20 **Abstract**

21 The WRF-Chem model coupled with a single-layer Urban Canopy Model (UCM) is
22 integrated for 5 years at convection-permitting scale to investigate the individual and combined
23 impacts of urbanization-induced changes in land cover and pollutants emission on regional climate
24 in the Yangtze River Delta (YRD) region in eastern China. Simulations with the urbanization
25 effects reasonably reproduced the observed features of temperature and precipitation in the YRD
26 region. Urbanization over the YRD induces an Urban Heat Island (UHI) effect, which increases
27 the surface temperature by 0.53 °C in summer and increases the annual heat wave days at a rate of
28 3.7 d/yr in the major megacities in the YRD, accompanied by intensified heat stress. In winter, the
29 near-surface air temperature increases by approximately 0.7 °C over commercial areas in the cities
30 but decreases in the surrounding areas. Radiative effects of aerosols tend to cool the surface air by
31 reducing net shortwave radiation at the surface. Compared to the more localized UHI effect,
32 aerosol effects on solar radiation and temperature influence a much larger area, especially
33 downwind of the city-cluster in the YRD.

34 Results also show that the UHI increases the frequency of extreme summer precipitation
35 by strengthening the convergence and updrafts over urbanized areas in the afternoon, which favor
36 the development of deep convection. In contrast, the radiative forcing of aerosols results in a
37 surface cooling and upper atmospheric heating, which enhances atmospheric stability and
38 suppresses convection. The combined effects of the UHI and aerosols on precipitation depend on
39 synoptic conditions. Two rainfall events under two typical but different synoptic weather patterns
40 are further analyzed. It is shown that the impact of urban land-cover and aerosols on precipitation
41 is not only determined by their influence on local convergence, but also modulated by large-scale
42 weather systems. For the case with a strong synoptic forcing associated with stronger winds and

43 larger spatial convergence, the UHI and aerosol effects are relatively weak. When the synoptic
44 forcing is weak, however, the UHI and aerosol effects on local convergence dominate. This
45 suggests that synoptic forcing plays a significant role in modulating the urbanization-induced land-
46 cover and aerosol effects on individual rainfall event. Hence precipitation changes due to
47 urbanization effects may offset each other under different synoptic conditions, resulting in little
48 changes in mean precipitation at longer time scales.

56 **1. Introduction**

57 Urbanization affects climate and hydrological cycle by changing land cover and surface
58 albedo, which releases additional heat to the atmosphere, and by emitting air pollutants, which
59 interact with clouds and radiation (e.g., Shepherd, 2005; Sen Roy and Yuan, 2009; Yang et al.,
60 2011). The most discernible impact of urban land-use change is the urban heat island (UHI) effect
61 that can result in a warmer environment over urban areas than the surrounding areas (Landsberg,
62 1981; Oke, 1987). In addition to the thermal perturbations, the UHI has been well documented to
63 modify wind patterns (Hjemfelt, 1982), evaporation (Wienert and Kuttler, 2005), atmospheric
64 circulations (Shepherd and Burian, 2003; Baik et al., 2007; Lei et al., 2008), and precipitation
65 around urban areas (Braham, 1979; Inoue and Kimura, 2004). Previous studies have found an
66 increase of warm-season precipitation over and downwind of major cities due to the expanded
67 urban land cover (Huff and Changnon, 1972; Changnon, 1979; Zhong et al., 2015). Recent studies
68 suggested that the underlying urban surface also affects the initiation and propagation of storms
69 (Bornstein and Lin, 2000; Guo et al., 2006) and convective activities in city fringes (Baik et al.,
70 2007; Shepherd et al., 2010).

71 Concurrently increases in population and anthropogenic activities over urbanized areas
72 increase pollutant emissions and aerosol loading in the atmosphere. Atmospheric aerosols have
73 long been recognized to affect surface and top of the atmosphere (TOA) radiative fluxes and
74 radiative heating profiles in the atmosphere via aerosol-radiation interactions (ARI) (e.g., Coakley
75 et al., 1987; Charlson et al., 1992; Hansen et al., 1997; Yu et al., 2006; Qian et al., 2006, 2007,
76 2015; McFarquhar and Wang, 2006), which tend to induce cooling near the surface and heating at
77 the low and mid-troposphere (Qian et al., 2006; Bauer and Mennon, 2012). Anthropogenic aerosols
78 can also affect clouds and precipitation via aerosol-cloud interactions (ACI) (e.g., Rosenfeld, 2000,

79 2008; Qian et al., 2010; Fan et al., 2013; 2015; Tao et al., 2012; Zhong et al., 2015). Localized
80 changes in precipitation by strong aerosol perturbations can induce cold pools by evaporation,
81 which may alter the organization of stratocumulus clouds (e.g., Wang and Feingold, 2009;
82 Feingold et al., 2010). Aerosol impacts on deep convective clouds are complicated by the
83 interactions among dynamical, thermodynamical, and microphysical processes. For example, deep
84 convection could be invigorated by aerosols as more cloud water associated with the smaller cloud
85 drops is carried to higher levels where it freezes and releases more latent heat in a polluted
86 environment (Rosenfeld, 2008; Khain, 2009; Storer and van den Heever, 2013). Fan et al. (2013)
87 revealed a microphysical effect of aerosols from reduced fall velocity of ice particles that explains
88 the commonly observed increases in cloud top height and cloud cover in polluted environments.
89 Therefore, urbanization may influence precipitation and circulation through multiple pathways
90 that are more difficult to disentangle than the dominant effect on temperature.

91 As one of the most developed regions in China, the Yangtze River Delta (YRD) has been
92 experiencing rapid economic growth and intensive urbanization process during the past three
93 decades. With the highest city density and urbanization level in China, the YRD has become the
94 largest adjacent metropolitan areas in the world. It covers an area of 9.96×10^4 km², with a total
95 urban area of 4.19×10^3 km² (Hu et al., 2009). Observations have shown that the urban land-use
96 expansion in this region has induced a remarkable warming due to the significant UHI effect (Du
97 et al., 2006; Wu and Yang 2012, Wang et al., 2015). The annual mean warming reached up to
98 0.16°C/10yr based on station measurements in large cities (Ren et al., 2008), which accounted for
99 47.1% of the overall warming during the period of 1961-2000. Urbanization in the YRD was found
100 to destabilize the atmospheric boundary layer (Zhang et al., 2010) and enhance convection and
101 precipitation (Yang et al., 2012, Wan et al., 2013). Meanwhile, human activities associated with

102 the ever-growing population have led to a dramatic increase in air pollutant emissions (Wang et
103 al., 2006). Several observational and numerical studies have revealed that additional aerosol
104 loading in this region could reduce solar radiation reaching the surface (Che et al., 2005; Qian et
105 al., 2006, 2007), modify warm cloud properties (Jiang et al., 2013), and suppress light rainfall
106 events (Qian et al., 2009).

107 The individual effects of urbanization-induced UHI and aerosol emission on local and
108 regional climate have been examined separately in several modeling studies using short
109 simulations of selected weather episodes at high spatial resolution or multiple-year climate
110 simulations at coarse resolution. To more robustly quantify the urbanization-induced UHI and
111 aerosol effects, convection-permitting simulations may reduce uncertainties in representing
112 convection and its interactions with aerosols, which are parameterized in coarse-resolution models.
113 Additionally, multi-year simulations are needed to understand and quantify the overall effects of
114 land-cover change and aerosols in different large-scale environments (Oleson et al., 2008). In this
115 study, a state-of-the-art regional model coupled with online chemistry (WRF-Chem) and a single-
116 layer Urban Canopy Model (UCM) is used to simulate climate features in the YRD region. The
117 climatic effects of the separate and combined land-cover and aerosol changes induced by
118 urbanization are investigated using a set of 5-year (2006-2010) simulations with a horizontal
119 resolution at convection-permitting scale (3 km). The paper is organized as follows. Section 2
120 describes the model configuration, experiment design, and model evaluation. The urbanization
121 effects on extreme temperature and precipitation are presented in Section 3, followed by a
122 summary of the conclusions in Section 4.

123

124 **2. Method**

125 **2.1 Model configuration**

126 The WRF-Chem model (Grell et al., 2005; Fast et al., 2006; Qian et al., 2010) simulates trace
127 gases, aerosols and meteorological fields interactively (Skamarock et al., 2008; Wang et al., 2009),
128 including aerosol-radiation interactions (Zhao et al., 2011, 2013a) and aerosol-cloud interactions
129 (Gustafson et al., 2004). The coupled single-layer UCM (Kusaka et al., 2001; Chen et al., 2001) is
130 a column model that uses a simplified geometry with two-dimensional, symmetrical street canyons
131 to represent the momentum and energy exchanges between the urban surface and the atmosphere.
132 The RADM2 (Regional Acid Deposition Model 2) gas chemical mechanism (Stockwell et al.,
133 1990) and the MADE (Modal Aerosol Dynamics Model for Europe) and SORGAM (Secondary
134 Organic Aerosol Model) aerosol module (Schell et al., 2001) are used. Detailed configuration of
135 the above models can be found in Zhao et al. (2010). No cumulus parameterization is used at the
136 convection-permitting resolution. The physical parameterization schemes used in our simulations
137 are listed in Table 1.

138 **2.2 Numerical experiments**

139 Simulations are performed over a model domain centered at (120.50 °E, 31.00 °N) with a
140 horizontal grid spacing of 3 km and 50 vertical levels extending from the surface to 50 hPa. The
141 lowest 10 model layers are placed below 1 km to ensure a fine vertical resolution within the
142 planetary boundary layer. Initial and boundary conditions for meteorological fields are derived
143 from the National Center for Environmental Prediction (NCEP) FNL global reanalysis data on 1°
144 × 1° grids at 6-hour interval. Lateral boundary conditions for chemistry are provided by a quasi-

145 global WRF-Chem simulation (Zhao et al., 2013b) that includes aerosols transported from regions
146 outside the model domain.

147 The dominant land cover within each model grid cell is derived from the U.S. Geological
148 Survey (USGS) 30 second dataset that includes 24-category land-use type, except that the land use
149 over urban areas is updated using the stable nighttime light product (version 4) at 1 km spatial
150 resolution (available at the National Geophysical Data Center,
151 <http://ngdc.noaa.gov/eog//dmsp/downloadV4composites.html>). Corresponding to the value of
152 lighting index of 25-50, 50-58, and >58 in the above product, each urban grid is identified as “Low
153 Intensity Residential (LIR)”, “High Intensity Residential (HIR)”, or
154 “Commercial/Industrial/Transportation (CIT)”, respectively. Figures 1a and 1b illustrate the urban
155 area within the model domain for year 1970 and 2006, respectively. The anthropogenic heating
156 (AH), characterized by a diurnal cycle with two peaks at rush hours of 0800 and 1700 LST,
157 respectively, is incorporated in the model simulations. The default maximum values of AH in WRF
158 for LIR (20 W m^{-2}), HIR (50 W m^{-2}) and CIT (90 W m^{-2}) are used in this study (Tewari et al.,
159 2007). Anthropogenic emissions of aerosols and their precursors are obtained from the Asian
160 emission inventory (Zhang et al., 2009b), which is a $0.5^\circ \times 0.5^\circ$ gridded dataset for 2006. Black
161 carbon (BC), organic matter (OM), and sulfate emissions over China are extracted from the China
162 emission inventory for 2008 (Lu et al., 2011), which provides monthly mean data on $0.1^\circ \times 0.1^\circ$
163 grids. It should be noted that the Noah land surface model defines a dominant land cover type for
164 each grid, so no subgrid variability is simulated.

165 The anthropogenic emission fluxes of SO_2 and BC in the simulation domain are shown in
166 Figures 1c and 1d, respectively. Areas with large emissions are mainly located in four city clusters,
167 i.e., Nanjing-Zhenjiang-Yangzhou, Suzhou-Wuxi-Changzhou, Shanghai, and Hangzhou Bay, all

168 inside the mega-city belt. Biomass burning emissions for the simulation period are obtained from
169 the monthly Global Fire Emissions Database Version 3 (GFEDv3), which provides monthly mean
170 data on $0.5^\circ \times 0.5^\circ$ grids and the vertical distribution is determined by the injection heights
171 described by Dentener et al. (2006) for the Aerosol Inter-Comparison project (AeroCom). Sea salt
172 and dust emissions are configured following the same approach of Zhao et al. (2013b).

173 In order to investigate the individual responses of local and regional climate to land-cover
174 change and increased aerosol loading, three experiments (i.e., LU06E06, LU70E70, and
175 LU70E06) are conducted for 5 years from 2006 to 2010. The configurations of land use and aerosol
176 emissions for these experiments are summarized in Table 2. All three simulations are performed
177 using the same initial and boundary conditions and physics schemes, but with different land use
178 types and/or anthropogenic emissions. LU06E06 is the control experiment, which represents the
179 “present” (2006) urbanization level for both land use and aerosol/precursor emissions. LU70E06
180 uses the present aerosol emission data but with the land use of the 1970s, which is derived from
181 the USGS dataset without the nighttime light correction. In LU70E70, both land use and emissions
182 are set to the conditions of the 1970s. The differences of LU06E06-LU70E06, LU70E06-
183 LU70E70, and LU06E06-LU70E70 can be used to derive the urban land-use effect, aerosol effect,
184 and their combined effect, respectively (Table 3). The simulations are initialized on December 15
185 of each year during 2005-2009 to allow for a 16-day spin-up time and then continuously integrated
186 for the next year (from January 1 to December 31). Results from January 1 to December 31 of all
187 five years (2006-2010) are analyzed.

188 **2.3 Model evaluation**

189 The surface skin temperature simulated in LU06E06 is averaged over 2006-2010 and
190 compared with the MODIS data. A spatial filtering method described by Wu and Yang (2012) is
191 applied to isolate the heterogeneous climatic forcing of urbanization. More specifically, for each
192 grid a spatial anomaly is defined as the departure from the average value over a region centered at
193 each grid. Then, the moving spatial anomalies are calculated for all the grids with the moving
194 region acting as a filtering window, which has a size of $1^\circ \times 1^\circ$. Figure 2 shows the moving spatial
195 anomalies of mean surface skin temperature from MODIS observations and the L06E06
196 simulation. The simulation captures the spatial distribution of observed surface skin temperature
197 very well. In particular, the warmer centers over highly urbanized areas are well reproduced,
198 despite slight underestimations in some mega cities in Zhejiang Province such as Hangzhou and
199 Ningbo. Shanghai and Su-Xi-Chang exhibit the highest temperatures that are 2°C above the
200 surrounding rural areas.

201 To further validate the model, the baseline simulation LU06E06 is evaluated against
202 meteorological station observations for 2006-2010. Figure 3 shows the averaged near-surface
203 temperature and precipitation from observations and LU06E06. The simulated spatial pattern of
204 near-surface air temperature agrees well with observations, with high temperature centers located
205 at meteorological stations in major cities such as Shanghai and Hangzhou. The simulated
206 temperature displays substantial spatial variability associated with heterogeneity in topography,
207 land cover, and other regional forcings. The model captures the general north-to-south gradient of
208 increasing precipitation in the observations. However, the model overestimates precipitation in
209 Shanghai and central Jiangsu Province but underestimates the precipitation in the southwestern
210 part of the domain.

211

212 **3. Results**

213 **3.1 Urbanization impact on surface temperature, radiation flux and heat waves**

214 **3.1.1 Mean near-surface air temperature**

215 Figure 4 shows the differences in 2-meter near surface air temperature (T2m) among the
216 three experiments to quantify the UHI and aerosol effects from urbanization (Table 3). The UHI
217 effect causes an increase in near-surface temperature over the urbanized area in summer. The
218 average temperature increase is about 0.53 °C over urban area and 1.49 °C in commercial areas
219 outlined by the green contours (see Fig. 4a). In winter, the UHI warming effect occurs primarily
220 in commercial areas, where the mean temperature increases by about 0.7 °C. In areas surrounding
221 the central commercial region, however, temperature decreases due to the urban land-cover change
222 (shown in Fig. 4d). Such a cooling effect in winter has also been found in previous studies (e. g.,
223 Oke, 1982; Jauregui et al., 1992; Wang et al., 2007). The “cool island” effects of urbanization
224 during daytime in winter can be explained by the much larger surface thermal inertia of urban areas
225 than that of rural areas with very low vegetation cover during winter (Wang et al., 2007). Although
226 the wintertime cooling effect in urbanized area is not widely recognized, it is an important
227 phenomenon that is also simulated by the model.

228 The increased aerosols induced by urbanization exert a cooling effect over the entire
229 simulation domain in both summer and winter (Fig. 4b and 4e). On a domain average, the
230 temperature reduction induced by increased aerosols is less than the warming induced by the UHI
231 effect in both seasons. Therefore, the net urbanization impact (including both land-cover change
232 and aerosol increase) on near-surface temperature is dominated by the UHI warming effect (Fig.
233 4c and 4f) resulted from the land-cover change in the YRD.

234 **3.1.2 Surface solar radiation**

235 The effects of urban land-cover change and increased aerosols on surface net shortwave
236 radiation are shown in Fig. 5. As the building clusters reduce surface albedo (Oke, 1987), land-
237 cover change increases the net shortwave radiation over urbanized areas, with an average increase
238 of 9.11 W m^{-2} in summer and 8.49 W m^{-2} in winter. The net increase is greater in summer than in
239 winter because of the stronger summertime incoming solar radiation. On the contrary, aerosols
240 reduce the surface net shortwave radiation in the northern part of the domain corresponding to the
241 larger SO_2 and BC emission rates (Fig. 1), with a magnitude of 8.79 W m^{-2} in summer and 7.63 W
242 m^{-2} in winter. Different from the UHI effect that is more localized, the radiative impact of aerosols
243 is more widespread and significant west of the major urban areas and even over the ocean. Figure
244 6 shows the spatial pattern of mean surface winds simulated in LU70E70 and the difference in
245 column-integrated $\text{PM}_{2.5}$ mass concentration between LU70E06 and LU70E70. Consistent with
246 the prevailing monsoon circulation, southeasterly (northeasterly) flows dominate the YRD in
247 summer (winter), which lead to increases in the $\text{PM}_{2.5}$ concentration over the downwind area of
248 the YRD city clusters. The increased $\text{PM}_{2.5}$ concentrations downwind of the YRD reduce solar
249 radiation to the west (southwest) of the YRD in summer (winter), as shown in Figs. 5b and 5d.
250 Hence aerosol effects on radiation are not limited to the emission source areas in metropolitan
251 regions.

252 **3.1.3 Heat waves**

253 The UHI effect can significantly increase the near-surface temperatures in summer, thereby
254 exacerbating extreme heat waves in urbanized areas (Stone, 2012). By definition, a heat wave
255 occurs when the near-surface temperature reaches or exceeds $35 \text{ }^\circ\text{C}$ for three or more consecutive

256 days (Tan et al., 2004). The averaged heat wave days comparing LU06E06 and LU70E06 increase
257 at a rate of 3.7 d/yr in the major mega cities (Fig. 7a). The increase is most pronounced in Shanghai,
258 with a rate larger than 12 d/yr.

259 High temperature during heat wave contributes to heat exhaustion or heat stroke, but the
260 impact of atmospheric humidity on evaporation is also crucial. Here we use a heat stress index to
261 assess the combined effects of temperature and humidity on human health due to the UHI effect,
262 expressed as (Masterson and Richardson, 1979):

$$263 \quad \text{Humidex} = Ta + (5/9)(e - 10) \quad (1)$$

264 where Ta is near-surface air temperature ($^{\circ}\text{C}$) and e is water vapor pressure (hPa). Figure 7b depicts
265 a big increase in heat stress index (Humidex) over urbanized regions in the YRD, except for the
266 city of Hangzhou. The increase in heat stress index is more accentuated in Shanghai, with a mean
267 increase of 2.16, relative to other urban areas. This suggests that humidity has a larger influence
268 on heat stress in Shanghai because of its proximity to the ocean compared to urban areas further
269 inland. In contrast, increased aerosols have little impact on heat waves (results not shown) because
270 their impacts on near-surface temperature are much weaker (Fig. 4b).

271 **3.2 Urbanization effects on summertime precipitation**

272 **3.2.1 Long-term impact on extreme rainfall**

273 Previous studies have provided evidence of urbanization effect on precipitation distribution
274 in and around urban areas (e.g. Shepherd et al., 2003; Kaufmann et al., 2007; Miao et al., 2010).
275 Several mechanisms have been proposed for the effects of urbanization on precipitation: (1) the
276 UHI effect can destabilize the planetary boundary layer (PBL) and trigger convection; (2)

277 increased surface roughness may enhance atmospheric convergence that favors updrafts; (3)
278 building obstruction tends to bifurcate rainfall systems and delays its propagation; (4) the change
279 in land-cover decreases local evaporation, (5) anthropogenic emissions increase aerosol loading in
280 the atmosphere, with subsequent effects on precipitation through changes in radiation and cloud
281 processes. These mechanisms contribute to positive and negative changes in precipitation, leading
282 to more complicated effects on precipitation than temperature.

283 In this section we analyze the results of the three 5-year simulations to examine the long-
284 term impact of urbanization on precipitation. The results show that influences of both urban land
285 cover and elevated aerosols on annual and seasonal mean precipitation are relatively small (not
286 shown). This may be due to the urbanization effect for different rainfall events offsetting each
287 other, leading to an overall weak effect on a longer time scale (see Section 3.2.2). Here we focus
288 on the frequency of extreme rainfall over the YRD region. Extreme summer rainfall events are
289 defined using hourly precipitation rate that is above 95th percentile at each grid for the period of
290 2006-2010. Figure 8 shows the diurnal cycles of extreme rainfall frequency and urbanization-
291 induced changes in the areas around Nanjing, Shanghai, and Su-Xi-Chang (shown in Fig. 1b). The
292 frequency of hourly extreme rainfall reaches its maximum at around 16:00-17:00 LST over three
293 urban clusters. Urban land-cover change increases the occurrence of extreme precipitation in the
294 afternoon (12:00 to 20:00 LST). The maximum increase in the frequency of extreme hourly rainfall
295 events for Nanjing, Shanghai, and Su-Xi-Chang can reach 0.86%, 1.09%, and 0.79%, respectively,
296 with the peak increase occurring in the late afternoon. On the contrary, aerosols exert an opposite
297 impact to substantially reduce the frequency of extreme rainfall in the afternoon by up to 1.05%,
298 0.75%, and 0.72% for Nanjing, Shanghai, and Su-Xi-Chang, respectively. These impacts are
299 significant compared to the maximum frequency of hourly extreme rainfall of about 10% in each

300 area. However, opposite effects of land-cover and aerosol emission changes result in a small net
301 urbanization effect on extreme precipitation.

302 Because urbanization influences extreme precipitation primarily in the afternoon, we further
303 analyze extreme rainfall events with a focus on the averages from 1200 to 2000 LST. Figure 9
304 shows the substantial increase in extreme precipitation frequency concentrated over the major
305 metropolitan areas in the YRD, with some compensation in the surrounding areas in general.
306 Aerosols, however, reduce the occurrence of extreme precipitation more uniformly in most areas
307 of the domain. The most significant influence of aerosols is found in the northwest part of the
308 domain where aerosol concentrations increase the most downwind of the urban centers (Fig. 6a).
309 Similar to the effects on surface temperature and solar radiation (Figs. 4 and 5), aerosols have a
310 substantial impact on the occurrence of extreme precipitation over a wider area than the effects of
311 urban land-use change.

312 How do changes in land cover and aerosols modulate extreme rainfall frequency? Figure 10a
313 shows the diurnal time-height cross section of the impact of urban land-cover (i.e., the difference
314 between LU06E06 and LU70E06) on temperature and divergence averaged over the three city
315 clusters (Nanjing, Shanghai, and Su-Xi-Chang). Air temperature over the urbanized areas increases
316 significantly in the afternoon (from 1200 to 1800 LST) due to the UHI effect. The warming and
317 the increased roughness length in urban areas favor convergence in the lower atmosphere and
318 divergence above. As a result, the mean updraft increases over the urbanized areas in the afternoon
319 (Fig. 10b), which increases cloud water from the lower to middle troposphere in the afternoon.
320 Shortly before noon, there is a small reduction in low clouds, which may be related to the reduced
321 relative humidity due to warmer temperature and/or reduced evaporation from the urban land
322 cover, the so-called urban dry island effect (e.g., Hage, 1975; Wang and Gong, 2009). The increase

323 in cloud water in the afternoon is consistent with the enhanced updrafts. This mechanism
324 potentially explains the increased frequency of extreme precipitation in urban areas in the
325 afternoon (e.g. Craig and Bornstein, 2002; Rozoff et al., 2003; Wan et al., 2013; Zhong and Yang,
326 2015a, 2015b).

327 To understand the aerosol-induced reduction in extreme rainfall events, we analyze the
328 diurnal cycle of aerosol effect (i.e., the difference LU70E06 and LU70E70) on radiative heating,
329 vertical velocity, and net solar radiation at the surface (Fig. 11). As BC emission rates are relatively
330 high in the YRD region (Fig. 2d), aerosols heat the atmosphere due to absorption of solar radiation
331 during daytime (from 08:00 to 17:00 LST). As a result of absorption and scattering of solar
332 radiation by aerosols, less solar radiation reaches the surface. These changes at the surface and in
333 the atmosphere stabilize the atmosphere and reduce convective intensity in the afternoon (from
334 14:00 to 20:00 LST), which reduces the frequency of extreme rainfall events (Koren et al., 2004;
335 Qian et al., 2006; Zhao et al., 2006; 2011; Fan et al., 2007). Although aerosols can enhance
336 precipitation through cloud microphysical changes that invigorate convection (e.g., Khain et al.,
337 2009; Rosenfeld et al., 2008; Fan et al., 2013), aerosol radiative effects generally dominate in
338 China because of the high AOD and strong light-absorbing aerosol properties (Yang et al., 2011;
339 Fan et al., 2015).

340 **3.2.2 Synoptic influence on urbanization impacts**

341 The impacts of urbanization-induced UHI and aerosols on precipitation may be highly
342 variable under different synoptic conditions that influence the atmospheric circulation and cloud
343 and boundary layer processes. Precipitation changes due to urbanization effects may offset each
344 other under different synoptic conditions, leading to an overall weak effect on mean precipitation

345 at longer time scales as discussed in section 3.2.1. We select two typical heavy late-afternoon
346 rainfall events with different background circulations over the YRD region. Case A occurred from
347 08:00 LST 23 June to 08:00 LST 24 June 2006 and case B occurred from 08:00 LST 1 July to
348 08:00 LST 2 July 2006. Figure 12a and 12d show the mean precipitation rate and 850 hPa winds
349 for case A and case B, respectively. Southwesterly flow dominates the entire region in case A (Fig.
350 12a), while in case B (Fig. 12d) southwesterly and northwesterly winds dominate the southern and
351 northern parts of precipitation area, respectively. The averaged background wind speed in case B
352 is much stronger than that in case A, representing stronger synoptic forcing in case B. The effects
353 of urban land-cover change and aerosols on precipitation for the case A (case B) are illustrated in
354 Figs. 12b and 12c (Figs. 12e and 12f), respectively. Both cases show significant precipitation
355 responses to the forcing of urban land-cover and aerosols. We can see that urban land cover
356 increases the rainfall intensity in case A but aerosols decrease precipitation over the urbanized area
357 (Figs. 12b and 12c). The precipitation response to urban land cover and aerosols is just the opposite
358 in case B (Figs. 12e and 12f). Figs. 13a and 13d illustrate the evolution of precipitation in region
359 R1 (Fig. 12a) and R2 (Fig. 12d), respectively, for the two cases. In both cases, rainfall mainly
360 occurred between 08:00 LST and 20:00 LST. The corresponding impacts of urban land-cover and
361 aerosols are shown in Figs. 13b-c and Figs. 13e-f for cases A and B, respectively. In case A, the
362 urban land-cover substantially increases the precipitation intensity in the afternoon with a
363 maximum increase of 6.87 mm h^{-1} . Aerosol effects, on the contrary, decrease the rainfall intensity
364 with a maximum reduction of 3.85 mm h^{-1} . In case B, however, effects of urban land-cover and
365 enhanced aerosols on precipitation are opposite to that in case A. A maximum rainfall reduction of
366 3.81 mm h^{-1} is found to be associated with the effect of urban land cover and an increase of 2.85
367 mm h^{-1} is associated with the aerosol forcing.

368 Why do urban land-cover and aerosols exert opposite effects on precipitation during the
369 two rainfall events? Here we attempt to answer this question by examining the dynamical and
370 thermodynamical changes induced by the UHI and aerosols using the moisture flux convergence
371 (MFC), which is defined as:

$$372 \quad \text{MFC} = -\nabla \cdot (q\vec{V}_h) = -q\nabla \cdot \vec{V}_h - \vec{V}_h \cdot \nabla q \quad (2)$$

373 The first and second terms on the right hand side of Eq. 2 denote wind convergence (CON) and
374 moisture advection (MA), respectively.

375 Figures 14a and 14b illustrate the time-height cross sections of changes in moisture flux
376 convergence and cloud water mixing ratio induced by land-cover and aerosol changes over the
377 region R1 (Fig. 12a) during the rainy period in case A. Urban land-cover enhances the convergence
378 of moisture fluxes in the lower troposphere, which results in increased precipitation (Fig. 14a). On
379 the contrary, aerosols weaken the convergence of moisture fluxes and thus reduce precipitation
380 (Fig. 14b). These changes are consistent with those associated with extreme rainfall changes shown
381 in Fig. 10. Interestingly for case B over R2, urban land-cover weakens the convergence of moisture
382 fluxes (Fig. 14c) and thus suppresses precipitation (Fig. 13e) from 08:00 LST 1 July to 02:00 LST
383 2 July 2006. Aerosols, however, enhance the convergence of moisture fluxes over R2 (Fig. 14d)
384 and thus increase precipitation (Fig. 13f). These results establish obvious correspondence between
385 moisture flux convergence changes and the precipitation response to urban land cover and aerosols
386 in the two rainfall events and suggest different processes may dominate the moisture flux
387 convergence changes for the two cases.

388 Figure 15 presents the time-height cross section of the changes in the two terms of MFC,
389 i.e., CON (convergence) and MA (moisture advection), induced by land-cover and aerosol changes

390 averaged over R1 (Fig. 12a) for case A and over R2 (Fig. 12d) for case B. Urban land-cover
 391 enhances the wind convergence over R1 in case A (Fig. 15a), leading to an increase in CON by up
 392 to $1.56 \times 10^{-4} \text{ g kg}^{-1} \text{ s}^{-1}$, which is much larger than the increase of $0.61 \times 10^{-4} \text{ g kg}^{-1} \text{ s}^{-1}$ averaged over
 393 R2 (Fig. 15c) in case B. The larger enhancement of convergence in case A is attributed to the strong
 394 UHI-induced surface heating during this rainfall period (figure not shown). In contrast, aerosols
 395 reduce the convergence in both case A and case B due to the aerosol cooling effect near the surface,
 396 as discussed previously (Fig. 11). The reduction of convergence in case A is more significant than
 397 that in case B because of the larger aerosol loading and, therefore, stronger surface cooling over
 398 R1 in case A (not shown). Urban land-cover reduces moisture advection in both cases, with a
 399 maximum decrease of -0.99 and $-1.89 \times 10^{-4} \text{ g kg}^{-1} \text{ s}^{-1}$, respectively. Aerosols, however, increase
 400 moisture advection, and the maximum increases are 0.93 and $1.31 \times 10^{-4} \text{ g kg}^{-1} \text{ s}^{-1}$ in case A and case
 401 B, respectively. Our results show clearly that the changes in CON are opposite to that in MA. As
 402 the impacts of urban land-cover and aerosols on moisture advection are greater in case B than in
 403 case A, the net changes in the moisture flux convergence are dominated by MA in case B and by
 404 CON in case A, leading to opposite effects between the two cases.

405 The significant differences in the responses of MA between the two cases are related to
 406 different background circulations during the two events (Figs. 12a and 12d). Weaker southwesterly
 407 flow dominates the entire region in case A (Fig. 12a), while in case B (Fig. 12d) stronger
 408 southwesterly and northwesterly winds dominate the southern and northern parts of precipitation
 409 area, respectively. The changes in MA could be further decomposed into three terms, as shown
 410 below in Eq. 3:

$$411 \quad -\Delta \mathbf{V} \cdot \nabla \mathbf{q} = -\mathbf{V}_{\text{ctrl}} \cdot \Delta(\nabla \mathbf{q}) - (\nabla \mathbf{q})_{\text{ctrl}} \cdot \Delta \mathbf{V} - \Delta(\nabla \mathbf{q}) \cdot \Delta \mathbf{V} \quad (3)$$

412 The first term on the right-hand side of is associated with the change in water vapor, while
413 the second term is associated with the change in circulation. The third term is a nonlinear term
414 including the contribution of both the moisture and circulation changes. Figure 16 illustrates the
415 changes in the first and second term, respectively. The contribution of the third nonlinear term is
416 small and negligible compared to the other two terms (not shown). Urban land-cover reduces the
417 first term in both cases, with a maximum decrease of -0.34 and $-1.54 \cdot 10^{-4} \text{g kg}^{-1} \text{s}^{-1}$, respectively.
418 Aerosols, however, increase the first term, and the maximum increases are 0.49 and $1.78 \cdot 10^{-4} \text{g kg}^{-1}$
419 s^{-1} in case A and case B, respectively. The urban land-cover and aerosol effects on the second
420 term are quite similar for both cases. Therefore, the most significant difference between these two
421 cases is the change in the first term, which is directly associated with the background circulation.
422 These changes in the first term are much larger in case B because of the stronger background winds
423 than in case A, contributing to a more significant modification in MA as shown in Figure 15.

424 In summary, case B represents stronger synoptic forcing than case A. The stronger winds
425 and larger spatial coverage of clouds and precipitation associated with the larger scale synoptic
426 system weakens the UHI and aerosol effects through ventilation and changes in radiation, resulting
427 in weaker CON and larger MA changes. Conversely, with weaker synoptic forcing, the stronger
428 UHI and aerosol effects enhance the changes in CON while MA effects are smaller due to the
429 weaker background winds. Therefore, our results highlight the distinguishing role of synoptic
430 forcing on how urban land-cover and aerosol influence the dynamical and thermo-dynamical
431 environments and precipitation.

432 **4. Summary**

433 In this study, the state-of-the-art WRF-Chem model coupled with a single-layer UCM, is run
434 at convection-permitting scale to investigate the influences of urbanization-induced land-cover
435 change and elevated aerosol concentrations on local and regional climate in the Yangtze River
436 Delta (YRD) in China. A 5-year period (2006-2010) is selected for multi-year simulations to
437 investigate urbanization effects on extreme events and the role of synoptic forcing. Three
438 experiments were conducted with different configurations of land cover and aerosol emissions: (1)
439 urban land and emissions in 2006, (2) urban land in the 1970s and emissions in 2006, and (3) urban
440 land and emissions in the 1970s. The experiment with the 2006 land-use type and anthropogenic
441 emissions reproduces the observed spatial patterns of near-surface air temperature and
442 precipitation fairly well.

443 The expanded urban land cover and increased aerosols have opposite impacts on the near-
444 surface air temperature. The urban land-use change increases 2-m air temperature due to the UHI
445 effect in commercial areas with a domain-averaged increase of 1.49 °C in summer and 0.7 °C in
446 winter. In the surrounding areas, however, surface air temperature increases in summer but
447 decreases in winter. The latter is attributed to the much greater thermal inertia over urban areas
448 than over rural areas in wintertime when both vegetation cover and soil moisture are at their
449 seasonal minimum. Compared to the effect of land-cover change, aerosol effect exerts a less
450 significant influence on near-surface temperature with minor decreases in both summer and winter.
451 Overall, the impact of urban land-use change outweighs that of enhanced aerosols on regional
452 temperature especially in summer. The increase in near-surface temperature induced by the UHI
453 effect leads to an increase in heat wave days by 3.7 days per year over the major mega cities in the
454 YRD region. The greater response of solar radiation to urban land-cover in summer is the major
455 factor contributing to the larger changes in surface temperature in summer than in winter.

456 Compared to the urban land-use effect, aerosol effect on reducing the surface solar radiation occurs
457 over a much broader region including the downwind area of the city clusters.

458 The urban land-cover change and increased aerosols have opposite effects on the frequency
459 of extreme rainfall during summer. The UHI effect leads to more frequent extreme precipitation
460 over the urbanized area in the afternoon because of an enhanced near-surface convergence and
461 vertical motion. In contrast, aerosol tends to decrease the frequency of extreme precipitation
462 because of its cooling effect near the surface and heating effect (by light-absorbing particles)
463 above, leading to an increased atmospheric stability and weakened updrafts. Additional aerosols
464 can also induce decreases in the frequency of extreme precipitation over non-urban areas,
465 particularly in the downwind area of the city clusters.

466 The effects of both urban land-cover and increased aerosols on summertime rainfall vary
467 with synoptic weather systems and environmental conditions. Two late-afternoon rainfall events
468 are selected for in-depth analysis. For the two cases, urbanization exerts similar impacts on local-
469 scale convergence and mean wind speed, which modify the strength of moisture transport. More
470 specifically, the effect of urban land-cover increases local-scale convergence due to the UHI-
471 induced circulation and reduces low-level wind speed, while aerosols have an opposite effect due
472 to the cooling near the surface. We found that the impacts of urban land-cover and aerosol on
473 precipitation are determined not only by their effect on local-scale convergence, but also
474 modulated by the large-scale weather systems. Our analyses suggest that synoptic forcing plays a
475 significant role in how urbanization-induced land-cover and aerosols influence individual rainfall
476 event. Although the two rainfall events selected for the analysis do not represent all types of
477 precipitation events in the YRD Region, they demonstrate how the effect of urbanization on
478 precipitation may vary and offset each other under different synoptic conditions, leading to an

479 overall weak effect on mean precipitation at longer time scales. To further quantify urbanization
480 effects, uncertainties in anthropogenic emissions and heating, unresolved urban building and
481 streets structure, and representation in aerosol-cloud interactions and cloud microphysics in the
482 model should be investigated in future studies. Further investigation is also needed to have a better
483 and more comprehensive understanding of the complicated mechanisms through which
484 urbanization influences heavy rainfall under a full range of weather conditions.

719 **Table and Figure Captions**

720 **Table 1** Configurations of the WRF physics schemes used in the present study.

721 **Table 2** Numerical experiments and corresponding urban land use and aerosol emissions.

722 **Table 3** Analysis strategies for the investigation of urban land-use and/or aerosol effects.

723 **Figure 1** Land-use categories for year (a) 1970; (b) 2006; and (c) SO₂ (units: mol km⁻² h⁻¹) and (d)
724 black carbon (BC) emission rates (units: ug m⁻² s⁻¹) averaged over 2006-2010. Surface topography
725 is also shown in Fig. 1a (contour; units: m). The boxes in Fig. 1b outline three mega-city clusters
726 of Nanjing, Su-Xi-Chang, and Shanghai.

727 **Figure 2** Moving spatial anomalies of averaged surface skin temperature (units: °C) with a filtering
728 window size of 1° ×1° for (a) MODIS observation and (b) the L06E06 simulation. The “High
729 Intensity Residential” and “Commercial/Industrial/Transportation” areas are marked with green
730 lines and yellow lines, respectively.

731 **Figure 3** Annual mean (a) near-surface temperature (units: °C) and (b) precipitation (units: mm d⁻¹)
732 from observations (shaded circles) and the LU06E06 simulation (shaded).

733 **Figure 4** Differences in mean 2-m temperature (Units: °C) between simulations (a, d) LU06E70
734 and LU70E70, (b, e) LU70E06 and LU70E70, (c, f) LU06E06 and LU70E70 for summer (upper
735 panels) and winter (bottom panels). “Commercial/Industrial/Transportation” areas are marked with
736 green lines. The black dots mark the area with statistically significant changes.

737 **Figure 5** Differences in net shortwave fluxes at the surface (units: W m^{-2}) between simulations (a,
738 c) LU06E70 and LU70E70, and (b, d) LU70E06 and LU70E70 in summer (upper panels) and
739 winter (bottom panels).

740 **Figure 6** Differences in column burden of PM_{2.5} (g m^{-2}) between simulations LU70E06 and
741 LU70E70, superimposed with near-surface winds simulated in LU70E70, for (a) summer and (b)
742 winter.

743 **Figure 7** Differences in mean summertime (a) heat wave days (units: d/yr) and (b) heat stress
744 (units: $^{\circ}\text{C}$) between simulations LU06E70 and LU70E70.

745 **Figure 8** Diurnal cycles of the frequency of summertime extreme rainfall events for LU70E70
746 (defined using hourly precipitation intensity above 95th percentile, black lines, right axis) and the
747 differences between simulations over (a) Nanjing, (b) Shanghai, and (c) Su-Xi-Chang. Red lines
748 are for Land use effect, blue lines for Aerosol effect, and green lines for the combined effect.

749 **Figure 9** Differences in the frequency of summertime extreme rainfall events (averaged from
750 12:00 to 20:00 LST) between simulations (a) LU06E70 and LU70E70, and (b) LU70E06 and
751 LU70E70.

752 **Figure 10** (a) Time-height cross-sections of differences (between LU06E70 and LU70E70) in
753 temperature (contour; units: $^{\circ}\text{C}$) and divergence (shade; units: 10^{-5} s^{-1}) averaged over the three city
754 clusters (Nanjing, Shanghai, and Su-Xi-Chang); (b) same as (a), but for vertical velocity (shade;
755 units: 10^{-2} m s^{-1}) and cloud water mixing ratio (contour; $10^{-3} \text{ kg kg}^{-1}$).

756 **Figure 11** Time-height cross-sections of differences between LU70E06 and LU70E70 in radiative
757 heating profile (shade; units: K d^{-1}), vertical velocity (contour; units: 10^{-2} m s^{-1}) and surface solar

758 radiation (blue bars; units: W m^{-2}) averaged over the three city clusters (Nanjing, Shanghai, and
759 Su-Xi-Chang).

760 **Figure 12** Rain rate (units: mm h^{-1}) superimposed with wind vectors at 850 hPa for case A from
761 08:00 LST 23 June to 08:00 LST 24 June 2006 (a) simulated in the LU06E06 simulation, (b)
762 differences between LU06E70 and LU70E70, (c) differences between LU70E06 and LU70E70.
763 Panels (d-f) are the same as (a-c) but for case B from 08:00 LST 1 July to 08:00 LST 2 July 2006.
764 The boxes R1 in (a) and R2 in (d) outline the three regions over which further analysis are
765 conducted. Lines across the center of each box mark the cross-sections to be analyzed.

766 **Figure 13** The time evolution of precipitation (units: mm h^{-1}) along the line *ab* (marked in Fig.
767 12a) from 08:00 LST 23 June to 02:00 LST 24 June 2006 (case A) (a) simulated in the LU06E06
768 simulation, (b) differences between LU06E70 and LU70E70, (c) differences between LU70E06
769 and LU70E70. Panels (d-f) are the same as (a-c) but for case B along line *cd* (marked in Fig. 12d)
770 from 08:00 LST 1 July to 02:00 LST 2 July 2006.

771 **Figure 14** The time-height cross-sections of differences in moisture flux convergence (shaded;
772 units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) and water vapor mixing ratio (black lines; units: $10^{-2} \text{ g kg}^{-1}$) from 08:00 LST
773 23 June to 02:00 LST 24 June 2006 (case A) over region R1 (denoted in Fig. 12a) between (a)
774 LU06E70 and LU70E70; (b) LU70E06 and LU70E70; Panels (c, d) are the same as (a, b) but for
775 case B from 08:00 LST 1 July to 02:00 LST 2 July 2006 over R2 (denoted Fig. 12d).

776 **Figure 15** Same as Fig. 14 but for differences in the CON term (shaded; units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) and
777 MA term (black lines; units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) in eq. (2).

778 **Figure 16** Same as Fig. 15 but for differences in the first term $(-\mathbf{V}_{\text{ctrl}} \cdot \Delta(\nabla q))$ (shaded; units: 10^{-4}
779 $\text{g}^{-1} \text{kg}^{-1} \text{s}^{-1}$) and the second term $(-\nabla q)_{\text{ctrl}} \cdot \Delta \mathbf{V}$ (black lines; units: $10^{-4} \text{g}^{-1} \text{kg}^{-1} \text{s}^{-1}$) in Eq.3.

Table 1 Configurations of the WRF physics schemes used in the present study.

Physical processes	Parameterization Scheme
Microphysics	Morrison 2-moment scheme (Morrison et al., 2009)
Long-wave radiation	RRTMG scheme (Iacono et al., 2008)
Short-wave radiation	RRTMG scheme
Surface layer	Monin-Obukhov scheme (Monin and Obukhov, 1954)
Land surface process	Noah land-surface model (Chen et al., 1996; Chen and Dudhia, 2001)
Planetary boundary layer process	Mellor-Yamada-Jajic TKE scheme (Mellor and Yamada, 1982; Janjic, 2001)

Table 2 Numerical experiments and corresponding urban land use and aerosol emissions.

Experiment	Land-use category	Anthropogenic emissions
LU06E06	2006	2006
LU70E06	1970	2006
LU70E70	1970	1970

Table 3 Analysis strategies for the investigation of urban land-use and/or aerosol effects.

Difference	Mechanism
LU06E06- LU70E06	Urban
LU70E06- LU70E70	Aerosol
LU06E06- LU70E70	Urban and aerosol

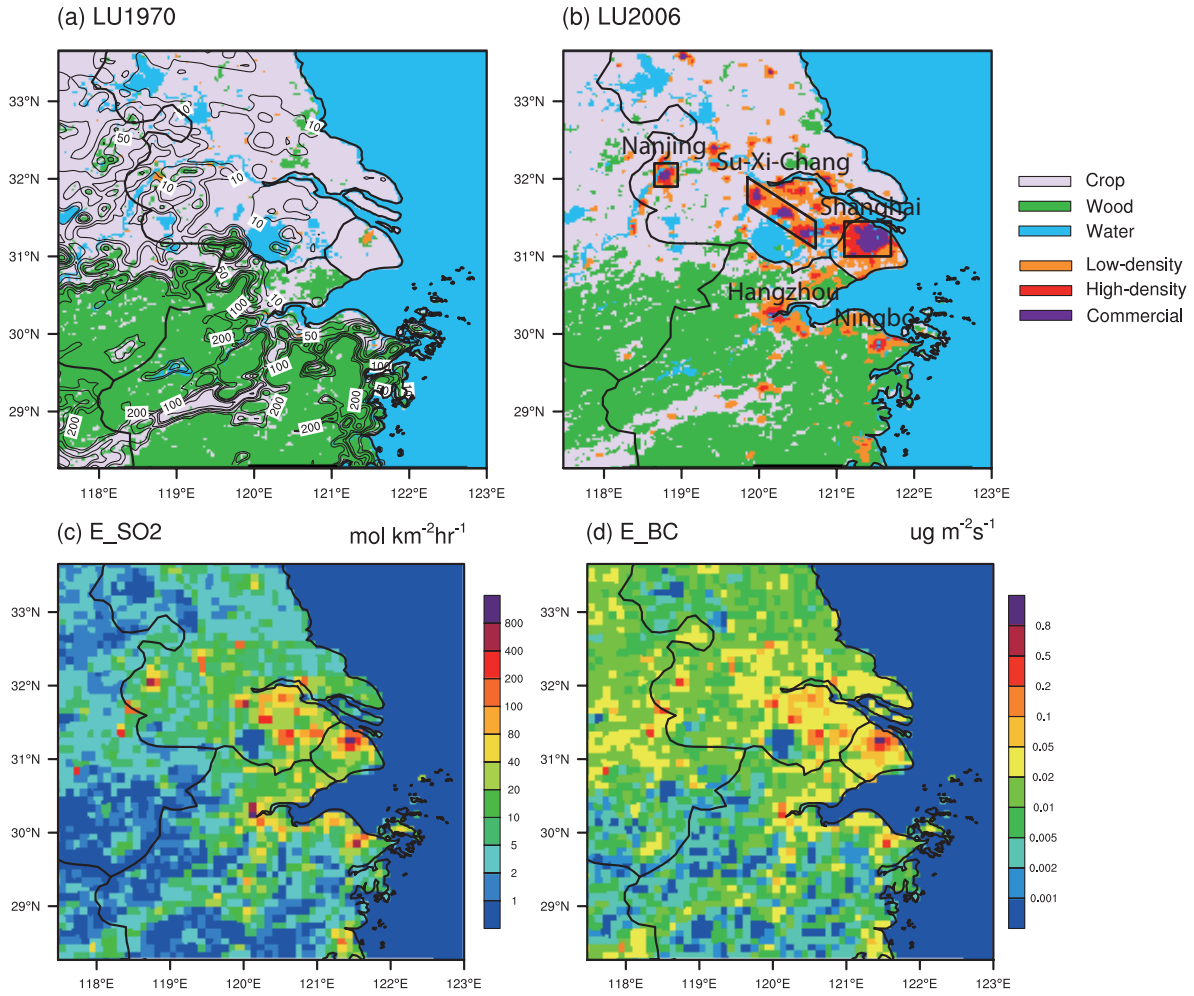

Figure 1 Land-use categories for year (a) 1970; (b) 2006; and (c) SO₂ (units: mol km⁻² h⁻¹) and (d) black carbon (BC) emission rates (units: ug m⁻² s⁻¹) averaged over 2006-2010. The topography is also shown in Fig. 1a (contour; units: m). The boxes in Fig. 1b outline three mega-city clusters of Nanjing, Su-Xi-Chang, and Shanghai.

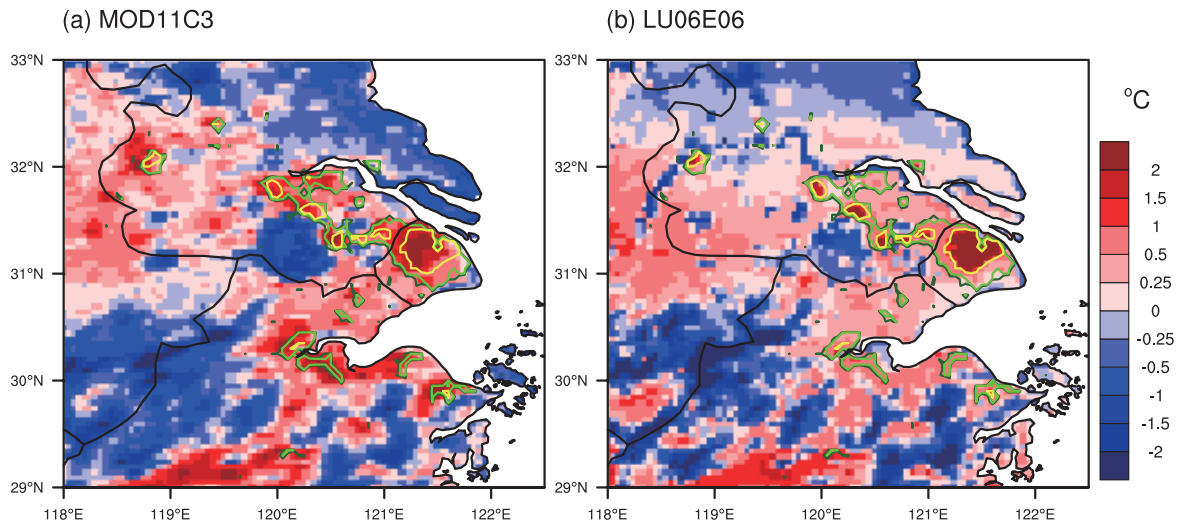

Figure 2 Moving spatial anomalies of averaged surface skin temperature (units: °C) with a filtering window size of $1^{\circ} \times 1^{\circ}$ for (a) MODIS observation and (b) the L06E06 simulation. The “High Intensity Residential” and “Commercial/Industrial/Transportation” areas are marked with green lines and yellow lines, respectively.

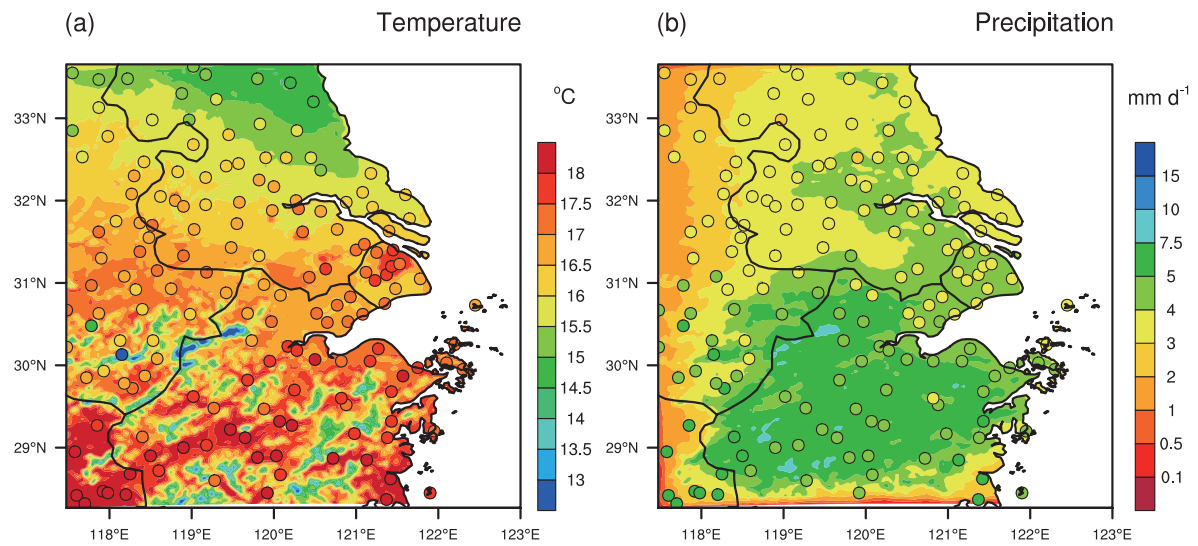

Figure 3 Annual mean (a) near-surface temperature (units: °C) and (b) precipitation (units: mm d⁻¹) from observations (shaded circles) and simulation of the LU06E06 (shaded).

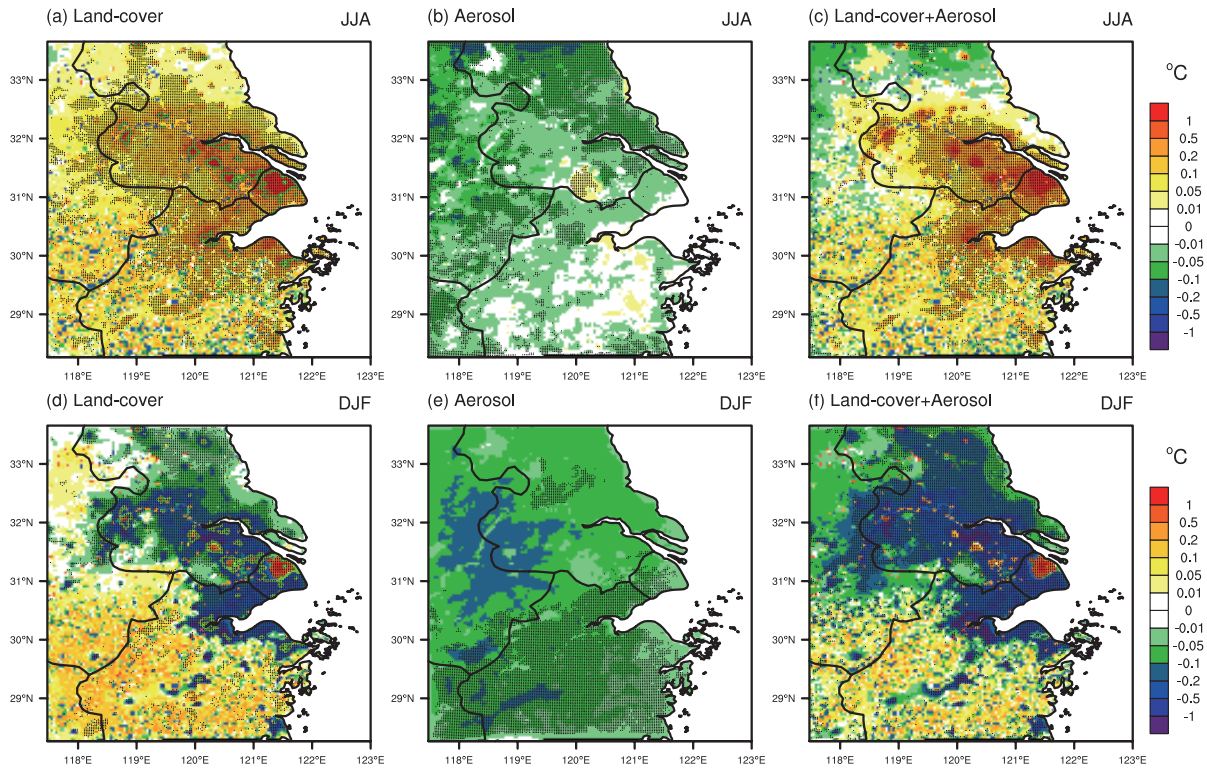

Figure 4 Differences in mean 2-m temperature (Units: °C) between simulations (a, d) LU06E70 and LU70E70, (b, e) LU70E06 and LU70E70, (c, f) LU06E06 and LU70E70 for summer (upper panels) and winter (bottom panels). “Commercial/Industrial/Transportation” areas are marked with green lines. The black dots mark the area with statistically significant changes.

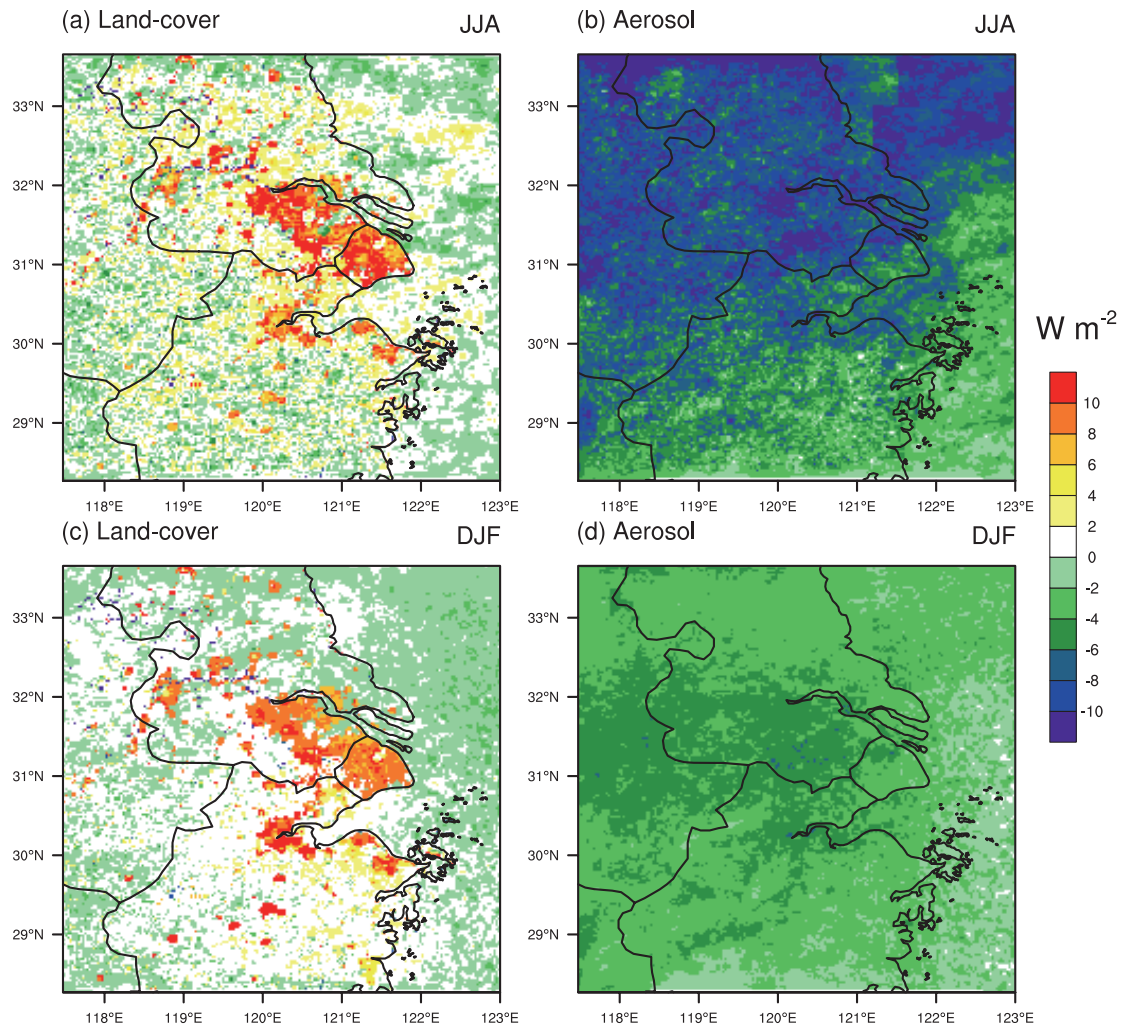

Figure 5 Differences in net shortwave fluxes at the surface (units: $W m^{-2}$) between simulations (a, c) LU06E70 and LU70E70, and (b, d) LU70E06 and LU70E70 in summer (upper panels) and winter (bottom panels).

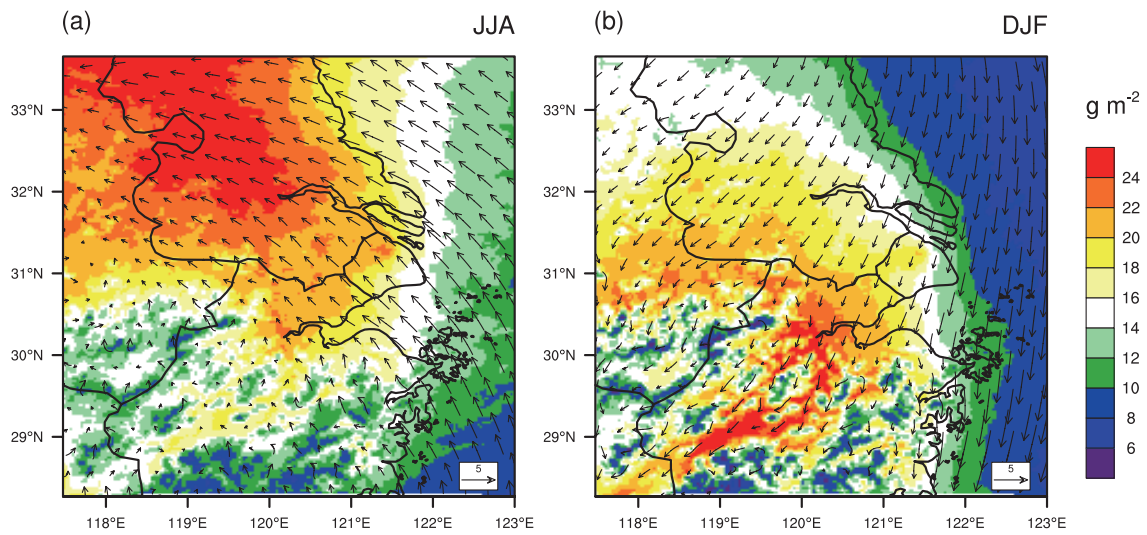

Figure 6 Differences in column burden of PM2.5 (g m^{-2}) between simulations LU70E06 and LU70E70, superimposed with near-surface winds simulated in LU70E70, for (a) summer and (b) winter.

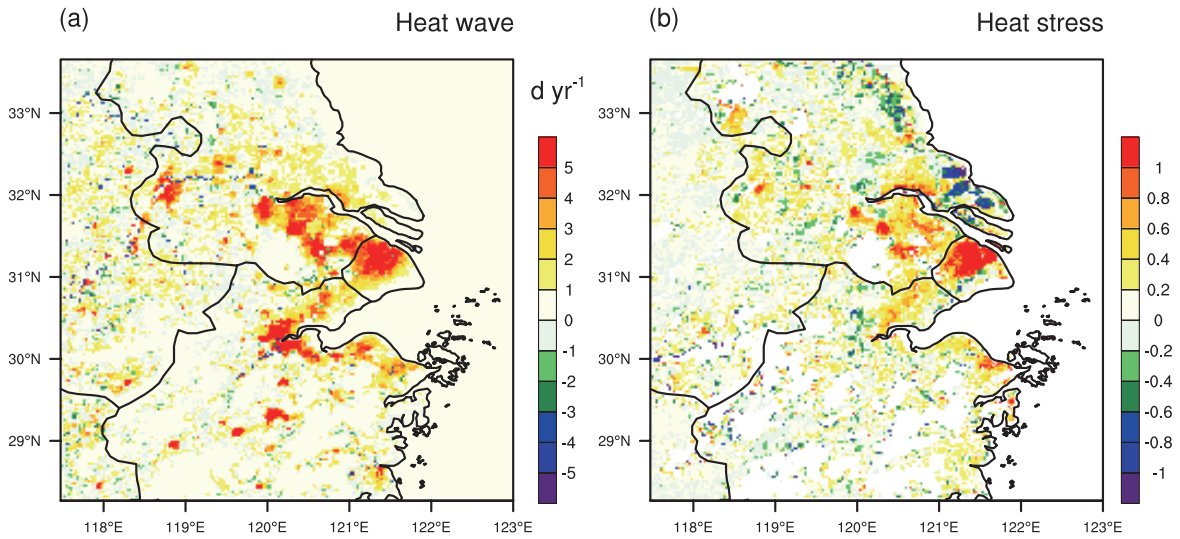

Figure 7 Differences in mean summertime (a) heat wave days (units: d/yr) and (b) heat stress (units: $^{\circ}C$) between simulations LU06E70 and LU70E70.

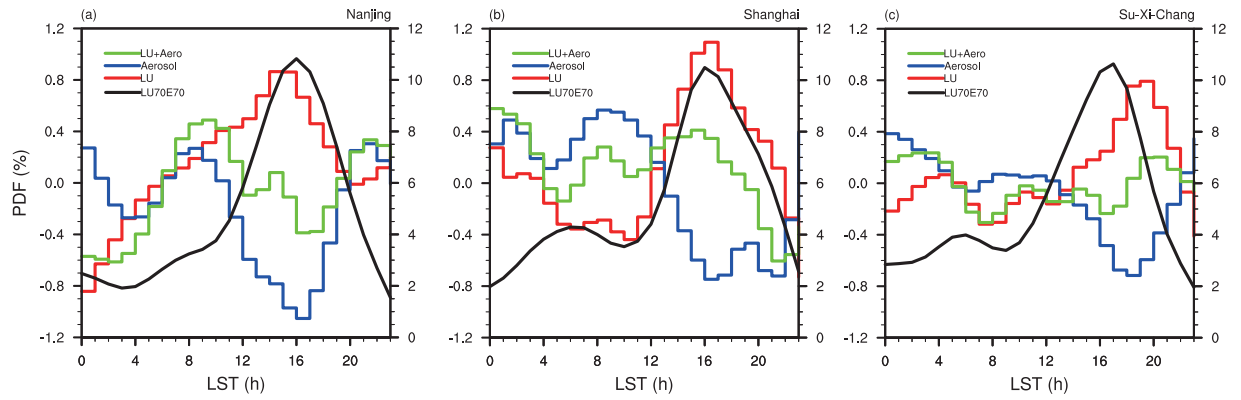

Figure 8 Diurnal cycles of the frequency of summertime extreme rainfall events for LU70E70 (defined using hourly precipitation intensity above 95th percentile, black lines, right axis) and the differences between simulations over (a) Nanjing, (b) Shanghai, and (c) Su-Xi-Chang. Red lines are for land use effect, blue lines for aerosol effect, and green lines for the combined effect.

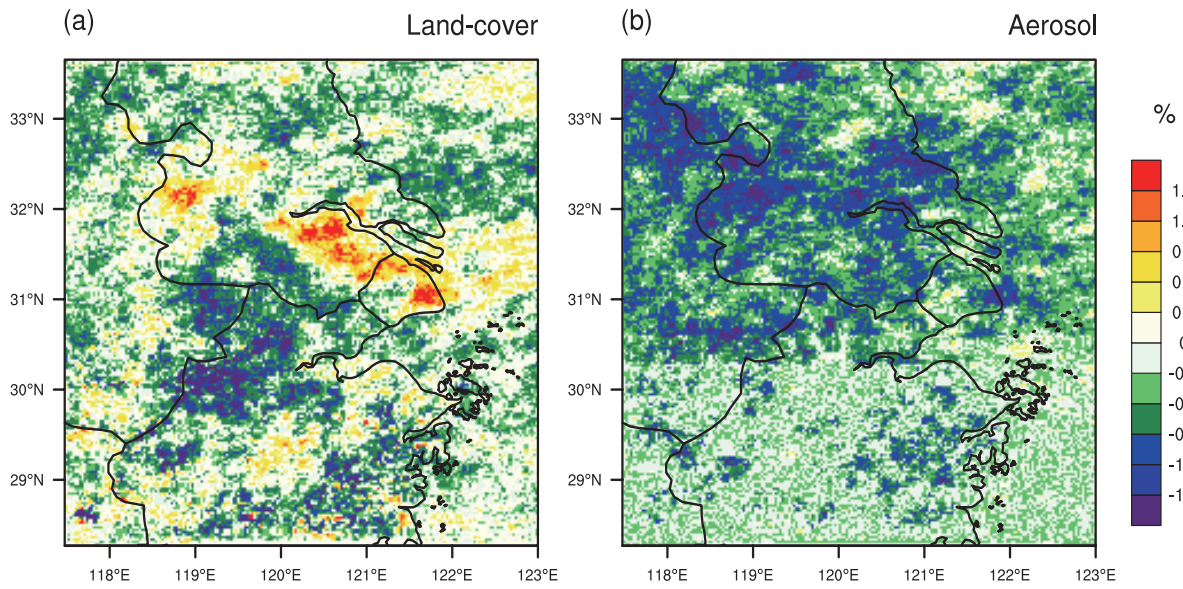

Figure 9 Differences in the frequency of summertime extreme rainfall events (averaged from 12:00 to 20:00 LST) between simulations (a) LU06E70 and LU70E70, and (b) LU70E06 and LU70E70.

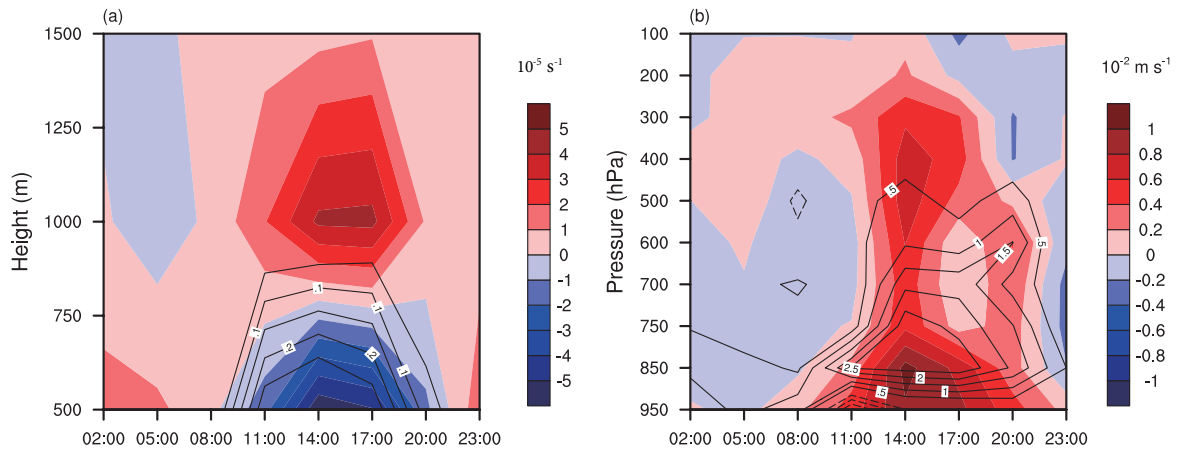

Figure 10 (a) Time-height cross-sections of differences (between LU06E70 and LU70E70) in temperature (contour; units: $^{\circ}\text{C}$) and divergence (shade; units: 10^{-5} s^{-1}) averaged over the three city clusters (Nanjing, Shanghai, and Su-Xi-Chang); (b) same as (a), but for vertical velocity (shade; units: 10^{-2} m s^{-1}) and cloud water mixing ratio (contour; $10^{-3} \text{ kg kg}^{-1}$).

Figure 11 Time-height cross-sections of differences (between LU70E06 and LU70E70) in radiative heating profile (shade; units: K d^{-1}), vertical velocity (contour; units: 10^{-2} m s^{-1}) and surface solar radiation (blue bars; units: W m^{-2}) averaged over the three city clusters (Nanjing, Shanghai, and Su-Xi-Chang).

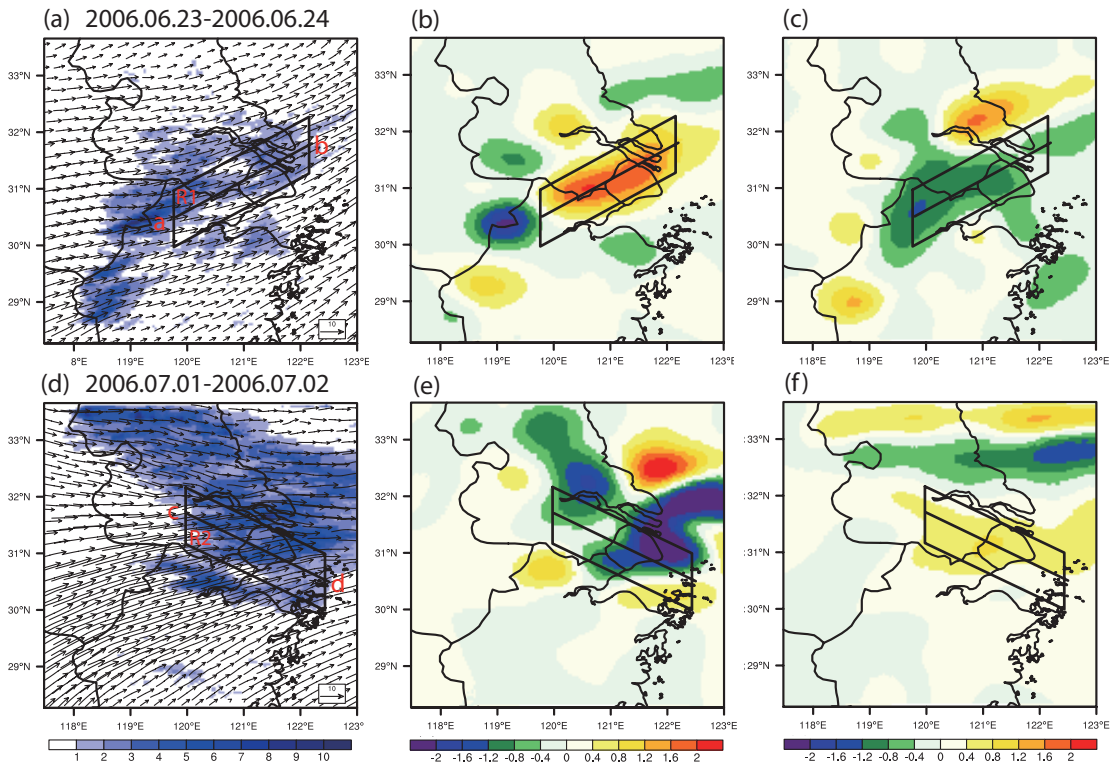

Figure 12 Rain rate (units: mm h⁻¹) superimposed with wind vectors at 850 hPa for case A from 08:00 LST 23 June to 08:00 LST 24 June 2006 (a) simulated in the LU06E06 simulation, (b) differences between LU06E70 and LU70E70, (c) differences between LU70E06 and LU70E70. Panels (d-f) are the same as (a-c) but for case B from 08:00 LST 1 July to 08:00 LST 2 July 2006. The boxes R1 in (a), R2 in (d) outline the three regions over which further analysis are conducted. Lines across the center of each box mark the cross-sections to be analyzed.

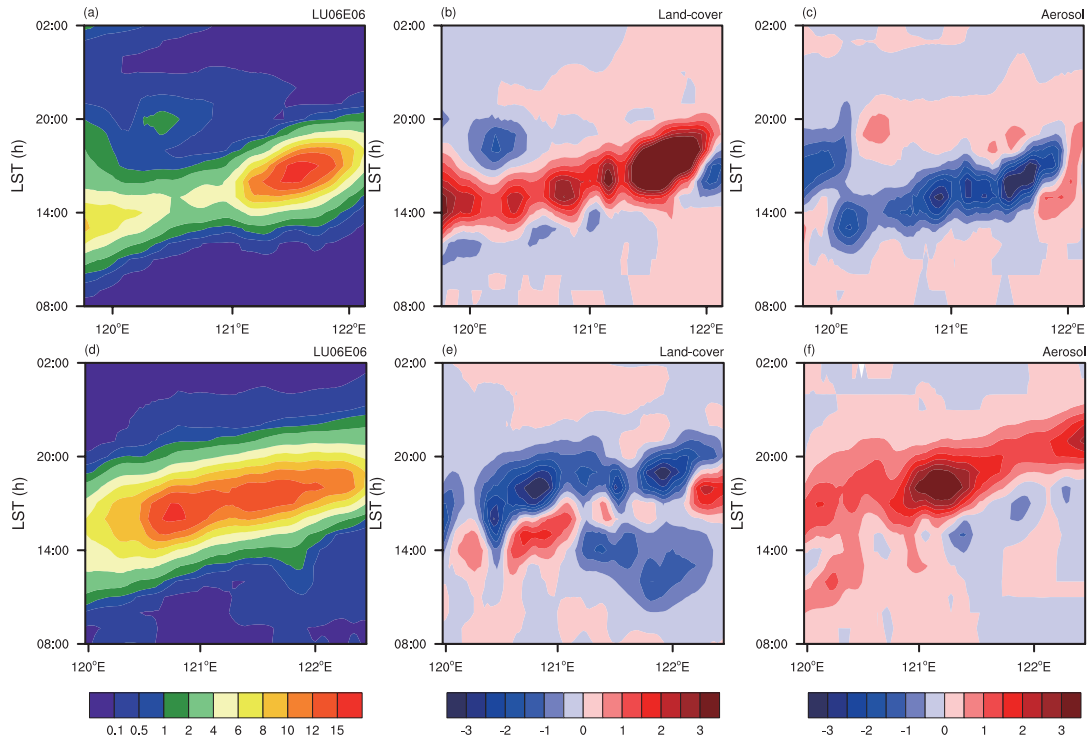

Figure 13 The time evolution of precipitation (units: mm h^{-1}) along the line *ab* (marked in Fig. 12a) from 08:00 LST 23 June to 02:00 LST 24 June 2006 (case A) (a) simulated in the LU06E06 simulation, (b) differences between LU06E70 and LU70E70, (c) differences between LU70E06 and LU70E70. Panels (d-f) are the same as (a-c) but for case B along line *cd* (marked in Fig. 12d) from 08:00 LST 1 July to 02:00 LST 2 July 2006.

Figure 14 Time-height cross-sections of differences in moisture flux convergence (shaded; units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) and water vapor mixing ratio (black lines; units: $10^{-2} \text{ g kg}^{-1}$) from 08:00 LST 23 June to 02:00 LST 24 June 2006 (case A) over region R1 (denoted in Fig. 12a) between (a) LU06E70 and LU70E70; (b) LU70E06 and LU70E70; Panels (c, d) are the same as (a, b) but for case B from 08:00 LST 1 July to 02:00 LST 2 July 2006 over R2 (denoted in Fig. 12d).

Figure 15 Same as Fig. 14 but for differences in the CON term (shaded; units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) and MA term (black lines; units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) in eq. (2).

Figure 16 Same as Fig. 15 but for differences in the first term ($-V_{\text{ctrl}} \cdot \Delta(\nabla q)$) (shaded; units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) and the second term ($-(\nabla q)_{\text{ctrl}} \cdot \Delta V$) (black lines; units: $10^{-4} \text{ g}^{-1} \text{ kg}^{-1} \text{ s}^{-1}$) in Eq.3.
