18 Highlights:

- 19 1. The WRF-Chem simulation successfully captures aerosol variations in the cold season in the  
20 San Joaquin Valley (SJV), but has poor performance in the warm season.
- 21 2. High resolution model simulation can better resolve inhomogeneous distribution of  
22 anthropogenic emissions in urban areas, resulting in better simulation of aerosols in the cold  
23 season in the SJV.
- 24 3. Observations show that dust is a major component of aerosols in the SJV, especially in the  
25 warm season. Poor performance of the WRF-Chem model in the warm season is mainly due  
26 to misrepresentation of dust emission and vertical mixing.

## 27 **Abstract**

28 WRF-Chem simulations of aerosol seasonal variability in the San Joaquin Valley (SJV),  
29 California are evaluated by satellite and in-situ observations. Results show that the WRF-Chem  
30 model successfully captures the distribution, magnitude and variation of SJV aerosols during the  
31 cold season. However, aerosols are not well represented in the warm season. Aerosol simulations  
32 in urban areas during the cold season are sensitive to model horizontal resolution, with better  
33 simulations at 4 km resolution than at 20 km resolution, mainly due to inhomogeneous distribution  
34 of anthropogenic emissions and better represented precipitation in the 4 km simulation. In rural  
35 areas, the model sensitivity to grid size is rather small. Our observational analysis reveals that dust  
36 is a primary contributor to aerosols in the SJV, especially during the warm season. Aerosol  
37 simulations in the warm season are sensitive to parameterization of dust emission in WRF-Chem.  
38 The GOCART (Goddard Global Ozone Chemistry Aerosol Radiation and Transport) dust scheme  
39 produces very little dust in the SJV while the DUSTRAN (DUST TRANsport model) scheme  
40 overestimates dust emission. Vertical mixing of aerosols is not adequately represented in the model  
41 based on CALIPSO (Cloud-Aerosol Lidar and Infrared pathfinder Satellite Observation) aerosol  
42 extinction profiles. Improved representation of dust emission and vertical mixing in the boundary  
43 layer are needed for better simulations of aerosols during the warm season in the SJV.

44

## 45 **1. Introduction**

46           The San Joaquin Valley (SJV) in the southern portion of the California Central Valley is  
47 surrounded by coastal mountain range to the west and the Sierra Nevada range to the east. With  
48 cool wet winters and hot dry summers, the unique natural environment makes SJV one of the most  
49 productive agricultural regions in the world (SJV APCD, 2012 and references therein). However,  
50 SJV is also one of the most polluted regions in US due to its unique geographical location. Frequent  
51 stagnant weather systems are conducive to air pollution formation, while the surrounding  
52 mountains block air flow and trap pollutions. Large seasonal and spatial variation of aerosol  
53 occurrence and distribution are observed in the SJV. Although significant progress made to  
54 improving local air quality in past decades has been achieved through strong emission controls,  
55 PM<sub>2.5</sub> (particulate matter with diameter  $\leq 2.5 \mu\text{m}$ ) concentrations in the SJV remain well above  
56 the national ambient air quality standards (NAAQS) threshold of  $12 \mu\text{g m}^{-3}$  on an annual basis and  
57  $35 \mu\text{g m}^{-3}$  on daily basis, occurring mainly during the cold season. Improved understanding of the  
58 aerosol variability and impacts is needed to provide further guidance for emission control strategies  
59 in the SJV.

60           Air quality models are a useful tool to understanding the formation and evolution of  
61 aerosols and their impacts on air quality, weather and climate. However, it is quite challenging to  
62 accurately simulate aerosol properties (Fast et al., 2014). Fast et al. (2014) summarized the factors  
63 contributing to the errors in regional-scale modeling of aerosol properties. They include 1)  
64 emission sources; 2) meteorological parameterizations; 3) representation of aerosol chemistry; 4)  
65 limited understanding of the formation processes of secondary organic aerosol (SOA); 5) spatial  
66 resolution; and 6) boundary conditions.

67           As one of the advanced regional air quality models available presently to the community,  
68 the Weather Research and Forecasting model with Chemistry (WRF-Chem) has been widely used  
69 to study aerosols and their impacts on regional air quality, weather and climate (e.g., Misenis and  
70 Zhang, 2010; Zhang et al., 2010; Zhao et al., 2010; 2013a, 2013b; 2014; Wu et al., 2011a, 2011b,  
71 2013; Fast et al., 2012, 2014; Scarino et al., 2014; Tessum et al., 2015; Campbell et al., 2016; Hu  
72 et al., 2016). For example, Fast et al. (2014) showed that WRF-Chem simulations at 4 km  
73 horizontal resolution captured the observed meteorology and boundary layer structure over  
74 California in May and June of 2010 and the spatial and temporal variations of aerosols were  
75 reasonably simulated. Aerosol simulations by WRF-Chem are usually sensitive to both local  
76 emission and long-range transport of aerosols from the boundary conditions provided by the global  
77 Model for Ozone and Related chemical Tracers, version 4 (MOZART-4). With a similar model  
78 set-up, Zhao et al. (2013b) conducted a one-year simulation at 12 km horizontal resolution and  
79 found that the WRF-Chem model represented the observed seasonal and spatial variation of  
80 surface particulate matter (PM) concentration over California. However, underestimation of  
81 elemental carbon (EC) and organic matter (OM) were noticed in the model simulation, with weak  
82 sensitivity to horizontal resolution.

83           In this study, we focus on simulating aerosol seasonal variability in the SJV, California  
84 using similar model configurations as that used in Zhao et al. (2013b) and Fast et al. (2014). This  
85 paper serves as the first step for future investigation of the aerosol impact on regional climate and  
86 the water cycle in California. Previous studies have demonstrated that aerosols are better simulated  
87 at higher model resolution (Misenis and Zhang et al., 2010; Qian et al., 2010; Stround et al., 2011;  
88 Fountoukis et al., 2013). However, most regional climate studies are still performed with coarse  
89 model resolutions (on the order of 10 km) due to the availability of computational resources. This

90 study will investigate the sensitivity of aerosol simulations to horizontal resolution and identify  
91 optimal model physical choices for reasonable representation of aerosol variabilities in the SJV.

92 Another application of air quality modeling is to provide initial *a priori* fields for remote  
93 sensing retrievals. The WRF-Chem model has been proposed as an input for retrieval algorithms  
94 to be developed for the recently-selected NASA (National Aeronautics and Space Administration)  
95 MAIA (Multi-Angle Imager for Aerosols) mission, which aims to map PM component  
96 concentrations in major urban areas (including the SJV, a testbed for the MAIA retrieval algorithm  
97 development). A significant challenge for aerosol remote sensing in retrieving spatial information  
98 on specific aerosol types, especially near the surface, is caused by the lack of information on the  
99 vertical distribution of aerosols in the atmospheric column and limited instrument sensitivity to  
100 aerosol types over land. The WRF-Chem model will be used to provide near-real-time estimation  
101 of particle properties, aerosol layer heights, and aerosol optical depths (AOD) to constrain the  
102 instrument-based PM retrievals. A reasonable estimate of aerosol properties from WRF-Chem is  
103 critical to ensuring retrieval speed and quality. Considering the sensitivity of WRF-Chem  
104 simulations to various factors such as initial and boundary conditions, model parameterizations  
105 and emission sources (e.g., Wu and Petty, 2010; Zhao et al., 2010, 2013a, 2013b; Wu et al., 2011a,  
106 2015; Fast et al., 2014; Campbell et al., 2016; Morabito et al., 2016), careful model evaluations  
107 are needed before the simulations can be used operationally for remote sensing retrievals. Thus,  
108 this study is important for the development of MAIA retrieval algorithms, critical to the success  
109 of the MAIA mission.

110 This paper is organized as follows. Section 2 describes observational datasets used for  
111 model evaluation. Section 3 provides the description of the WRF-Chem model and experiment

112 setup. Model simulations and their comparison with observations are discussed in section 4.  
113 Section 5 presents the conclusions.

## 114 **2. Observations**

### 115 **2.1 Column-integrated Aerosol Optical Properties**

116 AOD is a measure of column-integrated light extinction by aerosols and a proxy for total  
117 aerosol loading in the atmospheric column. The Aerosol Robotic Network (AERONET) provides  
118 ground measurements of AOD every 15 minutes during daytime under clear skies (Holben et al.,  
119 1998), with an accuracy approaching  $\pm 0.01$  (Eck et al., 1999; Holben et al., 2001; Chew et al.,  
120 2011). The monthly level 2.0 AOD product with cloud screening and quality control is used in this  
121 study. Ångström exponent (AE) is an indicator of aerosol particle size. Small (large) AE values  
122 are generally associated with large (small) aerosol particles (Ångström, 1929; Schuster et al.,  
123 2006). The AE between  $0.4 \mu\text{m}$  and  $0.6 \mu\text{m}$  is derived from AERONET observed AODs, and is  
124 used to evaluate the model-simulated AE. For comparison with simulated AOD, AERONET AOD  
125 is interpolated to  $0.55 \mu\text{m}$  from  $0.50 \mu\text{m}$  and  $0.675 \mu\text{m}$  using the AE. In the SJV, only one  
126 AERONET station at Fresno, CA ( $36.79^\circ\text{N}$ ,  $119.77^\circ\text{W}$ ) has regular observations throughout the  
127 California water year 2013 (WY2013) from October 2012 to September 2013.

128 The Multiangle Imaging Spectroradiometer (MISR) (Diner et al., 1998) instrument  
129 onboard the Terra satellite has provided global coverage of AOD once a week since December  
130 1999. The standard MISR retrieval algorithm provides AOD observations at  $17.6 \text{ km}$  resolution  
131 using  $16 \times 16$  pixels of  $1.1 \text{ km} \times 1.1 \text{ km}$  each. About 70% of MISR AOD retrievals are within 20%  
132 of the paired AERONET AOD, and about 50% of MISR AOD falls within 10% of the AERONET  
133 AOD, except in dusty and hybrid (smoke+dust) sites (Kahn et al., 2010). We use version 22 of  
134 Level 3 monthly AOD product at  $0.5^\circ$  resolution in this study.

## 135 **2.2 Surface Mass Concentration**

136 Surface PM<sub>2.5</sub> speciation and PM<sub>10</sub> (particulate matter with diameter  $\leq 10$   $\mu\text{m}$ ) data are  
137 routinely collected by two national chemical speciation monitoring networks: Interagency  
138 Monitoring of Protected Visual Environments (IMPROVE) and the PM<sub>2.5</sub> National Chemical  
139 Speciation Network (CSN) operated by Environmental Protection Agency (EPA) (Hand et al.  
140 2011; Solomon et al., 2014). IMPROVE collects 24-h aerosol speciation every third day at mostly  
141 rural sites since 1988. The same frequency of aerosol speciation dataset was collected at EPA CSN  
142 sites in urban and suburban areas since 2000. The observed organic carbon is converted to OM by  
143 multiplying by 1.4 (Zhao et al., 2013b; Hu et al., 2016). Some precursors of aerosol pollutions  
144 (such as NO<sub>2</sub> and SO<sub>2</sub>) are observed hourly by EPA (data available at:  
145 [https://aqhdr1.epa.gov/aqsweb/aqstmp/airdata/download\\_files.html](https://aqhdr1.epa.gov/aqsweb/aqstmp/airdata/download_files.html)) and are used in this study.  
146 Selected IMPROVE and EPA CSN sites used in this study are shown in Figure 1a.

## 147 **2.3 Aerosol Extinction Profile**

148 The aerosol extinction coefficient profile reflects the attenuation of the light passing  
149 through the atmosphere due to the scattering and absorption by aerosol particles as a function of  
150 range. Version 3 Level 2 532 nm aerosol extinction profiles derived from Cloud-Aerosol Lidar  
151 with Orthogonal Polarization (CALIOP) backscatter profiles collected onboard the Cloud-Aerosol  
152 Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) satellite are used (Omar et al.,  
153 2009; Young and Vaughan, 2009). Seasonal mean profiles are derived for WY2013 based on the  
154 methodology outlined in Campbell et al. (2012), whereby quality-assurance protocols are applied  
155 to individual profiles before aggregating and averaging the data. We highlight that no individual  
156 profiles are included in the averages if the CALIOP Level 2 retrieval failed to resolve any  
157 extinction within the column, a potential issue to create bias that has recently been described by

158 Toth et al. (2017). Level 2 532 nm aerosol extinction data classify aerosols into 6 types: clean  
159 marine, dust, polluted continental, clean continental, polluted dust and smoke. Dust and polluted  
160 dust are distinguished in the averages in this study for their contribution to total extinction and the  
161 vertical profile seasonally in the SJV.

## 162 **2.4 Meteorology**

163 AIRS (Atmospheric Infrared Sounder) onboard the Aqua satellite (Susskind et al., 2003;  
164 Divakarla et al., 2006) has provided global coverage of the tropospheric temperature and moisture  
165 at approximately 01:30 and 13:30 local time since 2002. AIRS retrievals have root-mean-squared  
166 (RMS) error of ~1 K for temperature and ~15% for water vapor (Divakarla et al., 2006). Level 3  
167 monthly temperature and moisture retrievals (version 6) at 1° x 1° grid are used in this study.  
168 Vertical gradient of equivalent potential temperature ( $\theta_e$ ) marks atmospheric stability and is  
169 computed from temperature and moisture profiles observed by AIRS. Surface observations,  
170 including air temperature, relative humidity (RH) and wind speed, are routinely collected at the  
171 California Irrigation Management Information System (CIMIS; <http://www.cimis.water.ca.gov/>).  
172 Precipitation used in this study is the Climate Prediction Center (CPC) Unified Gauge-Based  
173 Analysis of Daily Precipitation product at 0.25° x 0.25° resolution.

## 174 **3. Model Description and Experiment Setup**

175 The WRF-Chem model Version 3.5.1 (Grell et al., 2005) updated by Pacific Northwest  
176 National Laboratory (PNNL) is used in this study (Zhao et al., 2014). This study uses the CBM-Z  
177 (carbon bond mechanism) photochemical mechanism (Zaveri and Peters, 1999) coupled with the  
178 sectional-bin MOSAIC (Model for Simulating Aerosol Interactions and Chemistry) aerosol  
179 scheme (Zaveri et al., 2008) as the chemical driver. The major components of aerosols (nitrate,  
180 ammonium, EC, primary OM, sulfate, sea salt, dust, water and other inorganic matter) as well as

181 their physical and chemical processes are simulated in the model. For computational efficiency,  
182 aerosol particles in this study are partitioned into four-sectional bins with dry diameter within  
183 0.039-0.156  $\mu\text{m}$ , 0.156-0.625  $\mu\text{m}$ , 0.625-2.5  $\mu\text{m}$ , and 2.5-10.0  $\mu\text{m}$ . Zhao et al. (2013a) compared  
184 the impact of aerosol size partition on dust simulations. It showed that the 4-bin approach  
185 reasonably produces dust mass loading and AOD compared with the 8-bin approach. The size  
186 distribution of the 4-bin approach follows that of the 8-bin approach with coarser resolution,  
187 resulting in  $\pm 5\%$  difference on the ratio of  $\text{PM}_{2.5}\text{-dust}/\text{PM}_{10}\text{-dust}$  in dusty regions (more large  
188 particles and less small particles). Dust number loading and absorptivity are biased high in the 4-  
189 bin approach compared with the 8-bin approach.

190 Aerosols are considered to be spherical and internally mixed in each bin (Barnard et al.,  
191 2006; Zhao et al., 2013b). The bulk refractive index for each particle is calculated by volume  
192 averaging in each bin. Mie calculations as described by Ghan et al. (2001) are used to derive  
193 aerosol optical properties (such as extinction, single-scattering albedo, and the asymmetry  
194 parameter for scattering) as a function of wavelength. Aerosol radiation interaction is included in  
195 the shortwave and longwave radiation schemes (Fast et al., 2006; Zhao et al., 2011). By linking  
196 simulated cloud droplet number with shortwave radiation and microphysics schemes, aerosol  
197 cloud interaction is effectively simulated in WRF-Chem (Chapman et al., 2009). Aerosol snow  
198 interaction is implemented in this version of WRF-Chem (Zhao et al., 2014) by considering aerosol  
199 deposition on snow and the subsequent radiative impacts through the SNICAR (SNow, ICe, and  
200 Aerosol Radiative) model (Flanner and Zender, 2005, 2006).

201 The model simulations start on 1 September 2012 and run continuously for 13 months.  
202 With the first month used for the model spin-up, our analysis focuses on WY2013 from October  
203 2012 to September 2013. The model is configured with 40 vertical levels and a model top at 50

204 hPa. The vertical resolution from the surface to 1 km gradually increases from 28 m to 250 m. The  
205 model center is placed at 38°N, 121°W, with 250 x 350 grid points at 4 km horizontal resolution  
206 (referred to as “4km” hereafter; Table 1), covering California and the surrounding area. To test the  
207 sensitivity of the aerosol simulations to horizontal resolution, one simulation with the same model  
208 settings and domain coverage is conducted at 20 km horizontal resolution (referred to as “20km”  
209 hereafter).

210 The physics parameterizations used in the simulations include the Morrison double-  
211 moment microphysics scheme (Morrison et al., 2009), Rapid Radiative Transfer Model for General  
212 circulation model (RRTMG) shortwave and longwave radiation schemes (Iacono et al., 2008),  
213 Community Land Model (CLM) Version 4 land surface scheme (Lawrence et al., 2011). The  
214 Yonsei University (YSU) planetary boundary layer (PBL) scheme (Hong et al., 2006) is used in  
215 all of the simulations, except one sensitivity experiment that uses the ACM2 (Asymmetric  
216 Convective Model with non-local upward mixing and local downward mixing; Pleim, 2007) PBL  
217 scheme (referred to as “20km\_P7” hereafter, Table 1). Subgrid convection, convective transport  
218 of chemical constituents and aerosols, and wet deposition from subgrid convection are  
219 parameterized using the Grell 3D ensemble cumulus scheme (Grell and Devenyi, 2002) in the 20  
220 km simulations while convective processes are resolved in the 4 km simulations. The Interim  
221 European Center for Medium-Range Weather Forecasts Re-Analysis (ERA-Interim; Dee et al.,  
222 2011) serves as initial and boundary meteorological conditions for WRF-Chem. The MOZART-4  
223 global chemical transport model (Emmons et al., 2010) is used for initial and boundary chemical  
224 conditions. Fast et al. (2014) found that the MOZART-4 model overestimates aerosols in the free  
225 troposphere over California, which is also found in one of our sensitivity experiments

226 (“20km\_BC1” in the supplementary). Following Fast et al. (2014), the chemical initial and  
 227 boundary conditions from MOZART-4 are divided by two in all simulations except 20km\_BC1.

228 Anthropogenic emissions are provided by US EPA 2005 National Emissions Inventory  
 229 (NEI05), with area-type emissions on a structured 4-km grid and point-type emissions at specific  
 230 latitude and longitude locations (US EPA, 2010). Nineteen gases (including SO<sub>2</sub>, NO, NH<sub>3</sub> etc.)  
 231 are emitted, and aerosol emissions include SO<sub>4</sub>, NO<sub>3</sub>, EC, organic aerosols, and total PM<sub>2.5</sub> and  
 232 PM<sub>10</sub> masses. Anthropogenic emissions are updated every hour to account for diurnal variability,  
 233 while its seasonal variation is not considered in the simulations. A sensitivity experiment with  
 234 2011 NEI emissions (“20km\_NEI11” in the supplementary) does not produce significantly  
 235 different results from the 2005 NEI emissions. Biogenic emissions are calculated online using the  
 236 Model of Emissions of Gases and Aerosols from Nature (MEGAN) model (Guenther et al., 2006).  
 237 Biomass burning emissions are obtained from the Global Fire Emissions Database version 2.1,  
 238 with eight-day temporal resolution (Randerson et al., 2007) and updated monthly. Sea salt  
 239 emissions are derived from the PNNL-updated sea salt emission scheme that includes the  
 240 correction of particles with radius less than 0.2 μm (Gong et al., 2003) and dependence on sea  
 241 surface temperature (Jaeglé et al., 2011).

242 Following Zhao et al. (2013b), dust emission is computed from the GOCART (Goddard  
 243 Global Ozone Chemistry Aerosol Radiation and Transport) dust scheme (Ginoux et al., 2001) in  
 244 the 20km and 4km simulations. The GOCART dust scheme estimates the dust emission flux  $F$  as

$$245 \quad F = C S s_p u_{10m}^2 (u_{10m} - u_t) \quad ,$$

246 where  $C$  is an empirical proportionality constant,  $S$  is a source function for potential wind erosion  
 247 that is derived from 1° x 1° GOCART database (Freitas et al., 2011),  $s_p$  is a fraction of each size  
 248 class dust in emission,  $u_{10m}$  is 10-m wind speed and  $u_t$  is a threshold speed for dust emission.

249 As shown later, a significant amount of dust is observed in the SJV, whereas the GOCART  
 250 dust scheme produces little dust. Two sensitivity experiments at 20 km and 4 km horizontal  
 251 resolution (hereafter referred to as “20km\_D2” and “4km\_D2”, respectively) are conducted by  
 252 switching the dust emission scheme to the DUST TRANsport model (DUSTRAN) scheme (Shaw  
 253 et al., 2008). The DUSTRAN scheme estimates  $F$  as

$$254 \quad F = \alpha C u_*^4 \left(1 - \frac{f_w u_{*t}}{u_*}\right),$$

255 where  $C$  is an empirical proportionality constant,  $\alpha$  is the vegetation mask,  $u_*$  is the friction  
 256 velocity,  $u_{*t}$  is a threshold friction velocity and  $f_w$  is the soil wetness factor. The  $C$  value in both  
 257 GOCART and DUSTRAN is highly tunable for different regions. The original  $C$  values,  $1.0 \mu\text{g s}^2$   
 258  $\text{m}^{-5}$  in GOCART (Ginoux et al., 2001) and  $1.0 \times 10^{-14} \text{ g cm}^{-6} \text{ s}^{-3}$  in DUSTRAN (Shaw et al., 2008),  
 259 are used in this study.

## 260 **4. Model Simulation Results**

261 Shown in Fig. 1a, our model domain includes three urban sites (Fresno, Bakersfield and  
 262 Modesto) and two rural sites (Pinnacles and Kaiser) where surface measurements of aerosols are  
 263 available. Because aerosols properties and model performance are similar at all urban sites, our  
 264 discussion is focused on the results at Fresno and the simulations for other urban sites are provided  
 265 in the supplementary materials. Model simulations in the rural areas are presented in the last  
 266 subsection.

### 267 **4.1 Sensitivity to Horizontal Resolution**

268 Figure 1 features daily mean anthropogenic  $\text{PM}_{2.5}$  emission rates used in the 20km and  
 269 4km simulations, respectively. Although both emission rates are derived from the 4 km NEI05  
 270 dataset, localized high emission rates with sharp gradients are evident in urban areas from the 4km  
 271 simulation (Fig. 1b). The 20km simulation exhibits lower emission rates at the urban areas with

272 weaker gradients due to the reapportionment process (Fig. 1a). As precipitation is an important  
273 process that removes aerosols, we examine the simulated precipitation for the 20km and 4km runs  
274 and find that the 20km simulation produces 51% more precipitation, although the domain averaged  
275 precipitation is lower in the 20km run than the 4km run (Fig. 2a).

276 Consistent with higher emission rates and lower precipitation at Fresno, the 4km run  
277 simulates higher AOD than the 20km run in the cold season (October-November-December and  
278 January-February-March; OND and JFM in Fig. 3). Averaged over a broad area encompassing  
279 Fresno and Bakersfield, the most polluted region in the SJV (red box in Fig. 1a), the AOD is 0.090  
280 in the 4km and 0.073 in the 20km, a 23% difference. Compared to the MISR observations, the  
281 4km simulation reproduces the spatial distribution and magnitude of AOD in the cold season.  
282 However, the AOD difference between the 20km and 4km runs is small in the warm season (April-  
283 May-June and July-August-September; AMJ and JAS in Fig. 3), and both runs underestimate AOD  
284 by ~50% with respect to the MISR observations.

285 Comparing the point values at Fresno in the 4km and 20km simulations (Fig. 4a), we find  
286 similar results: the 4km AOD is closer to the AERONET measurements and is about 23% higher  
287 than that in the 20km run during the cold season, while both runs are biased low in AOD during  
288 the warm season. The different model sensitivities to horizontal resolution between the cold and  
289 warm seasons suggest that the dominant aerosol sources may be different for the two seasons. We  
290 will elaborate upon the aerosol composition in the following section. MISR and AERONET  
291 observations display weak seasonal AOD variation in the SJV and at Fresno, respectively, which  
292 is not well represented in the 20km and 4km simulations (Fig. 3 and 4a).

293 Aside from AOD, significant seasonal variability of AE (Fig. 4b) is shown at Fresno. AE  
294 exhibits a maximum about 1.50 in January and a minimum of 0.98 in April, suggesting relatively

295 small particles in the winter and large particles in the spring. A relatively large AE value of 1.40  
296 (corresponding to small particles) is observed in July, possibly related to the wild fires in late July  
297 in the SJV. WRF-Chem captures the seasonal variability of the AE well, with a correlation of 0.90  
298 in both the 20km and 4km simulations. The magnitude of AE is also approximately simulated in  
299 the cold season, with a mean of 1.15 (1.20) in the 20km (4km) runs compared to 1.33 in the  
300 observation. However, the simulated AE is underestimated by ~30% in the warm season,  
301 indicating that the simulated particle size is biased high during this period.

302 Significant seasonal variability of  $PM_{2.5}$  is observed in the SJV urban areas (Fig. 5a and  
303 Supplementary Fig. 4a and 5a).  $PM_{2.5}$  at Fresno peaks in January ( $26.18 \mu\text{g m}^{-3}$ ) and reaches a  
304 minimum of  $7.03 \mu\text{g m}^{-3}$  in June, with an annual nonattainment value of  $12.64 \mu\text{g m}^{-3}$  (Fig. 5a).  
305 Both the 20km and 4km runs approximately capture the observed seasonal variability of  $PM_{2.5}$ ,  
306 with a correlation around 0.90 (Table 2). In the cold season, the 4km simulation overestimates  
307  $PM_{2.5}$  by 27% while the 20km simulation exhibits a low bias of 19% compared with IMPROVE  
308 observations at Fresno (Table 3). The 4km simulation of  $PM_{10}$  is in good agreement with  
309 IMPROVE in the winter (December, January and February), but has significant low biases of  
310 between 30% and 85% in other months (Fig. 5b). The 20km simulation underestimates  $PM_{10}$   
311 throughout WY2013.

312  $PM_{2.5}$  is a mixture of nitrate ( $NO_3$ ), ammonia ( $NH_4$ ), OM, EC, sulfate ( $SO_4$ ), dust and other  
313 aerosols. High concentrations of  $PM_{2.5}$  are primarily the result of  $NO_3$  at Fresno (Fig. 5c). Both  
314 simulations produce the seasonal variability of  $NO_3$  with a correlation of 0.94, but high bias of  
315 17% (75%) is found in the 20km (4km) simulations during the cold season. As one precursor of  
316  $NO_3$ ,  $NO_2$  is underestimated by 43% in the 20km run (Fig. 6a). The overestimation in  $NO_3$  and  
317 underestimation in  $NO_2$  suggest that the precursor emissions may not be the reason for the high biases

318 in  $\text{NO}_3$ .  $\text{NH}_4$  shows a similar performance to  $\text{NO}_3$ , with an overestimation by 38% (111%) in the  
319 20km (4km) runs during the cold seasons (Fig. 5d). As shown later in section 4.3, both  $\text{NO}_3$  and  
320  $\text{NH}_4$  simulations are quite sensitive to the PBL scheme applied.

321 OM, the second largest contributing species to cold season  $\text{PM}_{2.5}$  in the SJV (Table 3), is  
322 significantly underestimated by 82% in the 20km simulation (Fig. 5f). The 4km simulation  
323 produces higher OM, but it is still lower than the IMPROVE observations by 63%. The  
324 underestimation of OM is expected, because SOA processes are not included in our model  
325 infrastructure. Fast et al. (2014) used the simplified two-product volatility basis set  
326 parameterization to simulate equilibrium SOA partitioning in WRF-Chem although SOA was still  
327 underestimated in their simulation. It remains ongoing research how to correctly represent SOA  
328 processes in regional climate models.

329 Both the 20km and 4km simulations reproduce the seasonal variability of EC, with a  
330 correlation of 0.98 between the modeled and observed time series (Table 2). The 20km simulation  
331 underestimates EC by 52% (16%) in the cold (warm) season (Fig. 5e and Table 3). The 4km  
332 simulated EC ( $1.12 \mu\text{g m}^{-3}$ ) exhibits good agreement with IMPROVE ( $1.08 \mu\text{g m}^{-3}$ ) in the cold  
333 season, but overestimates EC by 53% in the warm season.

334 The seasonal variability of  $\text{SO}_4$  at Fresno is very different from other  $\text{PM}_{2.5}$  species. It peaks  
335 in May at  $1.35 \mu\text{g m}^{-3}$  and reaches the minimum of  $0.67 \mu\text{g m}^{-3}$  in August (Fig. 5g). The 20km  
336 simulated  $\text{SO}_4$  exhibits good correlation of 0.63 with the observation (Table 2), but is biased low  
337 by 28% to 63% throughout WY2013 (Fig. 5g). Although the observed  $\text{SO}_2$ , the precursor of  $\text{SO}_4$ ,  
338 has approximately similar seasonal variation to the observed  $\text{SO}_4$  (Fig. 6b), the 20km simulated  
339 seasonal variability of  $\text{SO}_2$  resembles other anthropogenic emissions, with high values in the cold  
340 season and low values in the warm season, out of phase with the simulated  $\text{SO}_4$  and the observed

341 SO<sub>2</sub>. The 4km simulation produces higher SO<sub>4</sub> than the 20km run, resulting in better agreement  
342 with the observation (0.82 μg m<sup>-3</sup> vs. 0.87 μg m<sup>-3</sup>) during the cold season (Fig. 5g and Table 3).  
343 However, the 4km run produces an increase of SO<sub>4</sub> by only 13% comparing to the 20km run in  
344 the warm season, resulting in a correlation of -0.16 between the 4km simulation and the  
345 observation.

346 To explore the possible cause for the underestimation of SO<sub>4</sub> and SO<sub>2</sub> in the warm season  
347 in both the 20km and 4km simulations, we conduct a sensitivity experiment with different chemical  
348 boundary conditions from the baseline runs (20km\_BC1 in the supplementary). We find that SO<sub>4</sub>  
349 in the SJV is partly contributed to by marine intrusions (the different chemical boundary conditions  
350 between 20km\_BC1 and 20km\_D2) throughout the year (supplementary Fig. 2g), as pointed out  
351 by Fast et al. (2014). Including the marine intrusions, the 20km\_BC1 simulated SO<sub>4</sub> tracks the  
352 observation at a correlation of 0.78. Doubled chemical boundary conditions in the 20km simulation  
353 results in 41% increase in SO<sub>4</sub> at Fresno, with a stronger increase in the warm season. Compared  
354 to the observed SO<sub>4</sub> of 1.04 μg m<sup>-3</sup> in the warm season, the simulated SO<sub>4</sub> of 0.79 μg m<sup>-3</sup> in the  
355 20km\_BC1 run is closer to the observation than that simulated in the 20km\_D2 run (0.53 μg m<sup>-3</sup>).  
356 The relative contributions of local emissions and remote transports (as well as other emission  
357 sources, such as wild fires) to SO<sub>4</sub> concentrations in different seasons of the SJV require further  
358 investigation.

359 Overall, the 4km simulation produces higher AOD and surface PM than the 20km  
360 simulation in urban areas of the SJV, especially during the cold season, resulting in better  
361 agreement with satellite and surface observations than the 20km simulation. Both the 20km and  
362 4km simulations approximately capture the seasonal variability of PM<sub>2.5</sub> and most of its speciation.  
363 However, significant low biases of AOD and PM<sub>10</sub> are found during the warm season in both

364 simulations. The underestimation also exists in a sensitivity experiment (not shown) with the same  
365 model setups except initialized in April, indicating that the identified model biases during the warm  
366 season are not caused by potential model drift after a relatively long simulation period. The  
367 relatively good performance in simulating  $PM_{2.5}$  but not  $PM_{10}$  during the warm season suggests  
368 that coarse aerosol particle mass (CM;  $10\ \mu\text{m} \geq$  particulate matter with diameter  $> 2.5\ \mu\text{m}$ ), mainly  
369 dust in the SJV, is not properly represented in the model. The impact of dust parameterizations is  
370 investigated in the 4km\_D2 experiment.

## 371 **4.2 Sensitivity to Dust Scheme**

372 Limited amounts of  $PM_{2.5\_dust}$  (dust with diameter  $\leq 2.5\ \mu\text{m}$ ) are observed in the SJV cold  
373 season, with a minimum of  $0.37\ \mu\text{g m}^{-3}$  in December (Fig. 7a). The amount of  $PM_{2.5\_dust}$  increases  
374 in the warm season, with a peak of  $3.86\ \mu\text{g m}^{-3}$  in September. The 4km simulation produces  
375 comparable  $PM_{2.5\_dust}$  relative to IMPROVE in the winter, but almost no dust in other months  
376 (Fig. 7 and upper panel in Fig. 8). On the other hand, the dust emission rate in the 4km\_D2 run is  
377 significantly higher than the 4km run. We have found that the source function,  $S$ , for potential  
378 wind erosion in the SJV is set to zero in the  $1^\circ \times 1^\circ$  GOCART dataset used for the 4km simulation  
379 (Fig. 9). An updated source function,  $S$ , at higher resolution is needed for the GOCART dust  
380 scheme to correctly represent dust emissions in the SJV.

381 The 4km\_D2 simulation reproduces the amount of  $PM_{2.5\_dust}$  in OND (Fig. 7a). However,  
382 it overestimates  $PM_{2.5\_dust}$  by up to a factor of 3 in the warm season, resulting in an overestimation  
383 of  $PM_{2.5}$  by 52% (Fig. 7b and Table 3).  $PM_{2.5\_dust}$  is not sensitive to long-range transport (from  
384 chemical boundary conditions in the model simulation; Supplementary Fig. 2h). Both the 4km and  
385 4km\_D2 simulations capture the seasonal variability of  $PM_{2.5}$ , but not that of  $PM_{10}$  (Fig. 7c). The  
386 magnitude of  $PM_{10}$  in the 4km\_D2 run is larger than the 4km simulation.  $PM_{10}$  in the 4km\_D2 run

387 is overestimated in April-May-June (AMJ) but underestimated in July-August-September (JAS),  
388 leading to a comparable season mean of  $38.12 \mu\text{g m}^{-3}$  with IMPROVE observed  $34.82 \mu\text{g m}^{-3}$ . The  
389 overestimation of AMJ  $\text{PM}_{10}$  and  $\text{PM}_{2.5\_dust}$  in the 4km\_D2 run is likely associated with the high  
390 bias in the simulated wind speed (Fig. 2b).

391 On the relative contribution of different aerosol species, IMPROVE observations at Fresno  
392 show that  $\text{NO}_3$  is the primary contributor (32.3%) to  $\text{PM}_{2.5}$  while only 5.3% of  $\text{PM}_{2.5}$  is dust in the  
393 cold season (panel 1 of Fig. 10). Both the 4km and 4km\_D2 runs roughly reproduce the relative  
394 contributions to  $\text{PM}_{2.5}$  in the cold season, with an overestimation of  $\text{NO}_3$  and  $\text{NH}_4$  and an  
395 underestimation of OM, consistent with the time series in Fig. 5. Relative contributions of dust to  
396  $\text{PM}_{2.5}$  are better simulated in the 4km\_D2 run (7.3%) than the 4km one (<1.0%). IMPROVE shows  
397 that 46.6% of  $\text{PM}_{10}$  is CM in the cold season (panel 2 of Fig. 10). Both the 4km (6.3%) and  
398 4km\_D2 (20.6%) runs underestimate the contribution of CM to  $\text{PM}_{10}$ , mainly in October and  
399 November. In the warm season, dust (24.6%) becomes the primary contributor to  $\text{PM}_{2.5}$  while the  
400 contribution from  $\text{NO}_3$  decreases to 9.9% in IMPROVE observations (panel 3 of Fig. 10). Almost  
401 no  $\text{PM}_{2.5\_dust}$  is simulated in the 4km run while too much  $\text{PM}_{2.5\_dust}$  is produced in the 4km\_D2  
402 (50.5%) run during the warm season. The relative contribution of CM to  $\text{PM}_{10}$  is too small (27.6%)  
403 in the 4km run, while the 4km\_D2 run reflects a better relative contribution of 66.3% as compared  
404 to an IMPROVE observed 75.8% (panel 4 of Fig. 10).

405 AOD simulations are improved in the 4km\_D2 experiment (Fig. 11), with better agreement  
406 found from MISR (Fig. 3) in AMJ. AOD (0.114) in the 4km\_D2 run is comparable to observations  
407 (0.131) in AMJ, but still underestimated by 53% in JAS. Consistent with AOD, the vertical  
408 distribution of aerosol extinction is reasonably simulated during the cold season in the WRF-Chem  
409 simulations, while large discrepancies are found in the warm season (Fig. 12). As observed by

410 CALIOP at 532 nm, aerosols are mainly confined below 1 km above the surface in the cold season.  
411 Model simulations roughly capture the vertical distribution of aerosol extinction observed by  
412 CALIOP, with low biases in the boundary layer and high biases in the free atmosphere. Similar  
413 discrepancy between the model simulations and CALIOP is shown in other studies (Wu et al.,  
414 2011a; Hu et al., 2016). The difference between the 4km and 4km\_D2 runs is small during the  
415 cold season.

416 Dust in the boundary layer is a primary factor contributing to aerosol extinction in the SJV,  
417 as illustrated by the differences between the bulk seasonal CALIOP mean profile and those  
418 excluding the contributions of the dust and polluted dust (CALIOP\_nodust) profiles (Fig. 12).  
419 Simulated aerosol extinction falls between the two in all seasons, suggesting that dust is the  
420 primary factor contributing to the model biases in aerosol extinction. Although a small portion of  
421 PM<sub>2.5</sub> is dust in the cold season, it contributes to about 50% of total aerosol extinction (Fig. 12a  
422 and 12b). A predominant portion of aerosol extinction in the boundary layer is contributed by dust  
423 in the warm season (Fig. 12c and 12d). There, the 4km\_D2 simulation produces higher aerosol  
424 extinction in the boundary layer than the 4km simulation, although it is still lower than CALIOP.  
425 The simulated aerosol extinction in the free troposphere above the boundary layer is close to or  
426 larger than CALIOP, suggesting that aerosols transported from remote areas through chemical  
427 boundary conditions (e.g., the differences between the 20km\_BC1 and 20km\_D2 runs in  
428 Supplementary Fig. 3) may not be the major factor contributing to the underestimation of dust in  
429 the boundary layer in the SJV.

430 Overall, the poor simulations of dust in the boundary layer play a dominant role in the low  
431 bias of aerosols during the warm season. Both the GOCART and DUSTRAN dust emission  
432 schemes used in this study have difficulties in reproducing dust emissions in the SJV, with an

433 underestimation in GOCART and an overestimation in DUSTRAN (Fig. 7). Improvement on the  
434 dust emission schemes is needed for capturing the seasonal variability of aerosols in the SJV.

### 435 **4.3 The Role of Meteorology**

436 The WRF-Chem simulations approximately reproduce the seasonal variations of  
437 meteorological variables near the surface (correlations  $> 0.80$ ), including temperature, RH, wind  
438 speed and precipitation (Supplementary Fig. 6 and Supplementary Table 1). All of the model  
439 simulations exhibit warm and dry biases near surface and in the boundary layer, with cold and wet  
440 biases in the free atmosphere (Supplementary Fig. 6-8 and Supplementary Table 2). The dry bias  
441 in the 4km\_D2 run is about 10% near the surface throughout WY2013. Due to the relative dry  
442 environment ( $RH < 50\%$ ) in the warm season, the dry bias is likely not responsible for the  
443 underestimation of boundary layer aerosol extinctions and column-integrated AOD through  
444 hygroscopic effects (Feingold and Morley, 2003). In the cold season, the surface wind speed is  
445 underestimated by 0.67 m/s (1.00 m/s) in the 4km\_D2 (20km\_D2) runs. In the warm season, the  
446 4km\_D2 run overestimates wind speed by 0.78 m/s, while the 20km\_D2 run has an  
447 underestimation of 0.16 m/s. These results suggest that wind speed is also not the primary factor  
448 contributing to low biases in the boundary layer aerosols. The seasonal variability of precipitation  
449 is well captured in the simulations, while the magnitude of precipitation is smaller than the  
450 observations during the warm season (Supplementary Table 2). Wet removal processes are thus  
451 not likely the primary reason for the aerosol biases in the warm season.

452 In the warm season, more aerosols are observed at higher altitude than during the cold  
453 season (Fig. 12). A well-mixed layer of aerosols is observed below 1.5 km in AMJ (Fig. 12c),  
454 consistent with the unstable layers below 1.5 km observed by AIRS (Fig. 13c). However, the WRF-  
455 Chem model simulates neutral (or weakly stable) layers below 1.5 km (Fig. 13c), which may lead

456 to a failure in capturing the well-mixed layer of aerosols (Fig. 12c). Although the dust emission at  
457 the surface is large in the 4km\_D2 run, not enough convective vertical mixing is produced in the  
458 simulations, plausibly resulting in the low biases found in the boundary layer. Aerosol extinction  
459 gradually decreases with height in the simulations. Similar biases of aerosol and instability in the  
460 boundary layer are also shown in JAS (Fig. 12d and 13d). Relative static stability in the simulations,  
461 which limits convective vertical mixing of aerosols, likely enhances the low bias of column-  
462 integrated AOD in JAS (Fig. 11). Although the 4km\_D2 experiment produces comparable AOD  
463 and surface PM mass in AMJ (Fig. 6 and Fig. 11), the vertical distribution of aerosols is not well  
464 represented (Fig. 12). The comparable AOD in the 4km\_D2 run results from the low bias in the  
465 boundary layer and the high bias in the free atmosphere. In JAS (Fig. 12d), comparable aerosol  
466 extinction to CALIOP is simulated in the free atmosphere, suggesting that the low bias in AOD is  
467 not due to the halved chemical boundary conditions from MOZART-4. Albeit some discrepancies  
468 in the magnitude of atmospheric stability, all of the simulations capture the stable environment in  
469 the cold season (Fig. 13a and 13b), consistent with relatively good performance of aerosol  
470 simulations in the cold season.

471 As biases in the model simulations are found mainly within the boundary layer, a sensitivity  
472 experiment is conducted at 20 km resolution using the ACM2 PBL scheme (20km\_P7). Although  
473 the changes in the meteorological variables (Supplementary Fig. 6-8) and atmospheric static  
474 stability (Fig. 13) are rather small, the simulated surface  $\text{NO}_3$  and  $\text{NH}_4$  in the 20km\_P7 run  
475 decrease by 50% compared to the 20km\_D2 run (Fig. 14c, 14d and Table 3). Considering that  
476 more  $\text{NO}_3$  and  $\text{NH}_4$  are simulated at 4 km resolution than at 20 km resolution as shown in section  
477 4.1, the use of the ACM2 PBL scheme at 4 km simulation would largely resolve the high biases  
478 of  $\text{NO}_3$  and  $\text{NH}_4$  in the 4km\_D2 simulation. The decrease of  $\text{NO}_3$  and  $\text{NH}_4$  at the surface is because

479 more aerosols are transported to the layers above 0.5 km (Fig. 15a and 15b), resulting from  
480 different convective vertical mixing in the PBL schemes. However,  $PM_{2.5\_dust}$  is significantly  
481 overestimated by a factor of 4 in the 20km\_P7 simulation (Fig. 14h), leading to a small decrease  
482 of  $PM_{2.5}$  by only 8% compared with the 20km\_D2 run in the cold season. In the warm season,  
483  $PM_{2.5\_dust}$  in the 20km\_P7 run is overestimated by a factor of 5, causing an overestimation of  
484  $PM_{2.5}$  and  $PM_{10}$  (Fig. 14a and 14b). Aerosol extinctions in the boundary layer increase in the warm  
485 season (Fig. 15c and 15d), possibly related to overestimation of dust emissions and more  
486 conducive convective vertical transport in the PBL scheme.

487 In summary, the WRF-Chem model captures the seasonal variations of meteorological  
488 variables (temperature, RH, wind speed and precipitation), despite some deviations in magnitude.  
489 The low biases in aerosol optical properties of the warm season likely do not originate from  
490 hygroscopic effects, wet removal processes or dust emissions associated with the wind speed bias.  
491 The model simulates a stable environment in the warm season, which is opposite to the observed  
492 unstable environment. The simulated stable environment may be most likely responsible for low  
493 biases in the aerosol extinction in the boundary layer and the column-integrated AOD in the warm  
494 season. Switching to the ACM2 PBL scheme leads to improved vertical mixing in the boundary  
495 layer, thus an improvement in the simulations of  $NO_3$  and  $NH_4$  in the cold season. However, dust  
496 emissions are significantly overestimated with the ACM2 PBL scheme, which contributes partly  
497 to the better simulation of aerosol extinction in the boundary layer and AOD in the column. These  
498 results highlight that improving the simulation of boundary layer structure and processes are  
499 critical for capturing the vertical profiles of aerosol extinction.

#### 500 **4.4 Results in Rural Areas**

501 In general, low values of PM concentration are observed in the rural areas, Pinnacles and  
502 Kaiser (Fig. 16 and 17). The rural areas share some similar model performance to the urban areas,  
503 such as the overestimation of  $\text{NO}_3$ , reasonable simulation of EC, good representation of  $\text{SO}_4$  in the  
504 cold season and underestimation of  $\text{SO}_4$  in the warm season. However, the results are not sensitive  
505 to model resolution. It suggests that high resolution is particularly important for heavily polluted  
506 areas due to the inhomogeneity of emission sources, but less important for relatively lightly  
507 polluted areas.

508 In late July/early August, MODIS (Moderate Resolution Imaging Spectroradiometer) fire  
509 data (not shown) showed active wild fires close to Kaiser, which resulted in high concentration of  
510 aerosols locally (Fig. 17). Our model simulations with monthly-varying fire emissions fail to  
511 reproduce these fire events. Previous studies (e.g., Grell et al., 2011; Wu et al. 2011a; Archer-  
512 Nicholls et al., 2015) demonstrated that the WRF-Chem model can capture aerosols distributions  
513 from wild fires based on fire locations from satellite observations. Campbell et al. (2016) further  
514 described the difficulties in constraining total aerosol mass from operational satellite fire  
515 observations and the time needed by the model for diffusion within the near-surface layers to  
516 render both reasonable AOD and vertical profiles of aerosol extinction. For operational application  
517 of the WRF-Chem model in MAIA retrievals, the observations of daily fire events need to be more  
518 appropriately considered.

## 519 **5. Summary**

520 The WRF-Chem (Weather Research and Forecasting model with Chemistry) model is  
521 employed to simulate the seasonal variability of aerosols in WY2013 (water year 2013) in the SJV  
522 (San Joaquin Valley). Model simulations are evaluated using satellite and in-situ observations. In  
523 general, the model simulations conducted at 4 km resolution reproduce the spatial and temporal

524 variations of regional aerosols in the cold season, when aerosols are mainly contributed to by  
525 anthropogenic emissions in the SJV. The magnitude of simulated aerosols in the cold season  
526 however, especially in relatively dense urban areas, is sensitive to model horizontal resolution.  
527 The 4km simulation has comparable magnitude to available observations, while the 20km  
528 simulation underestimates aerosols. Differences in aerosol simulation fidelity as a function of  
529 variable resolutions are mainly due to the difference in aerosol emissions and simulated  
530 precipitation. Emissions at higher resolution can better resolve the inhomogeneity of  
531 anthropogenic emissions in the SJV than at lower resolution. The sensitivity to horizontal  
532 resolution is small in rural areas and during warm season, where/when the relative contribution of  
533 anthropogenic emissions is small.

534 Previous studies in the SJV are mainly focused on  $PM_{2.5}$  (particulate matter with diameter  
535  $\leq 2.5 \mu m$ ) and during cold season (e.g. Chow et al., 2006; Herner et al., 2006; Pun et al., 2009;  
536 Ying and Kleeman, 2009; Zhang et al., 2010; Chen et al., 2014; Hasheminassab et al., 2014; Kelly  
537 et al., 2014; Baker et al., 2015; Brown et al., 2016). CALIOP (Cloud-Aerosol Lidar with  
538 Orthogonal Polarization) and IMPROVE (Interagency Monitoring of Protected Visual  
539 Environments) observations show that dust is a primary contributor to the aerosols in the SJV,  
540 especially in the warm season. Dust contributes 24.6% to  $PM_{2.5}$  while more than 75.8% to  $PM_{10}$  in  
541 the warm season. For all seasons, the major component of aerosol extinction in the boundary layer  
542 is dust as observed by CALIOP, consistent with Kassianov et al. (2012). For a complete  
543 understanding of aerosol impacts on air quality, weather and climate, the full spectrum of aerosols  
544 should be considered during all seasons.

545 All the model simulations conducted fail to capture aerosol vertical distribution and  
546 variability in the SJV warm season, largely due to the misrepresentation of dust emissions, static

547 stability and vertical mixing in the boundary layer. The GOCART (Goddard Global Ozone  
548 Chemistry Aerosol Radiation and Transport) dust emission scheme significantly underestimates  
549 dust due to the non-active source function,  $S$ , for potential wind erosion used in this study while  
550 the DUSTRAN (DUST TRANsport model) scheme may overestimate dust emission in the SJV.  
551 Along with the bias in dust emissions, our simulations produce a relatively stable boundary layer  
552 in the warm season, in contrast with observations suggesting a more unstable environment, leading  
553 to a weak vertical mixing of aerosols in the boundary layer. Improved dust emission and better  
554 simulations of the boundary layer properties are needed for accurate simulation of aerosols in the  
555 SJV warm season.

556 Other biases are also identified in the model simulations.  $\text{NO}_3$  and  $\text{NH}_4$  in the cold season  
557 are overestimated in the model, but the results are sensitive to the choice of the PBL (planetary  
558 boundary layer) scheme. The SOA (secondary organic aerosol) processes contribute to the  
559 underestimation of OM (organic matter) in this study. The underestimation of sulfate in the warm  
560 season may be caused by the misrepresentation of emissions and the chemical boundary conditions  
561 related to marine intrusions. Aerosols from wild fires are not captured in the simulations with  
562 monthly updated fire data. Further investigations are needed to improve model simulations in the  
563 SJV for both scientific and operational applications.

## 564 **Acknowledgements**

565 This study was carried out at the Jet Propulsion Laboratory, California Institute of  
566 Technology, under a contract with the National Aeronautics and Space Administration. The  
567 authors thank the funding support from the NASA ACMAP program and JPL PDF program. This  
568 work is partially sponsored by California Energy Commission under grant #EPC-14-064. Author

569 JRC acknowledges the support of the NASA ACCDAM program and its manager Hal Maring.

570 The authors thank the three anonymous reviewers for their helpful comments.

836 **List of Table**

837 Table 1. Experiment description

Experiment ID	Experiment description
20km	Simulation with the GOCART dust scheme at 20 km horizontal resolution.
20km_D2	Same as 20km, but with the DUSTRAN dust scheme.
20km_P7	Same as 20km_D2, but with the ACM2 PBL scheme.
4km	Same as 20km, but at 4 km horizontal resolution.
4km_D2	Same as 4km, but with the DUSTRAN dust scheme.

838

839 Table 2. Correlation with observations for different species at Fresno, CA

Species	20km	4km	4km_D2	20km_D2	20km_P7
PM <sub>2.5</sub>	0.89	0.90	0.86	0.78	0.03

847

848 **List of Figures**

849

850 Figure 1. Daily mean anthropogenic  $PM_{2.5}$  emission rate ( $\mu\text{g m}^{-2} \text{hr}^{-1}$ ) at (a) 20km and (b) 4km  
 851 simulation. Domain-averaged emission rate is shown at right corner of each figure. Red dashed  
 852 lines in Figure 1a represent the region used for the domain averages in the discussions. Yellow  
 853 circle: IMPROVE site; yellow diamond: EPA CSN site. Three urban sites: Fresno, Bakersfield and  
 854 Modesto; two rural sites: Pinnacles and Kaiser.

855  
 856 Figure 2. (a) Monthly precipitation (mm/day) from CPC, 20km and 4km; (b) monthly wind speed  
 857 (m/s) from CIMIS, 20km and 4km. 4km\_D2 (not shown) is similar to 4km.

858

859 Figure 3. Spatial distribution of seasonal mean 550 nm AOD from MISR and the WRF-Chem  
 860 (20km and 4km) simulations in WY2013. OND: October-November-December; JFM: January-  
 861 February-March; AMJ: April-May-June; JAS: July-August-September.

862

863

864 Figure 4. (a) Monthly mean 550 nm AOD; (b) monthly mean 400-600 nm Ångström exponent at  
 865 Fresno, CA from October 2012 to September 2013.

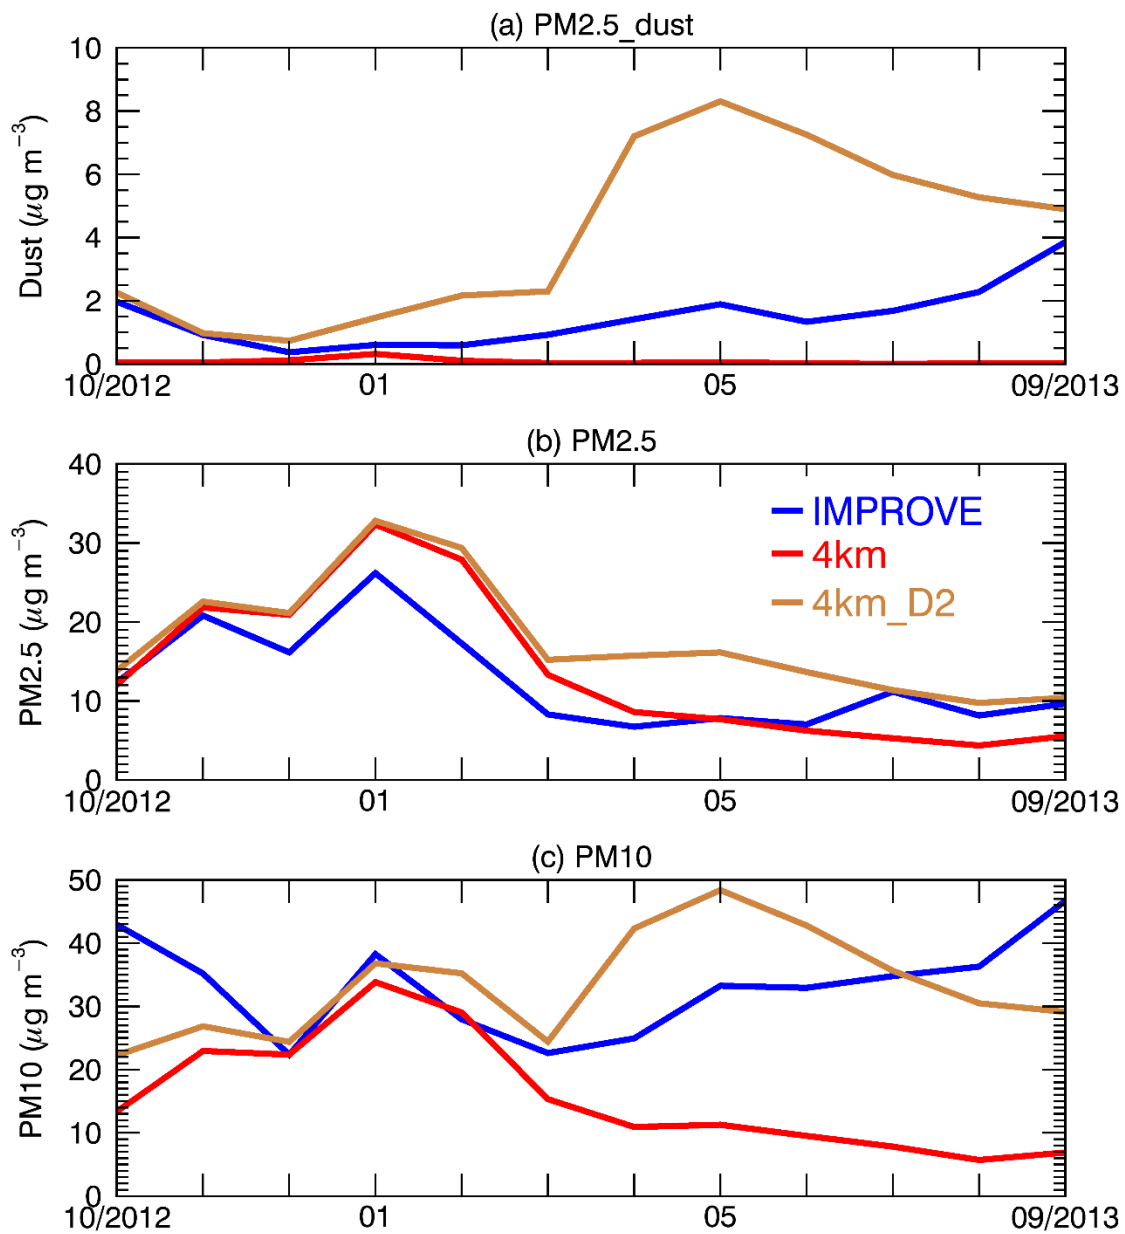

866

867 Figure 5. Aerosol mass ( $\mu\text{g m}^{-3}$ ) for different species from OBS, the 20km and 4km simulations at  
 868 Fresno, CA.  $\text{NH}_4$  observations are from EPA; other observations are from IMPROVE.  $\text{PM}_{2.5\_}\text{NO}_3$   
 869 represents  $\text{NO}_3$  with diameter  $\leq 2.5 \mu\text{m}$ . Similar definition for  $\text{NH}_4$ , EC, OM and  $\text{SO}_4$  in the figures.

870

871 Figure 6. (a) NO<sub>2</sub> and (b) SO<sub>2</sub> from EPA (OBS) and the 20km run at Fresno, CA.

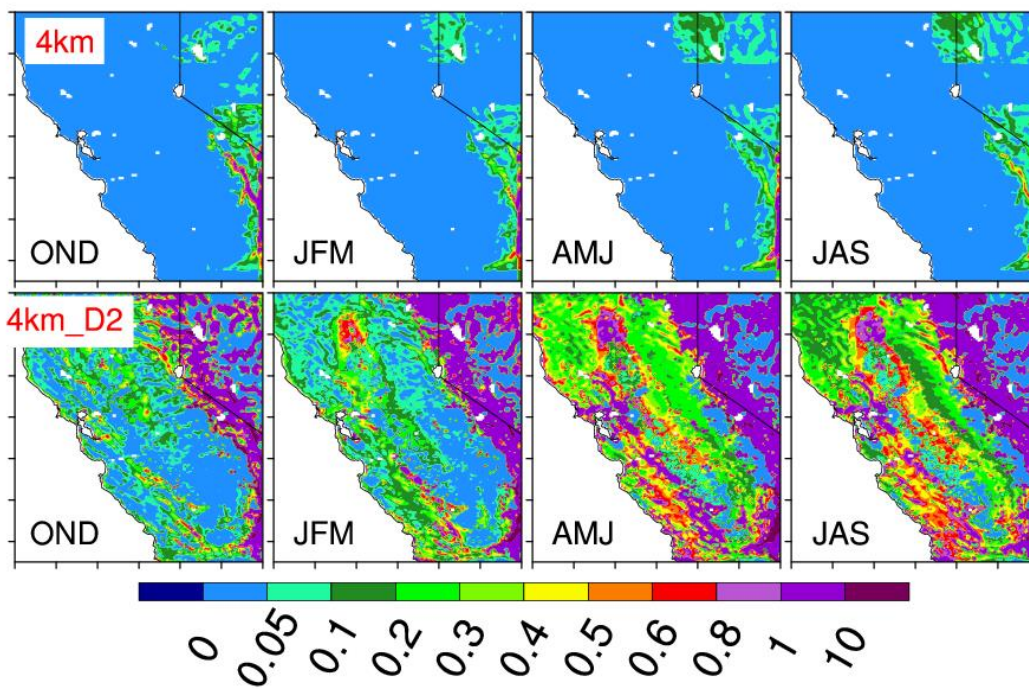

872

873 Figure 7. (a) PM<sub>2.5\_dust</sub>; (b) PM<sub>2.5</sub>; and (c) PM<sub>10</sub> from IMPROVE, the 4km and 4km\_D2

874 simulations at Fresno, CA.

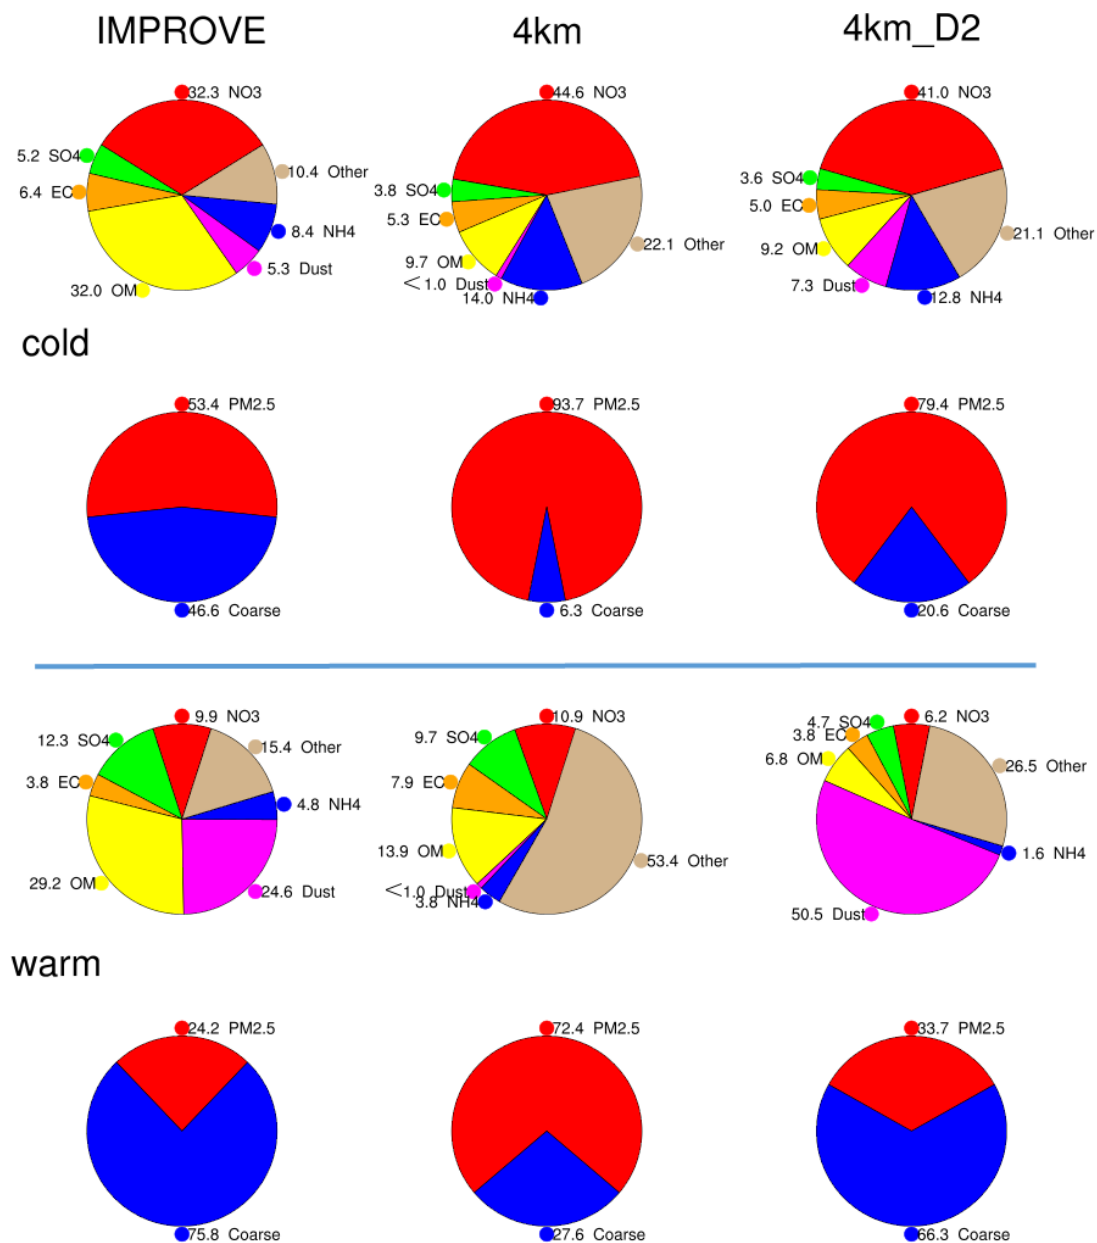

875

876 Figure 8. Mean dust emission rate ( $\mu\text{g m}^{-2} \text{s}^{-1}$ ) from the 4km and 4km\_D2 runs.

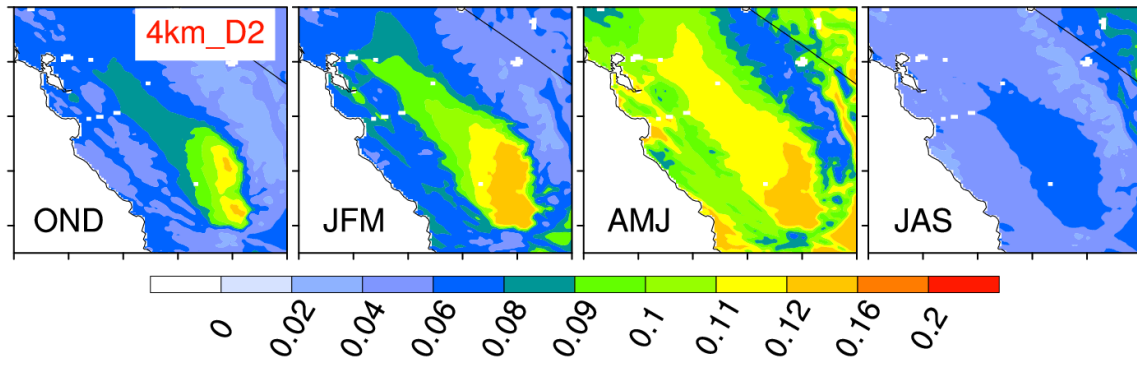

877

878 Figure 9. Fraction of erodible surface in the GOCART dataset used in this study.

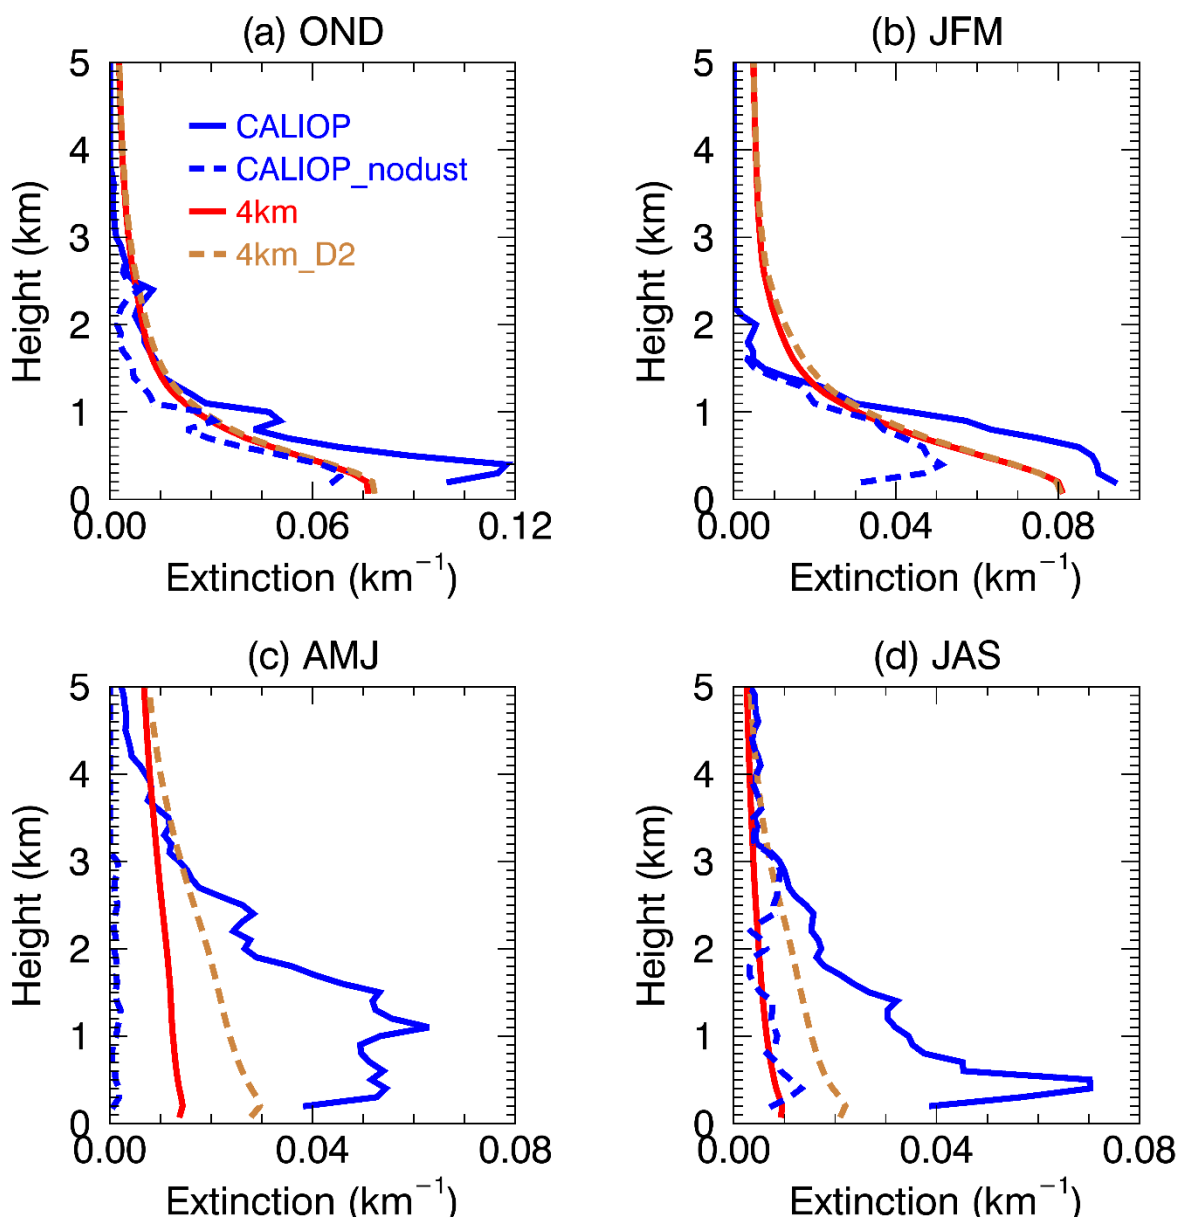

879

880 Figure 10. Relative contribution (%) of aerosol species from IMPROVE and the WRF-Chem (4km  
 881 and 4km\_D2) simulations at Fresno, CA in WY2013. (Panel 1) Contribution to PM<sub>2.5</sub> in the cold  
 882 season; (Panel 2) relative contribution of PM<sub>2.5</sub> and coarse mass (CM) to PM<sub>10</sub> in the cold season;  
 883 (Panel 3) same as Panel 1 but in the warm season; (Panel 4) same as Panel 2 but in the warm season.  
 884 “Other” refers to the difference of PM<sub>2.5</sub> total mass and specified PM<sub>2.5</sub> (NO<sub>3</sub>, NH<sub>4</sub>, OM, EC, SO<sub>4</sub>  
 885 and dust).

886

887 Figure 11. Spatial distribution of seasonal mean 550 nm AOD from the 4km\_D2 run in WY2013.

888

889 Figure 12. Vertical distribution of seasonal mean 532 nm aerosol extinction coefficient ( $\text{km}^{-1}$ )  
 890 from CALIOP (blue) and the WRF-Chem (4km and 4km\_D2) simulations over the red box  
 891 region in Fig. 1a in WY2013. Blue dashed lines (CALIOP\_nodust) represent the CALIOP  
 892 profiles without dust (dust and polluted dust).

893

894 Figure 13. Vertical distribution of season mean equivalent potential temperature ( $\theta_e$ ; K) from AIRS  
 895 and the WRF-Chem (4km\_D2, 20km\_D2 and 20km\_P7) simulations over the red box region in  
 896 Fig. 1a in WY2013. The 4km run (not shown) is similar to the 4km\_D2 run.

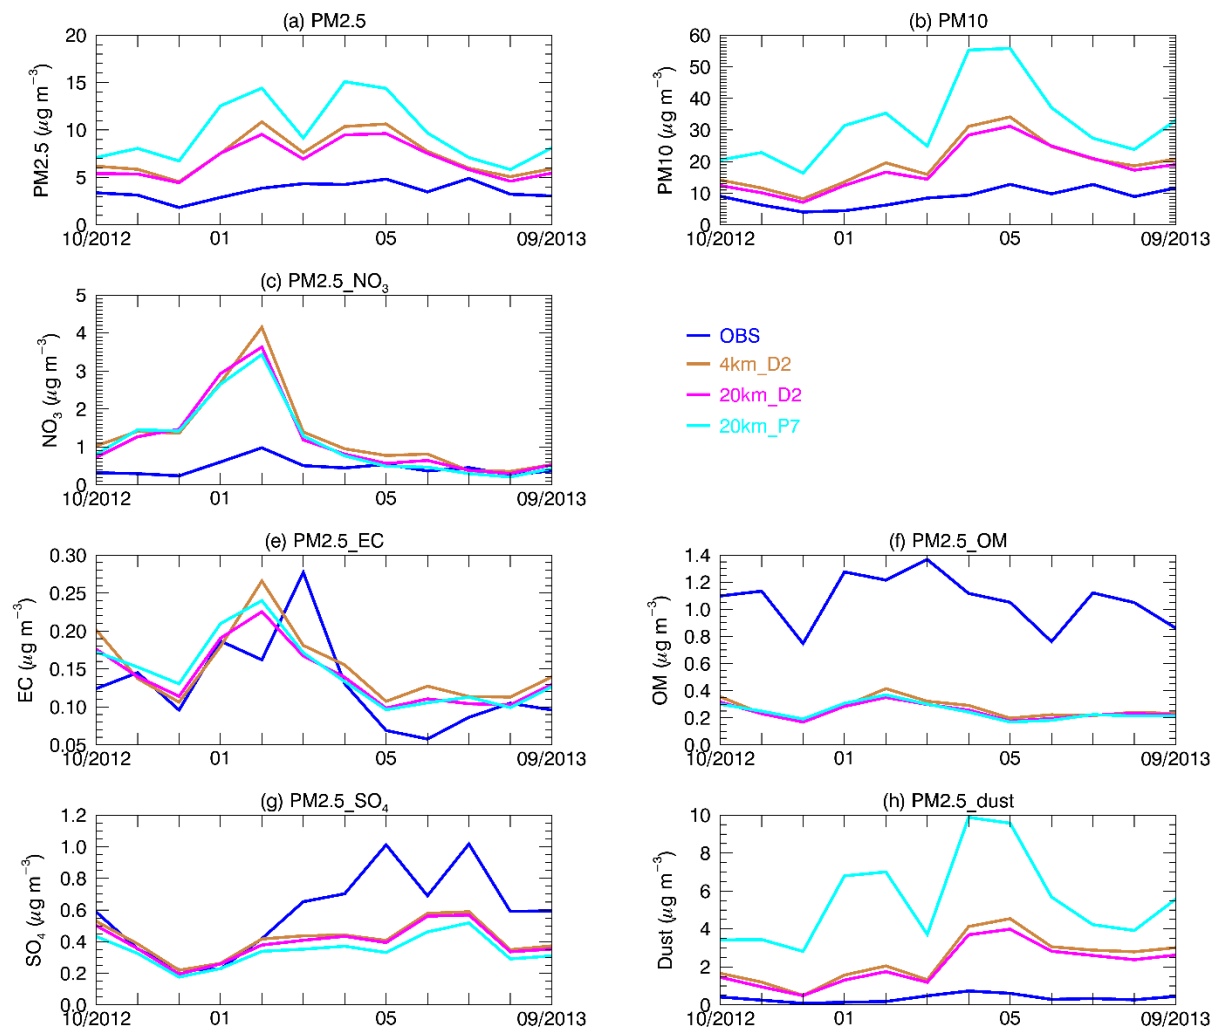

897  
 898 Figure 14. Aerosol mass ( $\mu\text{g m}^{-3}$ ) for different species from OBS, the 4km\_D2, 20km\_D2 and  
 899 20km\_P7 simulations at Fresno, CA. NH<sub>4</sub> observations are from EPA; other observations are from  
 900 IMPROVE. PM<sub>2.5</sub>\_NO<sub>3</sub> represents NO<sub>3</sub> with diameter  $\leq 2.5 \mu\text{m}$ . Similar definition for NH<sub>4</sub>, EC,  
 901 OM, SO<sub>4</sub> and dust in the figures.

902  
 903 Figure 15. Vertical distribution of seasonal mean 532 nm aerosol extinction coefficient ( $\text{km}^{-1}$ )  
 904 from CALIOP, CALIOP\_nodust, and the WRF-Chem (4km\_D2, 20km\_D2 and 20km\_P7)  
 905 simulations over the red box region in Fig. 1a in WY2013.

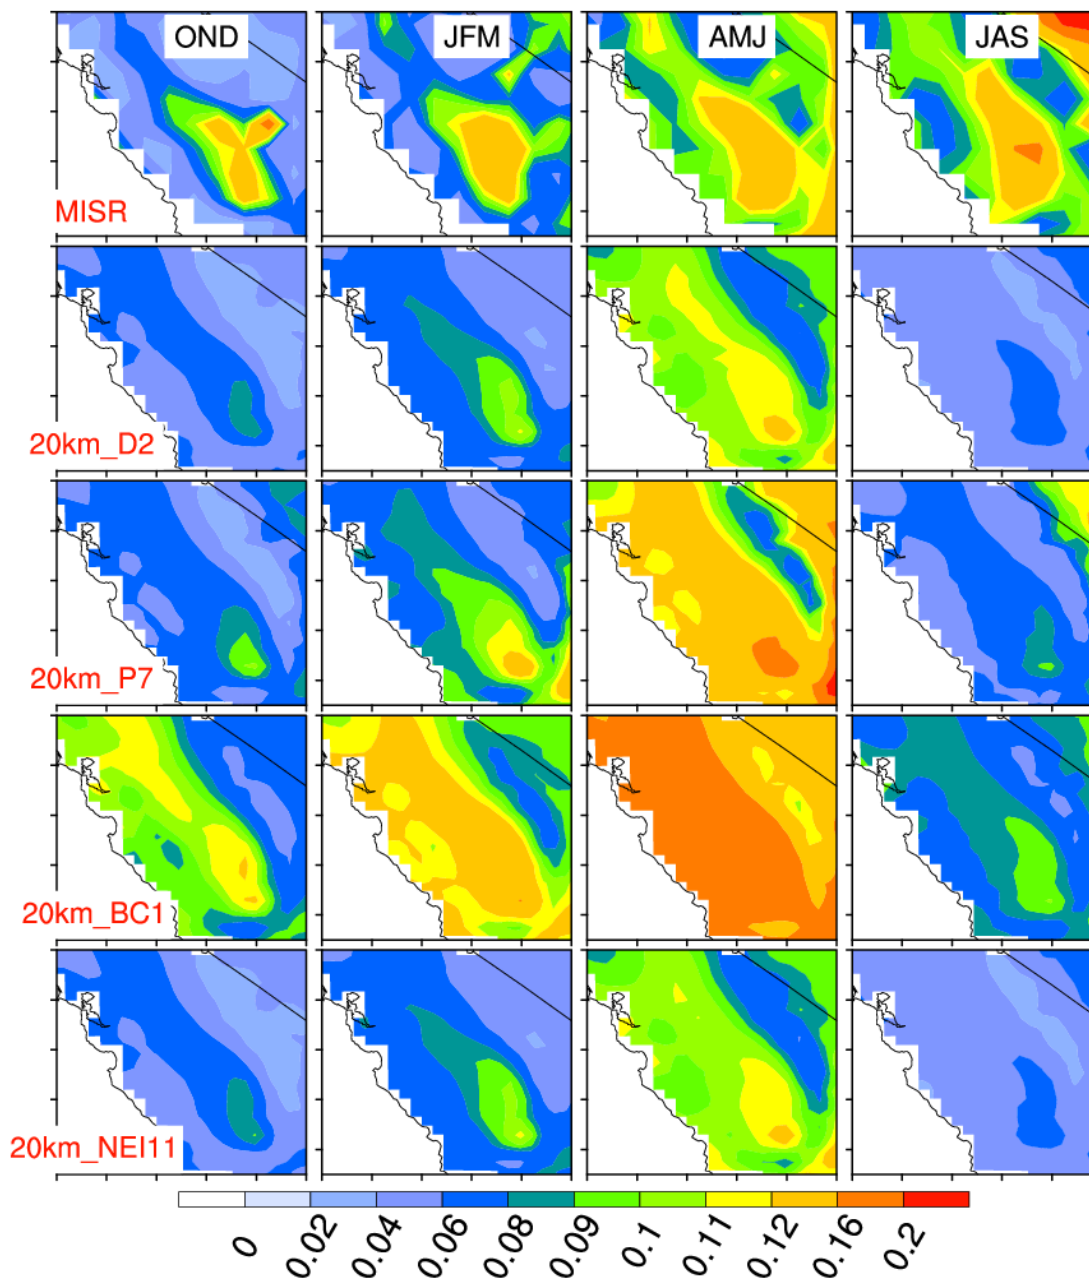

906

907 Figure 16. Aerosol mass ( $\mu\text{g m}^{-3}$ ) for different species from IMPROVE (OBS), the 4km\_D2,  
 908 20km\_D2 and 20km\_P7 simulations at Pinnacles, CA.

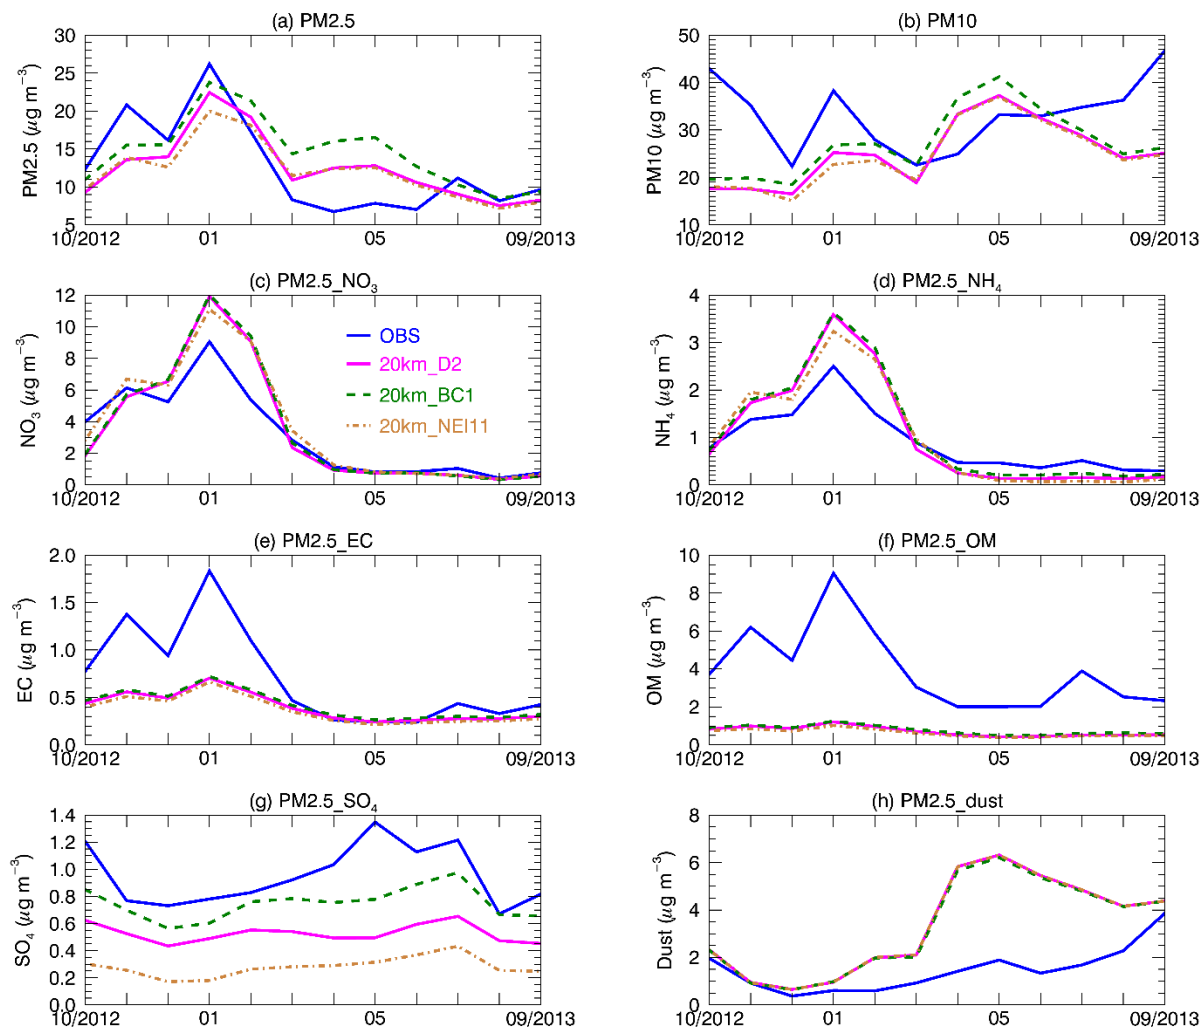

909

910 Figure 17. Aerosol mass ( $\mu\text{g m}^{-3}$ ) for different species from IMPROVE (OBS), the 4km\_D2,  
 911 20km\_D2 and 20km\_P7 simulations at Kaiser, CA.

912

913 Supplementary Figure 1. Spatial distribution of seasonal mean 550 nm AOD from MISR and the  
 914 WRF-Chem (20km\_D2, 20km\_P7, 20km\_BC1 and 20km\_NEI11) simulations in WY2013. OND:  
 915 October-November-December; JFM: January-February-March; AMJ: April-May-June; JAS: July-  
 916 August-September. The 20km\_BC1 run is the same as the 20km\_D2 run except that chemical  
 917 boundary conditions use MOZART-4 original data. The 20km\_NEI11 run is the same as the  
 918 20km\_D2 run except with NEI11 anthropogenic emissions.

919  
 920 Supplementary Figure 2. Aerosol mass ( $\mu\text{g m}^{-3}$ ) for different species from OBS, the 20km\_D2,  
 921 20km\_BC1 and 20km\_NEI11 simulations at Fresno, CA.  $\text{NH}_4$  observations are from EPA; other  
 922 observations are from IMPROVE.  $\text{PM}_{2.5\_}\text{NO}_3$  represents  $\text{NO}_3$  with diameter  $\leq 2.5 \mu\text{m}$ . Similar  
 923 definition for  $\text{NH}_4$ , EC, OM,  $\text{SO}_4$  and dust in the figures.

924  
 925 Supplementary Figure 3. Vertical distribution of seasonal mean 532 nm aerosol extinction  
 926 coefficient (km<sup>-1</sup>) from CALIOP, CALIOP\_nodust, and the WRF-Chem (20km\_D2, 20km\_BC1  
 927 and 20km\_NEI11) simulations over the red box region in Fig. 1a in WY2013.

928

929 Supplementary Figure 4. Aerosol mass ( $\mu\text{g m}^{-3}$ ) for different species from EPA CSN (OBS), the  
 930 4km\_D2, 20km\_D2 and 20km\_P7 simulations at Bakersfield, CA. PM<sub>2.5</sub>\_NO<sub>3</sub> represents NO<sub>3</sub>  
 931 with diameter  $\leq 2.5 \mu\text{m}$ . Similar definition for SO<sub>4</sub>, EC, OM, NH<sub>4</sub> and dust in the figures.

932

933 Supplementary Figure 5. Aerosol mass ( $\mu\text{g m}^{-3}$ ) for different species from EPA CSN (OBS), the  
 934 4km\_D2, 20km\_D2 and 20km\_P7 simulations at Modesto, CA.

935  
 936 Supplementary Figure 6. Monthly mean of (a) 2-m temperature ( $^{\circ}\text{C}$ ); (b) 2-m relative humidity  
 937 (%); (c) 10-m wind speed (m/s); (d) precipitation (mm/day) at Fresno, CA. The 20km (not shown)  
 938 run is similar to the 20km\_D2 run while the 4km (not shown) run is similar to the 4km\_D2 run.

939

940 Supplementary Figure 7. Vertical profile of seasonal mean temperature (K) bias in the WRF-Chem  
 941 simulations comparing to AIRS. The 20km run (not shown) is similar to the 20km\_D2 run while  
 942 the 4km run (not shown) is similar to the 4km\_D2 run.

943

944 Supplementary Figure 8. Vertical profile of seasonal mean relative humidity (%) in the WRF-Chem

945 simulations comparing to AIRS. The 20km run (not shown) is similar to the 20km\_D2 run while

946 the 4km run (not shown) is similar to the 4km\_D2 run.
