from the first and third integrated moments of the size distribution as detailed by Whitby et
219 al. (1991).

220 ***2.3 Emulation of the SAM-TOMAS output***

221 As running the full SAM-TOMAS model is too computationally expensive for implementation in
222 global aerosol models, we built an offline emulator of the model for use as a parameterization in these
223 global models. We created the emulator using the Gaussian Emulation Machine for Sensitivity Analysis
224 (GEM-SA) developed by the Centre for Terrestrial Dynamics (<http://www.ctcd.group.shef.ac.uk/gem.html>).
225 The GEM-SA software uses a Gaussian process to design a SAM-TOMAS simulator (the emulator)
226 based on the behavior of the known SAM-TOMAS inputs and outputs (the training data). A complete
227 description of GEM-SA statistics and assumptions can be found in Kennedy and O'Hagan (2001) and
228 Kennedy et al. (2008). A description of its application as an estimator in atmospheric-aerosol modelling
229 can be found in Lee et al. (2011). This software was previously used in sensitivity studies in
230 atmospheric-aerosol (Lee et al., 2011, 2012) and vegetation models (Kennedy et al., 2008).

231 We used 400 data points from the set of 100 SAM-TOMAS simulations to train the emulator.
232 GEM-SA assumes that the outputs are a continuous and differentiable function of the inputs to
233 statistically emulate the model and estimate the SAM-TOMAS output (D_{pm} and σ). We used a new set

234 of completed SAM-TOMAS simulations (624 non-training data points) to test our GEM-SA
235 parameterization for accuracy relative to SAM-TOMAS (see Sect. 3.2-3.3).

236 The GEM-SA parameterization requires seven input parameters: D_{pm0} , σ_0 , mass flux, fire area,
237 wind speed, mixing depth and time, and generates predicted aged D_{pm} and σ as outputs. These
238 estimated D_{pm} and σ describe an aged lognormal aerosol mode incorporating the sub-grid scale
239 coagulation taking place inside concentrated biomass-burning plumes and can be used in
240 global/regional models. We have made the GEM-SA parameterization (emulator Fortran subroutine and
241 input files) available as Supplementary Material.

242 3. Results

243 3.1 SAM-TOMAS simulation output

244 Figure 4 shows the D_{pm} (panels a and c) and σ (panels b and d) as a function of distance for each of the
245 100 SAM-TOMAS simulations used to train the emulator (Sect. 3.2). The influence of several factors
246 (the distance from the source, emissions mass flux, and fire area) on the final aerosol size distributions
247 is apparent in the output of SAM-TOMAS simulations. Panels a and b are colored by the emissions
248 mass flux, whereas panels c and d are colored by dM/dx (kg m^{-1} , the amount of aerosol mass in an
249 infinitesimally thin slice of air perpendicular to the direction of the wind, i.e. mass flux \cdot fire area /
250 wind speed). All simulations showed D_{pm} increasing with distance as coagulation progressed in each
251 plume. The coloring in panel a shows that D_{pm} generally increases more rapidly and to higher values
252 with higher emission fluxes. However, panel c shows that dM/dx appears to be a better predictor for the
253 increase of D_{pm} with distance than the emissions flux, and the distance and dM/dx capture much of the
254 variability in D_{pm} . D_{pm0} appears to have little influence on D_{pm} (note, however, that the first points on
255 these plots already include some processing and are not the initial diameters).

256 Panels b and d show that σ tends to converge with distance as simulations with large initial σ
257 generally decrease with distance more rapidly than simulations with smaller initial σ . This convergence
258 happens slowly relative to the times simulated, so the initial σ have a strong influence even at 200 km.
259 The colors and panels b and d show that σ in high emissions-flux and dM/dx cases converge more
260 rapidly than low-emissions cases. However, as opposed to the 1.32 modal-width asymptote in the limit
261 of infinite coagulation found by Lee (1983), the SAM-TOMAS simulations converge to a limit of

262 1.2-1.25. This is likely due to the size-distribution bin-spacing in the SAM-TOMAS model, where
263 modal widths <1.32 are smaller than a single TOMAS size bin width, which results in less accurate fits
264 of σ for smaller σ values.

265 Figure 5 is a scatterplot of D_{pm} vs σ for each point seen in Fig. 4, excepting those at distances
266 less than 25 km (points close to the emissions source have been removed). The points are colored by
267 dM/dx . Thus, Fig. 5 shows the results of Fig. 4 panels c and d together but removes the distance
268 information. At these distances over 25 km, D_{pm} is relatively well constrained by dM/dx alone, showing
269 that the mean growth by coagulation is strongly influenced by the mass of particles in the slice of air.
270 On the other hand, σ is unconstrained at low values of dM/dx but more constrained towards 1.2-1.4 at
271 high values of dM/dx . At high dM/dx values, the convergence towards the steady-state σ proceeds
272 much more rapidly than at low dM/dx as also shown in Fig. 4d.

273 These SAM-TOMAS results show that dM/dx is a powerful determinant of aged
274 biomass-burning size. In these tests, we also explored dividing dM/dx by the final mixing depth to
275 create $dM/dxdz$ (mass flux \cdot fire area / wind speed / mixing depth). Large mixing depths dilute particle
276 concentrations and reduce coagulation, so we expected that $dM/dxdz$ may be a better predictor of
277 biomass-burning size-distribution aging than dM/dx . However, Fig. 4 and Fig. 5 did not look
278 qualitatively different when using $dM/dxdz$. We quantitatively evaluate the fidelity of dM/dx and
279 $dM/dxdz$ as proxies for biomass-burning size-distribution aging in Sect. 3.4. In the following two
280 subsections, we use the emulator to determine the contribution of the individual inputs to the changes
281 in simulated D_{pm} and σ .

282 ***3.2 Model parameterization evaluation***

283 We tested the GEM-SA-derived emulator parameterization against additional SAM-TOMAS model
284 runs that were not used in the fitting of the parameterization, and we show the results in Fig. 6. We use
285 624 additional SAM-TOMAS-simulated data points that were not used for GEM-SA training in this
286 evaluation. The emulator parameterization-predicted outputs corresponding to these data points for D_{pm}
287 and σ are plotted against the SAM-TOMAS D_{pm} and σ . Predicted D_{pm} has an R^2 value of 0.83 with a
288 slope of 0.92. Larger absolute errors in D_{pm} are found at the larger diameter sizes, but 86% are found
289 within 10% of the SAM-TOMAS D_{pm} (76% of predicted D_{pm} are within 5% of SAM-TOMAS D_{pm}).
290 The small mean normalized bias (MNB) of -0.06 indicates a slight negative bias in the

291 parameterization. This bias is generally seen towards the higher final D_{pm} values in the simulations
292 (>250 nm), which are reached only by the most aged plumes with the heaviest aerosol loads. The σ plot
293 (Fig. 6b) shows a similar correlation coefficient ($R^2=0.91$) and has a slope of 0.93. The MNB is 0.01
294 and 77% of the predicted σ points are within 5% of the σ calculated from SAM-TOMAS. The cluster of
295 points near $\sigma=1.2$ -1.3 is indicative of the modal width steady-state limit. This limit is not captured by
296 the σ parameterization, which assumes a smooth function towards even lower σ values.

297 ***3.3 Sensitivity of aged size distribution to input parameters***

298 Figures 7 and 8 show the sensitivities of the parameterization outputs (D_{pm} and σ , respectively) to the
299 input parameters ($D_{\text{pm}0}$, σ_0 , mass flux, fire area, wind speed, time, and mixing depth) as determined by
300 the GEM-SA emulation of the SAM-TOMAS output. (Note that distance was used as the dependent
301 variable in Fig. 4, while we use time in the emulator. Time can be converted to distance by multiplying
302 by the wind speed). In every panel, each line shows the change in D_{pm} (Fig. 7) or σ (Fig. 8) as an input
303 parameter (e.g. $D_{\text{pm}0}$ in panel a) is varied systematically from its minimum to maximum tested value
304 with a randomly chosen set of the other six input parameters. Each panel contains 100 lines, which
305 means that 100 sets of the six other input parameters were randomly chosen to make these lines. We
306 normalize each line by the value of D_{pm} or σ at the midpoint of the x-axis (i.e. where the input
307 parameter is at the midpoint of its tested range). For time since emission (panel f) we normalize by the
308 values at $t=0$ min instead of at the midpoint of the range. These plots therefore show the percent change
309 in D_{pm} or σ , $\Delta\%_{\text{output}}$, as each input is changed from its midpoint value (or $t=0$ min for time), in order to
310 emphasize the parameterization's output response to each isolated input variable.

311 The D_{pm} sensitivity plots (Fig. 7) show a number of well-defined responses of D_{pm} to the inputs.
312 D_{pm} increases monotonically with increases in mass flux and fire area (Fig. 5b,d), and decreases nearly
313 monotonically with wind speed. These trends are due to the interrelationships of these inputs with
314 starting number concentration. These results are consistent with Fig. 4 and Fig. 5, where D_{pm} increased
315 with increasing dM/dx in the SAM-TOMAS simulations. Additionally, the D_{pm} also decreases
316 monotonically with mixing depth (albeit more weakly than mass flux, fire area, and wind speed), so
317 $dM/dxdz$ may also be a good proxy for biomass-burning size-distribution aging (evaluated in Sect. 3.4).
318 Higher dM/dx and $dM/dxdz$ values lead to higher initial number concentration in these plumes, which
319 drive higher rates of coagulation due the squared dependence of coagulation rate on number
320 concentrations.

321 D_{pm} also increases nearly monotonically with time (the regions of slight decreases with time
322 show that the parameterization is not necessarily always physically representative due to the statistical
323 nature of the fit over the parameter space). The rapid rise in D_{pm} for time <2 hrs is due to the high
324 number concentrations (N) and coagulation rates near the source. As dilution and coagulation progress,
325 N decreases and coagulation slows, resulting in a slowing of D_{pm} increase. Mass flux has the largest
326 range of output D_{pm} associated with the input ranges specified here ($\sim -50\%$ to $+100\%$).

327 The relationship between D_{pm} and the initial size parameters (D_{pm0} and σ_0) is more complicated.
328 Neither D_{pm0} nor σ_0 show monotonic increases or decreases in D_{pm} due to changes in either of these
329 isolated inputs. In general, there is an increasing trend in output D_{pm} with increasing D_{pm0} , but for some
330 cases it decreases. These decreases in D_{pm} are likely due to (1) decreasing particle number
331 concentrations with increasing D_{pm0} , which leads to reduced coagulation rates and (2) imperfections in
332 the statistical fit of the parameter space. The larger σ_0 indicate broader emission size distributions, with
333 more large particles and small particles. Since coagulation progresses fastest between large and small
334 particles (as opposed to particles of approximately the same size), this favors higher D_{pm} at higher σ .
335 However, the initial particle number decreases with increasing σ , which lowers the coagulation rate and
336 leads to lower D_{pm} .

337 The emulator-derived σ sensitivities are shown in Fig. 8. Since we expect σ to converge towards
338 an asymptotic limit with coagulation processing (Fig. 4b,d), we see with those input parameters
339 associated with higher plume number density (mass flux, fire area, wind speed⁻¹, mixing depth⁻¹), which
340 gave monotonic increases for D_{pm} , show mixed results for σ due to variability in the initial σ_0 . The time
341 sensitivity plot (Fig. 8f) shows decreasing σ with time similar to Fig. 4b,d.

342 Emission σ_0 shows the most pronounced and largest magnitude effect on output σ ($\sim -30\%$ to
343 $+30\%$). Thus, the timescales for σ evolving towards 1.2 is longer than the timescales tested here for
344 even the densest plumes. These sensitivity plots show that there is less variability in σ than in D_{pm} over
345 the tested input space.

346 ***3.4 Simplified fits to the aged size distributions***

347 In addition to the GEM-SA emulator fits, we determined simplified fits for both D_{pm} and σ based on the
348 behavior in Fig. 4 and Fig. 5. These fits are easier to implement in regional and global aerosol models
349 than the full GEM-derived parameterization. These equations are meant to produce approximate

350 estimates of D_{pm} and σ throughout plume size-distribution aging. The equations require: the initial
351 value of the size-parameter of interest (D_{pm0} or σ_0), a value proportional to the plume aerosol loading
352 ($dM/dxdz$: mass flux · fire area / wind speed / mixing depth or dM/dx : mass flux · fire area / wind
353 speed), and time since emission from the source fire (time). (Distance may also be used in these
354 equations rather than time, and distance/wind-speed should be used in place of time.) The functional
355 forms fitted for D_{pm} and σ are found below.

$$D_{pm} = D_{pm0} + A [dM/dx]^b (\text{time})^c \quad (1)$$

$$D_{pm} = D_{pm0} + A [dM/dxdz]^b (\text{time})^c \quad (2)$$

$$\sigma = \sigma_0 + A [dM/dx]^b (\text{time})^c (1.2 - \sigma_0) \quad (3)$$

$$\sigma = \sigma_0 + A [dM/dxdz]^b (\text{time})^c (1.2 - \sigma_0) \quad (4)$$

356

357 where A , b and c are determined by fitting each equation to the SAM-TOMAS data. For these
358 empirical equations, the units of dM/dx are kg m^{-1} , $dM/dxdz$ are kg m^{-2} , D_{pm} is nm and time since
359 emission is min . It should be noted that the equations for D_{pm} and σ are designed to be independent of
360 each other (i.e. D_{pm} is not dependent on σ_0), which differs from the GEM-SA emulator. The aerosol
361 loading parameter dM/dx was chosen based on the stratification seen in Fig. 4c and Fig. 5. $dM/dxdz$
362 was tested as well, as it incorporates the variance associated with mixing depth into the fit. The fit to
363 dM/dx rather than $dM/dxdz$ may be advantageous because we expect mixing depth of the plume to be
364 one of the more uncertain parameters in an atmospheric model, and the D_{pm} sensitivities to mixing
365 depth tend to be smaller than those to mass flux, fire area and wind speed in the GEM-SA emulator
366 (Fig. 7). The σ fits introduce a fourth factor, $(1.2 - \sigma_0)$, which represents the difference between the
367 SAM-TOMAS infinite-coagulation limit (Fig. 4b and d) and the initial modal width.

368 The scalar A , b and c variables were fit to the ensemble of SAM-TOMAS data. Their values are
369 summarized in Table 3. The fits were tested against independent SAM-TOMAS data in Fig. 9 (D_{pm}) and
370 Fig. 10 (σ). The simplified D_{pm} parameterizations, as expected, are not as good a fit of the
371 SAM-TOMAS data as the GEM-SA emulator (Fig. 6). The fit statistics for the simple
372 parameterizations are as follows: $D_{pm}(dM/dx)$: slope = 0.82, $R^2 = 0.67$, MNB = 0.003, $D_{pm}(dM/dxdz)$:
373 slope = 0.98, $R^2 = 0.77$, MNB = 0.008. The fit using $dM/dxdz$ generally performs better than that with

374 dM/dx . The simple σ fit also did not perform as well as the GEM-SA emulator with fit statistics of:
375 $\sigma(dM/dx)$: slope = 0.71, $R^2 = 0.75$, MNB = 0.07 and, $\sigma(dM/dxdz)$: slope = 0.71, $R^2 = 0.76$, MNB = 0.07).
376 Thus, $dM/dxdz$ fits do yield better results than dM/dx (in particular for D_{pm}); however, a user may
377 choose to use the dM/dx fit if the mixing depth is unknown. We note that these fits are only valid
378 within the parameter ranges shown in Table 1.

379 **3.5 OA production/loss**

380 One of the limitations of the coagulation-only parameterizations derived in this paper is that they do not
381 include the effects of potential condensation/evaporation of organic aerosol on the aged
382 biomass-burning size distribution. Both condensational growth and evaporative loss of OA been
383 observed previously in chamber studies and the field due to OA production or evaporation from
384 dilution/chemistry (Cubison et al., 2011; Hecobian et al., 2011; Hennigan et al., 2011; Grieshop et al.,
385 2009).

386 Here we present a simple correction to our coagulation-only parameterizations to account for
387 in-plume OA production/loss. Each parameterization presented in this paper may be corrected to
388 include OA production/evaporation using the corrections below. We assume that the OA production or
389 loss does not affect the coagulation rates or σ , but acts to increase the final D_{pm} . These assumptions are
390 imperfect as irreversible condensation (evaporation) increases (decreases) σ ; however, σ is preserved
391 during condensation or evaporation of semi-volatile material (Pierce et al., 2011). Regardless, for the
392 relatively small amounts of OA condensation/evaporation considered here, the change in σ and
393 coagulation rates should be minor. For larger changes in OA mass (more than a factor of ~ 2) due to
394 production/loss, our simple correction will have uncertainties due to these assumptions. Our correction
395 to the final D_{pm} has the following form:

$$D_{pm\ w/OA\ prod/loss} = D_{pm\ w/o\ OA\ prod/loss} \cdot \left(\frac{OAMass_{w/OA\ prod/loss} + BCMass}{OAMass_{w/o\ OA\ prod/loss} + BCMass} \right)^{1/3} \quad (5)$$

396

397 where $D_{pm\ w/o\ OA\ prod/loss}$ is the final D_{pm} from the coagulation-only GEM-SA emulator parameterization,
398 the biomass-burning aerosol OA mass (with and without additional production or loss) is in kg (per
399 particle or volume of air) and the BC mass is in kg (per particle or volume of air). Thus, for a doubling

400 of OA due to SOA production (one of the larger enhancements found in Hennigan et al., 2011),
401 particles that contain negligible BC will grow in diameter by 26% above the coagulation-only
402 predictions. If the particles contained 50% BC, then the diameter growth would only be 14%.

403 While these changes are expected to be on the large end for growth by SOA production, they
404 are significantly smaller than the ~200% variability in aged D_{pm} due to coagulation over the range of
405 initial fire conditions (Fig. 7). For example, variations in wind speed, mass flux, and fire area alone can
406 independently cause variability in the aged D_{pm} by a factor of 2 due to changes in coagulation rates
407 while variability in condensational growth appears to cause much smaller uncertainties (~25%) in the
408 aged D_{pm} . This indicates that although SOA condensational growth is certainly important in shaping
409 particle composition and total particle mass, it is not among the most dominant factors determining the
410 aged D_{pm} compared to those fire-condition parameters controlling coagulation growth. It should be
411 noted, however, that the D_{pm} growth attributed to OA condensation is not accompanied by a change in
412 particle number (additional OA mass is distributed among existing particles), whereas a similar
413 increase in D_{pm} growth by coagulation only would have an accompanying decrease in particle number.
414 Thus, the climatic influence of a size change due to coagulation and condensation are different.

415 4. Conclusions

416 We used the SAM-TOMAS large-eddy simulation model and an emulation technique to explore the
417 evolution of biomass-burning aerosol size distributions due to coagulation and build coagulation-only
418 parameterizations of this size-distribution evolution. We have also provided a simple correction to the
419 parameterization for cases with net OA production or loss. We used the SAM-TOMAS model to
420 simulate plume dispersion and aerosol coagulation. The SAM-TOMAS results show that the aged D_{pm}
421 can be largely described by dM/dx and the distance from the source (or time since emission). These
422 results also show that the aged σ moves from σ_0 towards a value of 1.2 at a rate that depends on dM/dx .

423 The GEM-SA program was used to derive a D_{pm} and σ emulator parameterization based on the
424 SAM-TOMAS results. The parameterization requires seven input parameters: emission D_{pm0} , emission
425 σ_0 , mass flux, boundary layer wind speed, fire area, plume mixing depth, and time since emission. The
426 predicted D_{pm} and σ can then be used as effective unimodal biomass-burning size-distribution
427 parameters in regional and global aerosol models.

428 The D_{pm} parameterization showed the strongest sensitivities to those input parameters associated

429 with the extent of aerosol loading within the plume (mass flux, fire area, wind speed). Across the fire
430 area and wind speed ranges tested here, final D_{pm} varied by $\pm 50\%$. Mass flux had the largest associated
431 D_{pm} sensitivity across the tested values (-50% to $+100\%$). These sensitivities were larger than those
432 associated with mixing depth ($\sim -20\%$ to 20%) or the initial size-distribution parameters (D_{pm0} : $\sim -25\%$
433 to 25% , σ_0 : $\sim 15\%$ to -15%). The σ parameterization showed a uniform decrease in σ with time and
434 strong sensitivities to the emission σ_0 (-30% to 30%). This strong sensitivity to σ_0 can be attributed to
435 the inertia in σ evolution in simulations with large modal widths and relatively small mass loading,
436 where σ will not converge quickly to the coagulation limit (1.2).

437 The GEM-SA-derived parameterization performed relatively well against the SAM-TOMAS
438 model with a correlation of $R^2=0.83$, slope of $m=0.92$ and a low mean normalized bias of $MNB=-0.06$
439 for D_{pm} . The σ parameterization has fit statistics of $R^2=0.93$, slope= 0.91 and $MNB=0.01$. The σ
440 parameterization was unable to capture the coagulation limit of 1.2 seen in the SAM-TOMAS results
441 and instead extrapolated to lower values. This 1.2 limit differs from the 1.32 σ limit proposed by Lee
442 (1983) due to the bin-spacing in SAM-TOMAS being coarser than lognormal modes with these small
443 modal widths.

444 We also provided simplified polynomial fits for D_{pm} and σ (Eqns 1-4, Table 3) for calculating
445 aged D_{pm} and σ as independent functions of: the fresh emission parameter (D_{pm0} or σ_0), the mass loading
446 of the aerosol (dM/dx or $dM/dxdz$) and the time since emission from the source fire. The σ fits also
447 require a convergence term to account for the coagulation limit (1.2 in the SAM-TOMAS model).
448 Tested against independent SAM-TOMAS data, the D_{pm} simplified fits performed as: $D_{pm}(dM/dx)$:
449 slope = 0.82, $R^2 = 0.67$, $MNB = 0.003$ and $D_{pm}(dM/dxdz)$: slope = 0.98, $R^2 = 0.77$, $MNB = 0.008$. The σ
450 simplified fits have statistics of $\sigma(dM/dx)$: slope = 0.71, $R^2 = 0.75$, $MNB = 0.07$ and $\sigma(dM/dxdz)$: slope
451 = 0.71, $R^2 = 0.76$, $MNB = 0.07$. The equations requiring $(dM/dxdz)$ performed better than their (dM/dx)
452 counterparts as they also account for the aerosol layer depth.

453 We provided a correction for OA production/loss, and showed that significant production of
454 SOA within the plume ($\sim 100\%$ OA mass enhancement) would cause a relatively small shift in the
455 size-distribution D_{pm} (14-26% increase) compared to other factors that control the coagulation rate (e.g.
456 dM/dx). Thus, variability in factors controlling coagulation may cause more variability in the aged
457 biomass-burning particle size than variability in SOA production. We note, however, that OA
458 production increases D_{pm} without loss of particle number while coagulation increases D_{pm} with a
459 decrease in number, thus the climatic impact of condensation and coagulation are different. The

460 simplified OA-production/loss correction assumes no change in σ with condensational growth. Further
461 testing should be done with explicit OA production and loss to better quantify the effects of
462 condensation of the size-distribution evolution.

463 Our analysis does not include any cloud processing of the plume particles, i.e. the production of
464 aqueous SOA within activated plume particles is not accounted for in our simple OA mass correction.
465 The production of SOA within droplets could result in additional SOA mass being only added to the
466 larger, activated particles during activation/evaporation cycling. This extra SOA mass would favor
467 increases in the diameters of the larger particles of the size-distribution only, which could create a
468 bimodal size distribution and increase the overall coagulation rates in the plume (more, larger
469 particles coagulate more rapidly with the small-diameter particles).

470 Future work includes (1) testing the parameterizations developed in this work against real world
471 observations of size distribution aging, and (2) incorporating the parameterizations into regional and
472 global aerosol models for further evaluation against regional/global measurements.
