re: manuscript number: **acp-2017-1038**

Title: “Large-Scale Tropospheric Transport in the Chemistry Climate Model Initiative (CCMI) Simulations”

Dear Dr. Hess:

We thank the referees for their reviews of our manuscript. The generally positive tone of the reviews is encouraging. After careful consideration of all reviewers’ suggestions we feel that the changes that we have made to the text have improved the manuscript. Before responding to the referees point-by-point, we first address the main issues that the referees raised.

We very much appreciate Reviewer 1’s critical reading of the manuscript. In particular, he/she highlighted that the inverse relationship between the global surface (e90) and Northern Hemisphere midlatitude loss tracers shown in Figure 4b is not intuitive, given that both tracers are subject to prescribed mixing ratios at the surface. We have since clarified in the text that this relationship depends sensitively on latitude and ultimately reflects differences in the meridional gradients of the tracers, consistent with differences in their surface boundary conditions. We feel that this section has improved as a result of the referee’s close reading of the manuscript, although our analysis still remains somewhat limited by the fact that we lack high temporal tracer output that we would need to address the referee’s concerns more thoroughly (i.e. to construct closed tracer

budgets). We hope that our changes are satisfactory to the referee. We also appreciate her/his comments regarding several plotting errors in our figures and ambiguity in some passages in the text.

We also agree with Reviewer 2's general comment that we should more directly address the possibility of constraining tropospheric transport from real observable tracers. To this end we have added a paragraph in the Conclusions section that addresses ways in which combinations of trace gases, including chlorofluorocarbons and sulfur hexafluoride, may be used to infer different aspects of the transit-time distribution (TTD) from observations. Given that previous studies show that the idealized loss tracers may be used to approximate some aspects of this distribution, future research efforts should be paid to extracting more observational estimates of the TTD. We hope that this paragraph addresses the referee's concerns.

We have considered all comments carefully and modified our manuscript accordingly. We have provided two versions of the revised manuscript, one of which includes the corrections highlighted in red. The point-by-point responses to the referee's comments are also attached. We hope that the manuscript is now acceptable for publication in ACP. I confirm that my coauthors, Huang Yang, Darryn W. Waugh, Guang Zeng, Olaf Morgenstern, Douglas E. Kinnison, Jean-Francois Lamarque, Simone Tilmes, David A. Plummer, John F. Scinocca, Beatrice Josse, Virginie Marecal, Patrick Jöckel, Luke D. Oman, Susan E. Strahan, Makoto Deushi, Taichu Y. Tanaka, Kohei Yoshida, Hideharu Akiyoshi, Yousuke Yamashita, Andreas Stenke, Laura Revell, Timofei Sukhodolov, Eugene Rozanov, Giovanni Pitari, Daniele Visioni, Kane A. Stone, Robyn Schofield and Antara Banerjee concur with the submission of our manuscript in its revised form. The revised version of the manuscript has been resubmitted electronically.

Yours sincerely,

Dr. Clara Orbe

**Response to Reviewer 1:**

We thank the reviewer for his/her insightful comments and close reading of the manuscript. ■

**Response to Minor Comments:**

**Comment #1** *P6 L15: the global tracers are also 'idealized loss tracers'.*

Good point. We have corrected this in the text.

**Comment #2** *Fig. 4: the legend is missing the purple points (ULAQ?)*

Thank you for catching this oversight! We have now added those points to the legend.

**Comment #3** *In all figures, several members are considered for some simulations. Please mention this somewhere. Also, there seem to be several members of the specified dynamics runs, what is the point of this if the dynamical fields are nudged and why do they differ substantially (e.g. Fig. 4b)?*

We only use one ensemble member per modeling group, despite the fact that several modeling groups submitted more than one ensemble member. We now state this clearly in the Methods section, where we refer to using only the first (“r1i1p1”) ensemble member for the REF-C1 and REF-C1SD experiments. With regards to the specified dynamics simulations WACCM-C1SDV1 and WACCM-C1SDV2, we hope to clarify to the referee that these are not ensemble members of the same experiment, but rather distinct simulations that use two different relaxation (nudging) times. Furthermore, one of the main conclusions from this study is that, even among simulations that use the same reanalysis fields, we find that there are large differences in their global-scale transport properties related to large differences in (parameterized) convection. Indeed, in some cases, these differences are larger than the convection differences among FR simulations using the same models. We hope that we are being clear.

**Comment #4** *P6 L16-L19: Could you explain why does the dilution argument only apply to the midlatitude tracers.*

Thank you for the comment. We agree with the referee that this is not obvious and more care should have been taken in handling this argument. Indeed, the relationship between the midlatitude tracers and e90 depends sensitively on latitude, a point that we failed to mention in the text. Ultimately, this reflects different (at places, opposite) meridional gradients in the tracer, which are related to the fact that the  $\chi_5$  and  $\chi_{50}$  are subject to prescribed mixing ratios over the NH midlatitude surface, whereas e90 is prescribed globally at the surface. We have amended the text as follows:

“Over the middle and northern edge of the midlatitude source region, however, the tracers exhibit an inverse (and relatively compact) relationship (Figure 4b). While this inverse relationship is not intuitive, it is consistent with differences in the meridional

gradients of the tracers, wherein  $\chi_5$  (e90) increases (decreases) moving poleward from the northern subtropics over northern midlatitudes. Perhaps fortuitously, the NH midlatitude tracers are only sourced in the region of strongest isentropic mixing so that  $\chi_5$  always decreases along an isentropic surface as one moves from the midlatitude surface poleward to the Arctic (Fig. 1a). By comparison, e90 features its largest concentrations over the Arctic (Fig. 1d) so that stronger mixing over midlatitudes can actually dilute tracer mixing ratios along a given isentrope. Thus, the relationship between the surface sourced tracers is not straightforward, but rather sensitive to how two-way mixing operates on different (and, at places, opposite) along-isentropic tracer gradients. More work is needed to disentangle this relationship but is beyond the scope of the current study.”

While the lack of high temporal model output (needed for calculating tracer budgets) precludes a further investigation of the relative roles of advection versus mixing on the tracer concentrations in this region we expect to pursue this further in future studies. We hope that the reviewer understands that we are limited by the available output. We will wait to hear back if our response is satisfactory.

**Comment #5** *P6: I don't see the blue and red curves being particularly low in Fig. 3a-b. This is true only for the comparison of these curves with ULAQ. Could you clarify what you mean? Are you referring to the 30-50N band?*

Thank you for the comment. We agree with the referee that we were not being clear. Yes, we are referring to southern edge of the NH midlatitude (30-50N) band, over which the red and blue dashed lines (Fig 3b) are low not only with respect to the ULAQ model, but also compared to the free-running simulations using the same models (Fig 3a). We have clarified this now in the text. Please also see our response to the previous comment.

**Comment #6** *Fig. 2 and 3- I suggest revising the legend to match the lines shown in the figures. What model does the orange solid line refer to? And the thin brown line? Figures 1 and 2: why are there solid lines in the REFC1SD panels corresponding to the EMAC model? Should these be dashed? Fig. 5: it is hard to distinguish the multi-model mean from the EMAC lines.*

As before, many thanks for this comment. Indeed, we did not include the orange (CMAM) lines in the legend and this has been fixed in the current version of the manuscript. Our apologies for any confusion this has caused. Regarding the solid lines in the REFC1SD panels in Figure 2, we hope to clarify that the grey lines in each panel always refer to the simulations that are not either REF-C1 (in left panels in) or REF-C1SD (in right panels). We never use dashed grey lines. This is mentioned in the caption to that figure and will wait to hear back from the referee if she/he requests further changes. Finally, regarding Figure 5 we understand that the multi-model mean (grey) line may be hard to distinguish from the EMAC lines. For that reason we have changed to a darker (and thicker) grey line. We have changed this in the new versions

of Figures 5 and 7 (for consistency).

**Comment #7** *P6 L31: That paper uses future runs, which cannot be Specified dynamics*

Thank you for pointing out this mistake! We have corrected this in the text. Please see the red comments in the revised manuscript.

**Comment #8** *P6 L33-34, Supplementary Figure 2 and Table 3: It would be helpful to briefly explain what exactly was (wrongly) implemented in the STE tracer for each of the runs.*

Thanks for the comment. We have added a sentence at the end of that paragraph emphasizing that care must be taken when analyzing the STE tracer output as several modeling groups applied the tracer's chemical loss incorrectly (i.e. below 80 mb, not the tropopause).

**Comment #9** *P7 L 2-6: It would be easier for the reader if you pointed to specific longitudes when you refer to regions such as 'over the oceans', 'downstream of the storm tracks' or 'over land'.*

We agree with the referee that adding longitude references would help orient the reader. Please see the new text on Page 7 where we have added those changes.

**Comment #10** *Fig. 6c: The midlatitude convection box located over south-west Asia is not really capturing midlatitude convection, and there is not much convection over most of the box. Instead this box could be placed over central Europe, where there is significant summertime convection.*

We agree with the referee that there are much larger values of CMF over Central Europe. However, note that this convection is north of the midlatitude origin region (as defined in this study) which spans latitudes between 30°N and 50°N. Furthermore, the midtropospheric isentropic surfaces intersect midlatitudes over South/Central Asia, not over Europe, so that this box spans the region that is most important for lifting boundary layer air aloft into the middle and upper troposphere. For both reasons, therefore, we keep the box centered over Asia.

**Comment #11** *Figs. 6 and 7: What are the units of CMF?*

The units of CMF are kg/m<sup>2</sup>/s (mass flux). This is already noted on the colorbars in Figure 6 and on the horizontal axes in Figure 7. We will wait to hear back if the referee prefers that we place these labels elsewhere. Otherwise, the figures have not been changed.

**Comment #12** *P8 L2-4: Is this true also for the other tracers (X50 and e90)?*

This is also true for the longer-lived (and global source) tropospheric loss tracers, as they feature similar gradients over northern midlatitudes. Because their vertical gradients are weaker, however, the impact of convection on the strength of the vertical profile is

slightly weaker.

**Comment #13** *P8 L16-18: Although a useful comparison of the large-scale flow, Supplementary Fig. 3 does not inform on the ‘relationship’ between large-scale flow biases over NH midlatitudes and the transport differences among the simulations? Could you rephrase or add information to justify the claim?*

Thank you for pointing this. Indeed, we are being generous in that claim. We simply mean to comment that there is no obvious relationship between the large-scale vertical velocity strength and the tracer ages among the CCMi simulations. We have added this caveat to the manuscript as follows:

“Note that a more rigorous examination comparing the large-scale flow and transport biases among the simulations is not presented here and would be more appropriate using sub-monthly output (for constructing tracer budgets). As such, our inference here is qualitative.”

Indeed, had we been provided with daily output from the simulations we would hope to have been able to do tracer budget decompositions in terms of the residual mean circulation. One example of such an analysis is presented in the following study (for the e90 tracer and for one model only):

Abalos, Marta, William J. Randel, Douglas E. Kinnison, and Rolando R. Garcia. “Using the artificial tracer e90 to examine present and future UTLS tracer transport in WACCM.” *Journal of the Atmospheric Sciences*, 74, no. 10 (2017): 3383-3403.

**Comment #14** *P9 L12: Could you give an approximate % value of the bias?*

Yes – this is a good suggestion. We have now added the following clause to the end of that line: “by 20-40% for most of the models but up to 60% for others.”

**Comment #15** *Fig. 11 caption: remove ‘strong’*

Thanks – we agree. We have removed that word from the caption.

**Comment #16** *Table 2: It seems that some symbols have disappeared, please revise.*

Thank you for catching this! Sorry that these do not appear clearly. We have changed this accordingly. Please see the new table.

**Response to Reviewer 2:**

We thank the reviewer for his/her comments and careful reading of the manuscript. Our responses are as follows:

**Response to Major Comment:**

**Comment #1** *Since these model transport differences can be attributed to differences in parameterized convection, it would be hard to reduce the transport uncertainties because we don't know which convective schemes are better. It seems that future efforts should be focused on comparing idealized tracers with realistic tracers that are available in observations, which may help to reduce the uncertainty in convective schemes.*

We agree with the referee that observational constraints of the idealized tracers are needed to discern which models are “better.” The mean age with respect to the NH midlatitude surface (noted herein as  $\Gamma_{\text{NH}}$ ) can be compared with surface observations of sulfur hexafluoride, after being recast in terms of an “SF<sub>6</sub>-age” as in *Waugh et al. 2013*. The estimates from that study indicate that the mean ages in the CMI simulations are old, compared to the observations. However, more work is needed to identify observable species that can be used to constrain other aspects of the underlying transit-time distribution (of which the mean is the “mean age”). One approach that looks promising is presented in another study (*Holzer and Waugh (2015)*, now cited), in which the authors use combinations of different chlorofluorocarbons (CFCs) and CFC-replacement compounds to constrain the TTD connecting the SH to the NH midlatitude surface. More work is needed to extend this approach to tracers with different source regions and to different regions in the troposphere. We now mention these issues in a new paragraph that we have added to the Conclusions section. We hope that this addresses the reviewer’s concerns.

**Response to Minor Comments:**

**Comment #1** *P4, L22: When the data are interpolated in pressure, were the pressure levels below the ground treated by missing values or linear interpolation?*

Our apologies for not mentioning this in the text. We treat values below the ground as missing (NaN) values. We have now added a sentence to the methods section mentioning this. Thanks for the comment.

**Comment #2** *P4, L30: This schematic refers to the mean meridional circulation only in the tropics*

Thank you for catching this! Indeed, in a previous version of the figure we had overlaid a schematic of the residual mean (thermally direct) circulation as it extends out to the extratropics. However, we failed to correct the corresponding text, which we have now

revised. Thank you for the comment.

**Comment #3** *It might be noted that the tracer isolines tend to be more vertical than the isentropic surfaces in summer compared to winter, which indicates moisture may also contribute to the isolation of the Arctic from midlatitudes in summer latent heat release allows moist air parcel rising along a front faster than a dry parcel*

We agree with the referee that this is an important point to include in the text. Indeed, because of transport associated with moist latent heat release the tracer isolines are not parallel to the (dry) surfaces of constant potential temperature (neither in summer nor winter). We have included this caveat in the text. Thanks for the comment.

**Abstract.** Understanding and modeling the large-scale transport of trace gases and aerosols is important for interpreting past (and projecting future) changes in atmospheric composition. Here we show that there are large differences in the global-scale atmospheric transport properties among models participating in the IGAC SPARC Chemistry-Climate Model Initiative (CCMI). Specifically, we find up to 40% differences in the transport timescales connecting the Northern Hemisphere (NH)

5 midlatitude surface to the Arctic and to Southern Hemisphere high latitudes, where the mean age ranges between 1.7 years

and 2.6 years. We show that these differences are related to large differences in vertical transport among the simulations and, in particular, to differences in parameterized convection over the oceans. While stronger convection over NH midlatitudes is associated with slower transport to the Arctic, stronger convection in the tropics and subtropics is associated with faster interhemispheric transport. We also show that the differences among simulations constrained with fields derived from the same reanalysis products are as large as (and, in some cases, larger than) the differences among free-running simulations, due to larger differences in parameterized convection. Our results indicate that care must be taken when using simulations constrained with analyzed winds to interpret the influence of meteorology on tropospheric composition.

## 1 Introduction

The distributions of greenhouse gases (GHG) and ozone-depleting substances (ODS) are strongly influenced by large-scale atmospheric transport. In the extratropics the midlatitude jet stream influences the long-range transport of pollutants and water vapor into the Arctic (e.g., *Eckhardt et al.*, 2003; *Shindell et al.*, 2008; *Liu and Barnes*, 2015), as well as surface ozone variability over the Western United States (*Lin et al.*, 2015). In the tropics, low-level inflow and seasonal variations in the Hadley Cell modulate trace gas variability in the tropics and interhemispheric transport into the Southern Hemisphere (SH) (*Prather et al.*, 1987; *Mahlman*, 1997; *Holzer*, 1999; *Bowman and Erukhimova*, 2004).

There are large uncertainties in our understanding of how large-scale atmospheric transport influences tropospheric composition. This is largely because transport is difficult to constrain directly from observations and because global-scale tropospheric transport properties differ widely among models. For example, *Denning et al.* (1999) found more than a factor of two difference in the interhemispheric exchange rate among simulations produced using both offline chemical transport models (CTMs) and online free-running general circulation models (GCMs).

One approach to reducing this uncertainty has been to use models constrained with analysis fields, although comparisons of the transport properties among these simulations also reveal large differences. For example, *Patra et al.* (2011) showed that the interhemispheric transport differences among CTMs participating in the TransCOM experiment differ by up to a factor of two, with models featuring faster interhemispheric transport also exhibiting faster exchange of methane and methyl chloroform. It is not clear, however, whether these differences reflect subgrid-scale differences among CTMs or differences in the prescribed large-scale flow, since that study included simulations that were constrained with three different sources of meteorological fields.

More recently, *Orbe et al.* (2017) compared the global-scale tropospheric transport properties among free-running simulations using internally generated meteorological fields as well as simulations constrained with analysis fields using models developed at NASA Goddard Space Flight Center and the Community Earth System Model framework (CESM) (run at the National Center for Atmospheric Research (NCAR)). They showed that the large-scale transport differences among simulations constrained with analysis fields are as large as (and, in some cases, larger than) the differences among free-running simulations. Furthermore, they found that these differences – manifest over southern high latitudes as a 0.6 year (or  $\sim 30\%$ ) difference in the mean age since air was last at the Northern Hemisphere (NH) midlatitude surface – were associated with large differences in

(parameterized) convection, particularly over the NH tropics and subtropics. By comparison, the mean age differences between the free-running simulations were found to be negligible, consistent with much more similar convective mass fluxes.

The results in *Orbe et al. (2017)* indicate that care must be taken when using simulations constrained with analysis fields to interpret the influence of meteorology on tropospheric composition. It is not clear, however, if the conclusions from that study reflect only that particular subset of models and/or the particular ways in which those models were constrained with analysis fields. To this end we exploit the broad range of both free-running online and offline (i.e. nudged and CTM) simulations submitted to the recent IGAC/SPARC Chemistry-Climate Model Initiative (CCMI) (*Eyring et al., 2013*) in order to test some of the key findings in that study. In particular, we focus on the CCMI hindcast simulations of the recent past, which include simulations constrained with both prescribed and internally generated meteorological fields, while sea surface temperatures (SSTs) and sea ice concentrations (SICs) are taken from observations. Thus, the CCMI hindcast experiment provides a relatively clean framework for assessing the influence of different meteorological fields on large-scale atmospheric transport.

As in *Orbe et al. (2017)* we focus on large-scale tropospheric transport diagnosed from idealized tracers that, unlike the usual basic flow diagnostics (e.g. mean winds, streamfunctions, mean eddy diffusivities), represent the integrated effects of advection and diffusion while cleanly disentangling the roles of transport from chemistry and emissions. Furthermore, unlike previous intercomparisons that have diagnosed atmospheric transport in terms of one single timescale (e.g. the interhemispheric exchange rate (*Denning et al., 1999; Patra et al., 2011*)), we utilize tracers with different prescribed atmospheric lifetimes and different source regions in order to probe the broad range of timescales and pathways over which tropospheric transport occurs (*Orbe et al., 2016*). Following a brief exposition of the methodology in Section 2 we present results in Sections 3 and conclusions in Section 4.

## 20 **2 Methods**

### **2.1 Models and Experiments**

Our analysis uses models participating in CCMI, which builds upon previous chemistry-climate model intercomparisons, including the SPARC Report on the Evaluation of Chemistry-Climate Models (*CCMVal, 2010*) and The Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) (*Lamarque et al., 2013*), by including several coupled atmosphere-ocean models with a fully resolved stratosphere. For example, more (nine) models are atmosphere-ocean (versus only one in CCMVal-2 and one in ACCMIP) and more models incorporate novel (e.g. cubed-sphere) grids (*Morgenstern et al., 2017*).

We focus only on those CCMI model simulations that output the idealized tracers (Table 1, Table 2). We present results from the pair of hindcast REF-C1 (simply C1) and REF-C1SD (or C1SD) simulations, which were constrained with observed SSTs and SICs. **For each model, we analyze the first ensemble member “r1i1p1” from the REF-C1 and REF-C1SD simulations.** Whereas the REF-C1 experiment simulates the recent past (1960-2010) using internally generated meteorological fields, the REF-C1SD or C1 “Specified Dynamics” simulation is constrained with (re)analysis meteorological fields and, correspondingly, only spans the years 1980-2010. Note that both online nudged simulations as well as offline CTMs are used, as indicated in the simulation name. Furthermore, while we have also examined tracer output from the REF-C2 simulation, which used SSTs

from a coupled atmosphere-ocean model simulation, we find that the differences in the idealized tracers between the REF-C2 and REF-C1 simulations are significantly smaller than among the hindcast (C1 versus C1SD) simulations. For that reason, hereon we exclude the REF-C2 results from our discussions.

The simulations presented in *Orbe et al. (2017)* using models from NASA and NCAR are included in our analysis and denoted in all figures using a color convention that is similar to what was used in that study. Note that this subset of runs includes two REF-C1SD simulations per modeling group. In particular, the GEOS-CTM and GEOS-C1SD simulations refer to one simulation of the NASA Global Modeling Initiative (GMI) Chemical Transport Model (*Strahan et al., 2013*) and one simulation of the Goddard Earth Observing System General Circulation Model Version 5 (GEOS-5) (*Reinecker et al., 2007; Molod et al., 2015*), respectively; they are both constrained with fields taken from The Modern-Era Retrospective Analysis for Research and Applications (MERRA) (*Rienecker et al., 2011*). Meanwhile, the WACCM-C1SDV1 and WACCM-C1SDV2 correspond to two simulations of the Whole Atmosphere Community Climate Model (*Marsh et al., 2013*) nudged to MERRA meteorological fields using two different relaxation timescales (i.e. 50 hours and 5 hours).

In addition to differences among the REF-C1 and REF-C1SD experiments, the models differ widely in terms of their horizontal resolution, which ranges from  $\sim 6$  degrees (e.g. ULAQ) to  $\sim 2$  degrees (e.g. NCAR and NASA), vertical resolution, and choices of sub-grid scale (i.e. turbulence and convective) parameterizations (*Morgenstern et al., 2017*). Table 1 summarizes some of the main differences among the models, as well as the method by which the large-scale flow was constrained in the REF-C1SD simulations (i.e. CTM versus nudging). For more details please refer to the comprehensive overview presented in *Morgenstern et al. (2017)*.

Finally, we complement our analysis of the idealized tracers with comparisons of the models' convective mass fluxes, horizontal and vertical winds, and temperature fields (when available) (Table 3). All tracer and dynamical variables were available as monthly mean output on native model levels. Therefore, we interpolated all output to a standard pressure vector with 4 pressure levels in the stratosphere (10, 30, 50 and 80 hPa) and 19 pressure levels in the troposphere spaced every 50 hPa between 100 hPa and 1000 hPa. **Note that values for pressure levels below the surface topography are treated as missing (NaN) values for all simulations.** To construct all of the multi-model means (denoted in the figures using solid grey lines) we first interpolated all model output to the same one-degree latitude by one-degree longitude grid and then took the average among the models. As in *Orbe et al. (2017)* our focus is on seasonal averages over December-January-February (DJF) and June-July-August (JJA) and on ten-year climatological means over the time period 2000-2009, which are denoted throughout using overbars.

## 2.2 Idealized Tracers

Several of the idealized tracers examined in this study (Table 2) were discussed in *Orbe et al. (2016, 2017)*. Figure 1 shows boreal winter (DJF) and boreal summer (JJA) climatological mean distributions of the tracers for one model simulation, which has been chosen purely for illustrative purposes. This is the GEOS-CTM simulation that was presented in *Orbe et al. (2017)* and described in the previous section. Schematic representations of the seasonally averaged mean meridional circulation in the

tropics and arrows denoting mixing by eddies over midlatitudes, are also shown to help guide the interpretation of the tracer distributions (Fig. 1f).

Three of the tracers' boundary conditions are zonally uniform and are defined over the same NH surface region over mid-latitudes,  $\Omega_{\text{MID}}$ , which we define as the first model level spanning all grid points between 30°N and 50°N (rows 2-4 in Table 2, Figure 1 a-b). The first two tracers,  $\chi_5$  and  $\chi_{50}$ , referred to throughout as the 5-day and 50-day idealized loss tracers, are fixed to a value of 100 ppb over  $\Omega_{\text{MID}}$  and undergo spatially uniform exponential loss at rates of 5 days<sup>-1</sup> and 50 days<sup>-1</sup>, respectively. The climatological mean distributions of the loss tracers, denoted throughout as  $\bar{\chi}_5$  and  $\bar{\chi}_{50}$ , decrease poleward away from the midlatitude source region during boreal winter, when tracer isopleths coincide approximately with isentropes that intersect the Earth's surface, reflecting the strong influence of isentropic mixing on surface source tracer distributions over middle and high latitudes (Fig 1f). **Note, however, that this is merely an approximation, since vertical mixing by synoptic eddies and moist convection renders the tracer isolines steeper than dry isentropic surfaces.** During summer, the idealized loss tracer patterns extend significantly higher into the upper troposphere over midlatitudes, consistent both with weaker isentropic transport over the northern extratropics and stronger convection over the continents (*Klonecki et al., 2003; Stohl, 2006; Orbe et al., 2015*). Compared to  $\bar{\chi}_5$ , which is mainly confined to the NH extratropics, large values of  $\bar{\chi}_{50}$  span the NH subtropics and tropics.

The third NH midlatitude tracer,  $\Gamma_{\text{NH}}$ , is initially set to a value of zero throughout the troposphere and held to zero thereafter over  $\Omega_{\text{MID}}$  (Fig.1c). Elsewhere over the rest of the model surface layer and throughout the atmosphere  $\Gamma_{\text{NH}}$  is subject to a constant aging of 1 year/year so that its statistically stationary value, the mean age, is equal to the average time since the air at a given location in the troposphere last contacted the NH midlatitude surface  $\Omega_{\text{MID}}$  (*Waugh et al., 2013*). The strongest meridional gradients in the mean age  $\Gamma_{\text{NH}}$ , which increases from  $\sim 3$  months in the NH extratropical lower troposphere to  $\sim 2$  years over SH high latitudes, are located in the tropics and migrate north and south in concert with seasonal shifts in the Intertropical Convergence Zone (ITCZ) and the mean meridional circulation (Fig. 1f) (*Waugh et al., 2013*).

In addition to the NH midlatitude source tracers, we also examine two other tracers with global sources. The first tracer,  $\chi_{\text{STE}}$ , is set to a constant value of 200 ppb above 80 hPa and undergoes spatially uniform exponential loss at a rate of 25 days<sup>-1</sup> in the troposphere. The second tracer, e90 is uniformly emitted over the surface layer and decays exponentially at a rate of 90 days<sup>-1</sup> such that mixing ratios greater than 125 ppb tend to reside in the lower troposphere and mixing ratios smaller than 50 ppb reside in the stratosphere (*Prather et al., 2011*). While their mean gradients are opposite in sign, due to differences in their boundary conditions, both tracers feature pronounced signatures of isentropic transport in the subtropical upper troposphere along isentropes spanning the middleworld (*Hoskins, 1991*). This is evident in the plume of large mixing ratios of  $\chi_{\text{STE}}$  and, conversely, small concentrations of e90, that extends down from the tropopause to the subtropical surface (Fig. 1 d-e). The seasonality of this isentropic transport is captured by the relatively larger (smaller) values of  $\chi_{\text{STE}}$  (e90) in the northern subtropical upper troposphere during winter, compared to during summer (and vice versa in the SH).

### 3 Results

#### 3.1 Transport to Northern Hemisphere High Latitudes

##### 3.1.1 Differences in Transport

Meridional profiles of  $\bar{\chi}_5$  and  $\bar{\chi}_{50}$ , averaged over the middle troposphere (400-700 hPa), differ widely among the simulations  
5 over the NH extratropics (Figure 2). Over northern midlatitudes  $\bar{\chi}_5$  differs by up to a factor of 5 during boreal winter and a  
factor of 2-3 during boreal summer. The spread in the 50-day loss tracer,  $\bar{\chi}_{50}$ , is similar, consistent with the strong compact  
relationship between the loss tracers, such that simulations featuring low concentrations of  $\bar{\chi}_5$  also feature low concentrations  
of  $\bar{\chi}_{50}$  (and vice versa) (see also Figure 4a below). During summer, the differences in  $\bar{\chi}_{50}$  extend all the way to the pole,  
where  $\bar{\chi}_{50}^{\text{JJA}}$  ranges between  $\sim 20$ -50 ppb among the simulations. Note that these differences are overall much larger than the  
10 differences among the simulations presented in *Orbe et al. (2017)* (red and blue lines, Fig. 2), which feature consistently larger  
concentrations of  $\bar{\chi}_5$  and  $\bar{\chi}_{50}$  over northern middle and high latitudes compared to the other simulations, indicative of more  
efficient poleward transport in those models.

Interestingly, the differences in the concentrations of  $\bar{\chi}_5$  and  $\bar{\chi}_{50}$  among the C1SD simulations are as large as the differences  
among the C1 simulations. For example, the 5-day loss tracer concentrations over midlatitudes range between 9-22 ppb during  
15 boreal summer among both the C1 and C1SD simulations (Fig. 2b). During boreal winter the spread among the C1 simulations  
is slightly larger, but closer inspection shows that this only reflects the inclusion of one outlier simulation (Fig. 2a,c). Overall,  
this is consistent with *Orbe et al. (2017)*, who found that the transport differences between two simulations of GEOS-5 and  
WACCM constrained with fields taken from MERRA were as large as (and, at places, larger than) the differences between  
free-running simulations generated using the same models.

20 Comparisons of the global source tracer e90 also reveal large differences among the simulations (Figure 3). **The spread in  
e90 mixing ratios is similar in magnitude to the spread in the concentrations of the idealized loss tracers, consistent with the fact  
that they all have prescribed surface mixing ratios. At the same time, the relationship between e90 and the midlatitude sourced  
tracers is complicated and depends sensitively on latitude. In particular, over the southern edge of the NH midlatitude source  
region we find that e90 and  $\chi_5$  are positively correlated, such that simulations with relatively large mixing ratios of  $\chi_5$  and  $\chi_{50}$   
25 (blue and red lines in Figure 2 a,c) also feature relatively larger mixing ratios of e90 (Figure 3 a). Over the middle and northern  
edge of the midlatitude source region, however, the tracers exhibit an inverse (and relatively compact) relationship (Figure 4b).  
While this inverse relationship is not intuitive, it is consistent with differences in the meridional gradients of the tracers, wherein  
 $\chi_5$  (e90) increases (decreases) moving poleward from the northern subtropics over northern midlatitudes. Perhaps fortuitously,  
the NH midlatitude tracers are only sourced in the region of strongest isentropic mixing so that  $\chi_5$  always decreases along an  
30 isentropic surface as ones moves from the midlatitude surface poleward to the Arctic (Fig. 1a). By comparison, e90 features its  
largest concentrations over the Arctic (Fig. 1d) so that stronger mixing over midlatitudes can actually dilute tracer mixing ratios  
along a given isentrope. Thus, the relationship between the surface sourced tracers is not straightforward, but rather sensitive**

to how two-way mixing operates on different (and, at places, opposite) along-isentropic tracer gradients. More work is needed to disentangle this relationship but is beyond the scope of the current study.

The spread in  $\chi_{\text{STE}}$  among the CCMi simulations is also large (Figure 3c-d). However, care must be taken when interpreting differences in  $\chi_{\text{STE}}$  as solely reflecting differences in stratosphere-troposphere-exchange. In particular, the distribution of  $\chi_{\text{STE}}$  in the outlier simulations (i.e. NIWA C1 and ACCESS C1) may reflect the fact that these models use a hybrid-height vertical coordinate such that the tracer's 80 hPa upper boundary condition is not parallel to any model level and, therefore, more easily communicated to lower levels (Supplementary Figure 1). Furthermore, while the NIWA and ACCESS simulations use essentially the same model, we note that there are small differences between them that may reflect differences in computing platforms.

Among the other simulations, by comparison, the differences in  $\chi_{\text{STE}}$  emerge below the tropopause, where they more likely reflect differences in isentropic mixing in the subtropical upper troposphere. Among those simulations there is a relatively compact relationship between  $\overline{\chi_{\text{STE}}}^{\text{DJF}}$  and  $\overline{e90}^{\text{DJF}}$  during boreal winter over the northern subtropical upper troposphere (Figure 4c), consistent with the *Abalos et al. (2017)* analysis of a free-running integration of WACCM similar to the WACCM-C1 simulation presented in this study, albeit constrained with model-generated sea surface temperatures and sea ice concentrations.

Similar to the findings in that study, our results suggest that both tracers may be useful metrics for discerning stratosphere-troposphere-exchange differences among models. Finally, comparisons of the spatial distributions of  $\chi_{\text{STE}}$  fail to reveal any consistencies with differences in tropopause height among the simulations, which are not negligible (Supplementary Figure 2). This indicates that differences in tropopause height are not likely to be the primary drivers of the  $\chi_{\text{STE}}$  differences within the CCMi ensemble. Furthermore, we note that special care must be taken when examining the  $\chi_{\text{STE}}$  tracer output since some modeling groups applied exponential loss at all levels below 80 hPa (instead of the tropopause, as recommended).

Zonal profiles of  $\overline{\chi}_5$  reveal that differences in the loss tracer distributions over the Arctic reflect differences in isentropic transport originating over the northern subtropical oceans (Figure 5). During winter large differences in  $\overline{\chi}_5^{\text{DJF}}$  emerge over the oceans in the lower troposphere (900 mb) (Fig. 5c) and propagate along isentropes towards high latitudes downstream of the stormtracks (180°E-120°W, 60°W-20°E) (Fig. 5e). By comparison, during boreal summer, the large differences in  $\overline{\chi}_5^{\text{JJA}}$  that emerge in the subtropics over land (120°W-60°W, 30°E-120°E) (Fig. 5b) remain relatively confined over midlatitudes. Rather, the differences in  $\overline{\chi}_5^{\text{JJA}}$  over the Arctic, more likely reflect differences that emerge over the midlatitude oceans over the northern edge of the source region (Fig. 5d). We interpret these transport differences next in terms of differences in the large-scale flow and (parameterized) convection among the simulations.

### 3.1.2 Differences in Northern Midlatitude Convection and Large-Scale Flow

One approach to interpreting the large differences in poleward transport among the CCMi simulations is to compare the (parameterized) convection and horizontal flow fields over northern midlatitudes (Figure 6). During winter the multi-model mean convective mass fluxes ( $\overline{\text{CMF}}^{\text{DJF}}$ ) in the lower troposphere (700-900 mb) (Fig. 6a) are concentrated over the Pacific and Western Atlantic (black boxes). These regions coincide with the climatological mean position of warm conveyor belts at the midlatitude jet entrance regions (*Eckhardt et al., 2004*) as well as with low values of potential temperature ( $280\text{K} < \theta < 290\text{K}$ )

approximately along which surface mixing ratios of  $\overline{\chi_5}^{\text{DJF}}$  propagate poleward into the upper and middle high latitude troposphere (Fig. 1a; Fig. 6b).

By comparison, during boreal summer the (parameterized) convective mass fluxes are generally weaker over midlatitudes and shift from the oceans toward land, coincident with weaker and zonally shifted storm tracks. Seasonal changes in the thermal structure of the extratropics also indicate that the Arctic is isentropically isolated from the northern midlatitude surface during summer, compared to winter (Klonecki *et al.*, 2003). The CCMI simulations capture this seasonality well, in terms of both the convective mass flux distributions (Fig. 6c) and in the redistribution of potential temperature surfaces (Fig. 6d). Any differences in transport among the simulations that emerge over the northern midlatitude surface, therefore, are more likely to be confined to the midlatitude upper troposphere during boreal summer, compared to during winter.

Comparisons of vertical profiles of the convective mass fluxes (CMF) over northern midlatitudes (black boxed regions in Figure 6), reveal large differences in (parameterized) convection among the models during both boreal winter and summer (Figure 7). Among the “weak midlatitude convection” simulations (i.e. NASA and NCAR), the strength of  $\overline{\text{CMF}}^{\text{DJF}}$  is at places half (West Pacific) and one third (West Atlantic) the strength in the “strong midlatitude convection” simulations (i.e. NIWA, ACCESS and EMAC). Note that the latter simulations use convection parameterizations that have a diagnostic closure scheme based on large-scale convergence (i.e. based on that of Tiedtke (1989)), whereas the former simulations’ utilize relaxed and/or triggered adjustment schemes in which adjustments to explicitly defined moist-convective equilibrium states are partly relaxed (Arakawa, 2004) (Table 1). While the former class of parameterizations tends to produce excessive precipitation relative to observations (Garcia *et al.*, 2017) further analysis of the differences among the models’ convection schemes is beyond the scope of this study.

Closer inspection of the loss tracer profiles at 30°N during boreal winter reveals that simulations with strong convection over the oceans also feature steeper vertical profiles of  $\overline{\chi_5}$ , compared to models with weaker convection (not shown). This reflects the influence of convective updrafts mixing large near-surface concentrations aloft and convective downdrafts mixing low upper-tropospheric concentrations to the surface (Zhang *et al.*, 2008). As a result, among simulations with stronger (parameterized) convective mass fluxes we find overall *smaller* concentrations of  $\overline{\chi_5}^{\text{DJF}}$  at the midlatitude surface and, correspondingly, smaller concentrations over the Arctic, compared to simulations with weaker convection over the midlatitude oceans.

This is illustrated more clearly in Figure 8, which shows strong negative correlations during boreal winter between lower tropospheric (800-950 hPa) convection ( $\overline{\text{CMF}}^{\text{DJF}}$ ), evaluated over the midlatitude oceans, and zonal mean concentrations of  $\overline{\chi_5}^{\text{DJF}}$ , averaged poleward of 60°N and over the middle troposphere (Figure 8 a-c). The strong negative correlations indicate that models with weak convection over the oceans are associated with more efficient transport to the Arctic (i.e. less surface dilution and larger mixing ratios of  $\overline{\chi_5}^{\text{DJF}}$ ). Note that this relationship is robust among the CCMI simulations over various ocean basins despite (large) interannual variability over the 2000-2009 climatological period examined in this study.

We also find evidence of a relationship between midlatitude convection and the loss tracer concentrations over the Arctic during boreal summer, although this relationship is relatively weaker (Figure 8 d-f). This most likely reflects the fact that the Arctic is isentropically isolated from the northern midlatitude surface during boreal summer, compared to during winter (Klonecki *et al.*, 2003). Preliminary analyses indicate that differences in the northern boundary of the Hadley Cell among the

simulations may also play an important role in understanding the differences in poleward transport during boreal summer, as discussed further in *Yang et al. (2017, In Prep)*. In contrast, comparisons of the pressure velocity  $\omega$  among the models do not reveal a consistent relationship between large-scale flow biases over NH midlatitudes and the transport differences among the simulations for either season (Supplementary Figure 3). **Note that a more rigorous comparison of the large-scale flow and transport biases among the simulations is not presented here as sub-monthly diagnostic output was not available (for example, daily output for constructing tracer budgets). As such, our comments here are qualitative.**

## 3.2 Interhemispheric Transport

### 3.2.1 Differences in Transport

We now compare different measures of interhemispheric transport among the models. As in *Orbe et al. (2016)* we recast the idealized loss tracer concentrations  $\chi_5$  and  $\chi_{50}$  in terms of “tracer ages”  $\tau_5$  and  $\tau_{50}$ , where  $\tau_T(\mathbf{r}, t) = -T \ln(\frac{\chi_T(\mathbf{r}, t)}{\chi_\Omega})$ ,  $\Omega$  is the NH midlatitude source region  $\Omega_{\text{MID}}$  and T refers to the exponential decay timescales 5 days and 50 days, respectively. This is a common approach in oceanography and facilitates comparison with the NH midlatitude mean age  $\Gamma_{\text{NH}}$  (*Deleersnijder et al., 2001; Waugh and Hall, 2002*).

Meridional profiles of the annually averaged  $\tau_5$ ,  $\tau_{50}$  and  $\Gamma_{\text{NH}}$  reveal large differences among all of the tracer ages over the middle troposphere (300-600 mb) (Figure 9), with Southern Hemisphere (SH) values of  $\tau_5$  ranging between 70 days and 90 days, or  $\sim 25\%$  of the multimodel mean, while the mean age  $\Gamma_{\text{NH}}$  varies between 1.7 years and 2.6 years, or about  $\sim 40\%$  of the multimodel mean. The differences in the tracer ages among the simulations emerge primarily in the tropics and are more-or-less consistent among the different ages such that simulations that tend to have small values of  $\tau_5$  (relative to the multi-model mean) also feature relatively small values of the mean age  $\Gamma_{\text{NH}}$ . This indicates that the age tracer differences arise due to transport differences in the tropical and subtropical lower troposphere and not in response to differences in the lower stratosphere, to which the 5-day age tracer is insensitive.

Consistent with the results in *Orbe et al. (2017)* we find that the interhemispheric transport differences among the C1SD simulations are as large as the differences among the free-running C1 simulations. Interestingly this applies not only to simulations constrained with MERRA analysis fields (i.e. GEOS-CTM, GEOS-C1SD, WACCM C1SDV1/V2, and CAM C1) but also simulations constrained with fields from ERA-Interim (i.e. CMAM-C1SD, MOCAGE-CTM and NIES-C1SD). For example, the mean age differs by  $\sim 0.5$  years between the MOCAGE-CTM and CMAM-C1SD simulations over the SH, compared to only about 0.15 years between the GEOS-C1 and CMAM-C1 free-running simulations, despite substantial differences in the large-scale flow among those models.

While  $\Gamma_{\text{NH}}$  cannot be observed directly, *Waugh et al. (2013)* show that it can be approximated in terms of the time lag between the mixing ratio of sulfur hexafluoride ( $\text{SF}_6$ ) at a given location and the NH midlatitude surface. We have confirmed this finding among three of the CCM simulations, for which both  $\text{SF}_6$  and  $\Gamma_{\text{NH}}$  were output (not shown). Furthermore, comparisons with observational estimates of  $\Gamma_{\text{NH}}$ , inferred in *Waugh et al. (2013)* from surface measurements of  $\text{SF}_6$ , indicate that all of the CCM models are old relative to the observations **by 20-40% for most of the models but up to 60% for others.**

Due to the paucity of SF<sub>6</sub> output among the models, however, we reserve a more detailed model-observation comparison for a future study.

### 3.2.2 Differences in Tropical Large-Scale Flow and Parameterized Convection

A possible source of differences in interhemispheric transport among the C1SD simulations are differences in the analysis fields themselves, which can differ significantly among reanalysis products (*Stachnik and Schumacher, 2011*). A comparison of the large-scale flow in the tropics, however, reveals much larger differences among the C1 simulations, where we have approximated the tropical meridional circulation in terms of the meridional and vertical components of the velocity field (Figure 10). This applies both to comparisons of the upper tropospheric meridional flow ( $V$ ) (Fig. 10 a-d) as well as comparisons of the pressure velocity ( $\omega$ ) among the simulations, although the differences in  $\omega$  among the C1SD simulations are by no means negligible (Fig. 10 e-h). Furthermore, the differences among the NCAR and NASA C1SD simulations are small, despite the fact that the differences in the mean age  $\Gamma_{\text{NH}}$  among those simulations spans most of the ensemble spread (Figure 9). Overall this suggests that the interhemispheric transport differences among the simulations are not driven to first order by differences in the large-scale flow.

Rather, *Orbe et al. (2017)* show that differences in interhemispheric transport between the NASA and NCAR C1SD simulations are related to differences in convection over the northern subtropical oceans. We test this result among all the CCMI models and expand our region of interest to also include latitudes in the deep tropics, in accordance with previous studies showing that deep tropical convection significantly enhances interhemispheric transport (*Gilliland and Hartley, 1998*).

Among the CCMI ensemble we find strong correlations between annually averaged lower tropospheric (700-900 mb) convection over the tropical oceans and Southern Hemisphere tracer ages averaged poleward of 60°S (Figure 11). Consistent with large differences in interhemispheric transport among the C1SD simulations, Figure 11 reveals large differences in parameterized convection among simulations constrained with analysis fields. Furthermore, note that, while the correlations are shown for the annual mean, we have performed a similar analysis accounting for seasonal variations in convection. That analysis reveals similar (if stronger) correlations (not shown).

## 4 Conclusions

Comparisons of idealized tracers among the CCMI hindcast simulations reveal large differences in their global-scale tropospheric transport properties. In particular:

- There are large (30-40%) differences in the efficiency of transport from the Northern Hemisphere midlatitude surface into the Arctic. To first order, these differences reflect differences in (parameterized) convection over the northern midlatitude oceans, particularly during boreal winter.

- There are large differences in interhemispheric transport from northern midlatitudes to southern high latitudes, where the mean age  $\Gamma_{\text{NH}}$  ranges between 1.7 years and 2.6 years. In general, stronger tropical and subtropical convection is associated with faster interhemispheric transport.
- The large-scale transport differences among simulations constrained with analyzed winds are as large as the differences among simulations using internally generated meteorological fields, consistent with the findings in *Orbe et al. (2017)*. This is because the differences in (parameterized) convection among specified-dynamics simulations can be larger than the differences among free-running simulations.

Our findings suggest that differences in parameterized convection over the oceans are the primary drivers of transport differences among the CCMI simulations. By comparison, we show that the differences related to how the large-scale flow is specified (e.g. CTM vs. nudging or source of analysis fields) are relatively smaller. Therefore, our results indicate that caution should be taken when using the C1SD simulations to interpret the influence of meteorology on tropospheric composition. In the future more attention will need to be paid to understanding the behavior of convective parameterizations in simulations constrained with analyzed winds, both in offline (CTM) and online (nudged) frameworks.

At this point it is not clear why the convection differences among the C1SD simulations are in certain cases larger than among free-running simulations using the same models. One possibility is that these differences arise due to inconsistencies (e.g. in resolution or unbalanced dynamics) between the driving large-scale flow fields and the convective mass fluxes, which are recalculated online in all of the nudged simulations as well as in the MOCAGE-CTM, or interpolated directly from analysis fields (e.g. GEOS-CTM). The analysis in this study has been limited by the small number of C1SD simulations that output all of the idealized tracers as well as convective mass fluxes (Table 3). Experiments using multiple sources of analysis fields as well as different convective parameterizations will need to be performed in order to examine this problem more carefully. A review of the CCMI C1SD simulations, with details of how these simulations were constrained, is also currently in preparation and may provide further insight.

One important caveat in this study is that our focus has been on tracers with zonally uniform boundary conditions. The implications of our findings will, therefore, vary among different species, depending on where they are emitted over the Earth's surface. In particular, our results highlight the differences in transport that arise due to large differences in (parameterized) oceanic convection among the simulations. We anticipate, therefore, that our results will primarily apply to species with oceanic sources, including marine-sourced volatile organic compounds and short-lived ozone-depleting halogenated species. By comparison, species with primarily land emissions (e.g. short-lived species) are expected to be more sensitive to other aspects of transport. To this end, a study is currently in preparation which addresses the implications of biases in the latitude of the midlatitude jet on carbon monoxide distributions over the Arctic among the CCMI models. We reserve further discussions to that study.

Finally, while we have shown that there are large differences in transport among the models, we have not made comparisons with observations. As mentioned in Section 3.2.1, estimates of  $\Gamma_{\text{NH}}$ , inferred from surface measurements of  $\text{SF}_6$  (*Waugh et al., 2013*), indicate that all of the CCMI models are old compared to the observations. More recently, *Holzer and Waugh (2015)*

present estimates of both the mean age and the spectral width of the underlying transit-time distribution (TTD) connecting the NH midlatitude surface to the Southern Hemisphere, based on surface measurements of SF<sub>6</sub> and various chlorofluorocarbons and their replacement gases. These additional estimates may provide important constraints on the idealized loss tracer distributions in the CCMI simulations, to the extent that the loss tracers approximate different aspects of the TTD, as demonstrated in *Orbe et al.* (2016) for the case of one model. We reserve more comparisons with observational constraints for future work.

*Acknowledgements.* We thank the Centre for Environmental Data Analysis (CEDA) for hosting the CCMI data archive. We acknowledge the modeling groups for making their simulations available for this analysis, and the joint WCRP SPARC/IGAC Chemistry-Climate Model Initiative (CCMI) for organizing and coordinating this model data analysis activity. # Climatological Mean Tracer Distributions

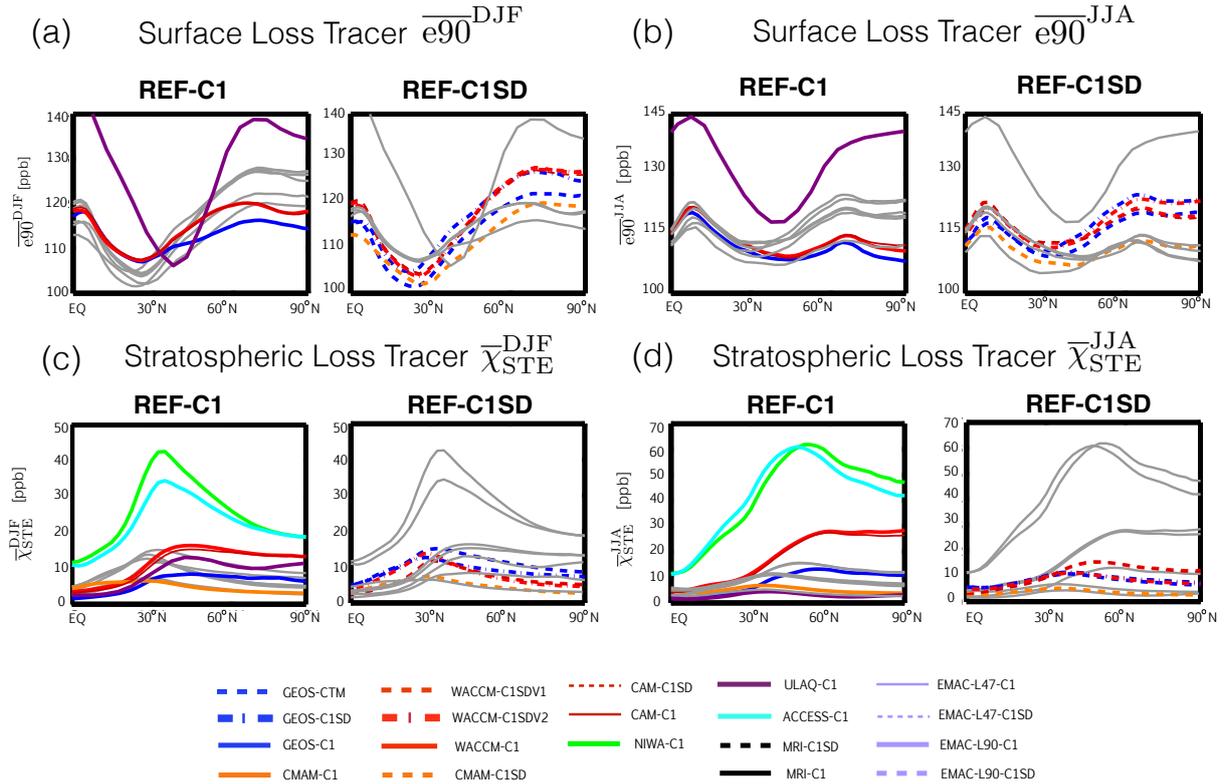

**Figure 1.** Climatological mean December-January-February (DJF) (left panels) and June-July-August (JJA) (right panels) zonally averaged distributions of the 5-day idealized loss tracer,  $\chi_5$  (a), the 50-day idealized loss tracer  $\chi_{50}$  (b), the mean age since air was last at the NH midlatitude surface  $\Gamma_{NH}$  (c), the stratospheric global source tracer  $\chi_{STE}$  (d) and the global surface source tracer  $e90$  (e). Schematic representations of the seasonally averaged mean meridional circulation, overlaid with arrows denoting eddy mixing, are shown in panel f. 2000-2009 climatological means are shown for the NASA Global Modeling Initiative (GMI) Chemical Transport Model (CTM), which is constrained with MERRA meteorological fields and denoted in all remaining figures as the GEOS-CTM simulation. Climatological seasonal mean dry potential temperature is shown in the grey contours.

## 400-700 mb NH Midlatitude Source Tracers

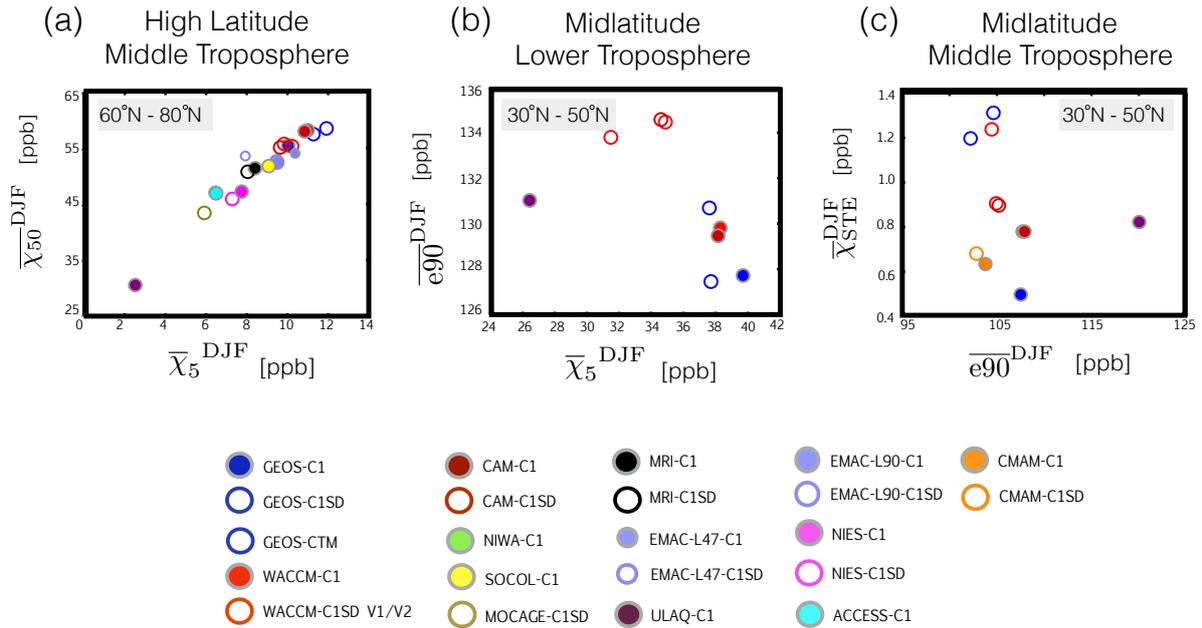

**Figure 2.** Meridional profiles of the 400-700 hPa zonally averaged DJF (a,c) and JJA (b,d) 5-day and 50-day loss tracers,  $\bar{\chi}_5$  and  $\bar{\chi}_{50}$ . Dashed lines in each right panel correspond to the REF-C1SD simulations, which are constrained with analysis meteorological fields, while solid lines in each left panel correspond to the free-running REF-C1 simulations. Grey solid lines in each panel correspond to the REF-C1SD and REF-C1 simulations in the left and right panels, respectively. Note that the x-axis only spans the Northern Hemisphere.

## 400-700 mb Global Source Tracers

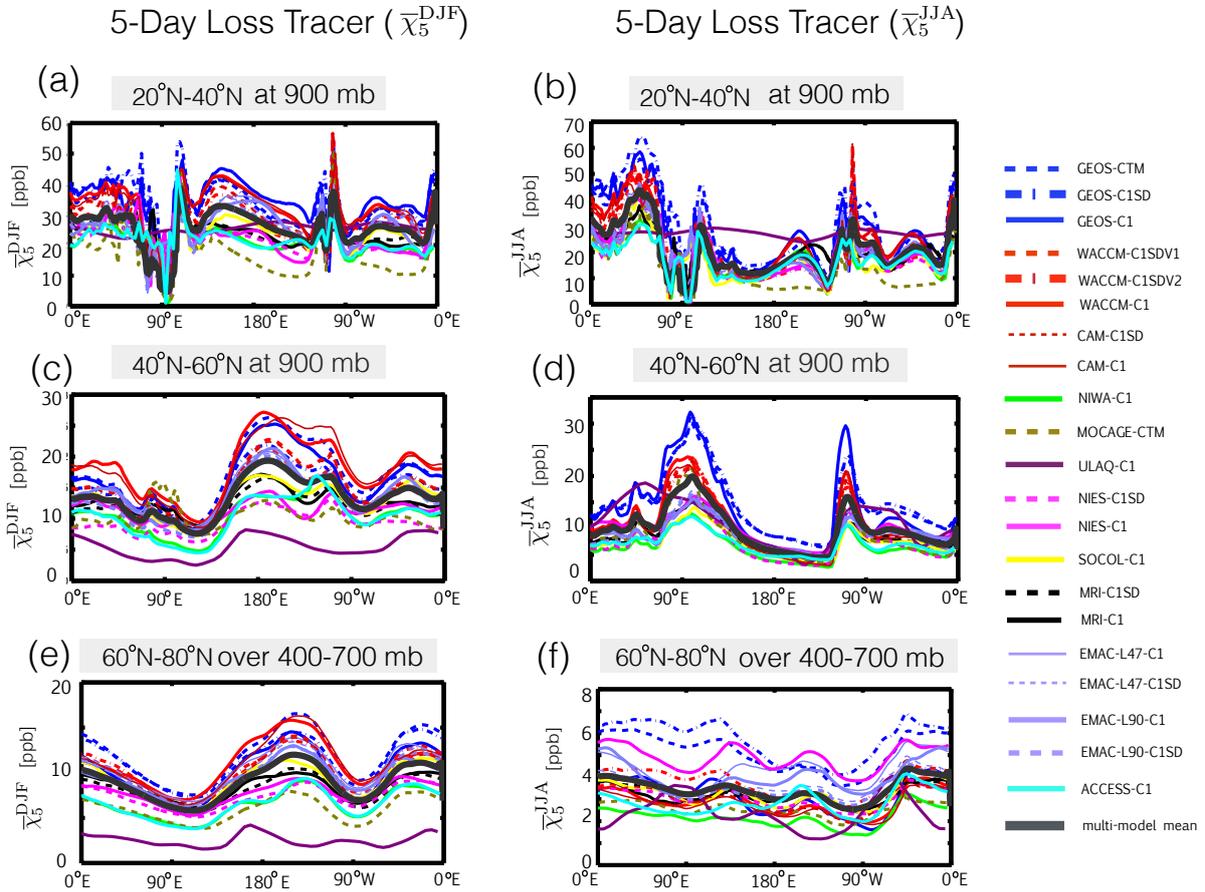

**Figure 3.** Same as Figure 2, except for the stratospheric and surface global source tracers,  $e90$  (top) and  $\chi_{\text{STE}}$  (bottom).

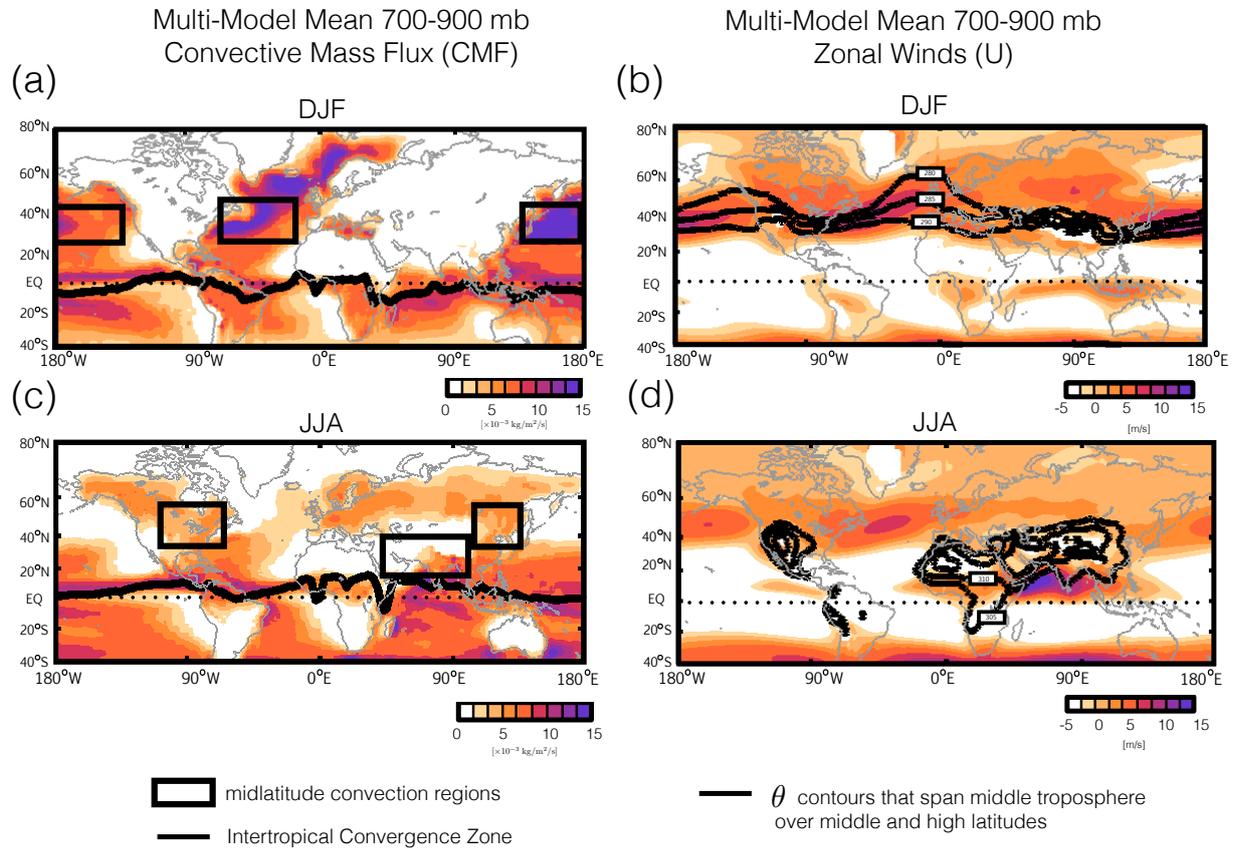

## Tracer-Tracer Correlations over the Northern Hemisphere

**Figure 4.** (a) Correlations of 400-700 hPa averages of  $\overline{\chi_{50}^{\text{DJF}}}$  and  $\overline{\chi_5^{\text{DJF}}}$  averaged over latitudes spanning 60°N and 80°N. (b) Correlations of  $\overline{\chi_5^{\text{DJF}}}$  and  $\overline{e90^{\text{DJF}}}$ , averaged over 700-900 hPa and over the midlatitude source region. (c) Same as (b), except for  $\overline{\chi_{\text{STE}}^{\text{DJF}}}$  and  $\overline{e90^{\text{DJF}}}$  and over 400-700 hPa. The different colors correspond to the different simulations, with open circles denoting REF-C1SD simulations and closed circles corresponding to REF-C1 (grey outline). Circles denote the climatological boreal winter mean over 2000-2009.

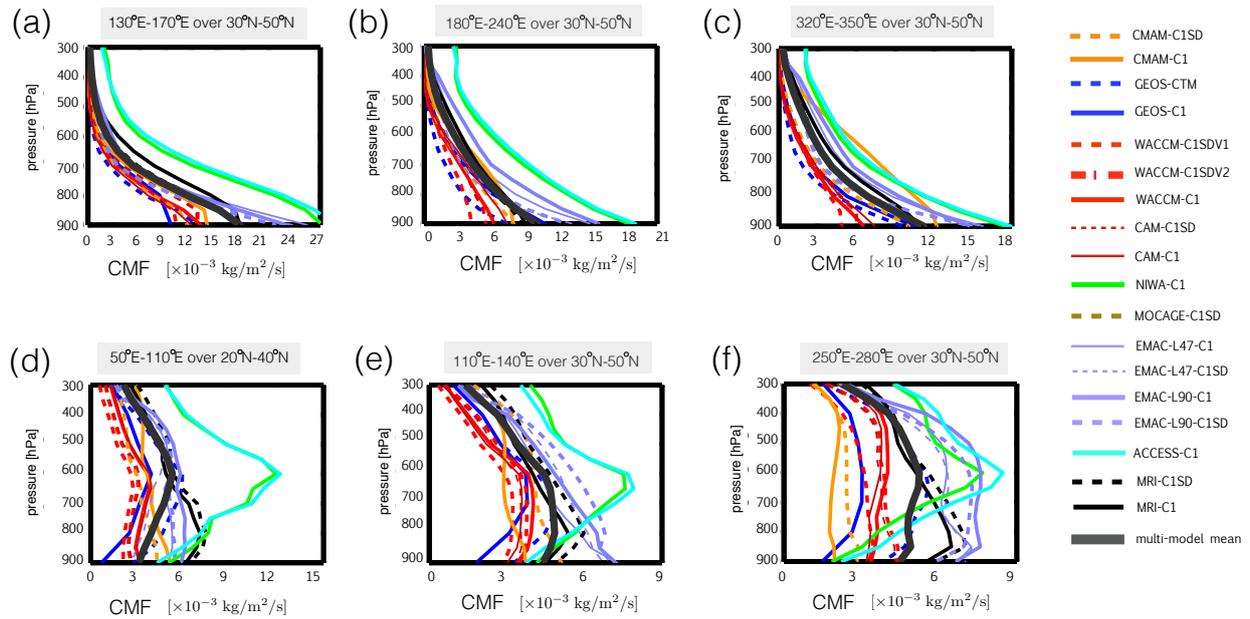

**Figure 5.** Zonal profiles of the climatological mean 5-day idealized loss tracer  $\bar{\chi}_5$  averaged over 900 hPa and over latitudes spanning 20°N-40°N (a-b) and 40°N-60°N (c-d) and over 400-700 hPa over latitudes between 60°N-80°N (e-f). Profiles are shown for DJF (left) and JJA (right). Dashed lines correspond to the REF-C1SD simulations, which are constrained with analysis meteorological fields, while solid lines correspond to the free-running REF-C1 simulations. The dark thick grey line represents the multimodel mean.

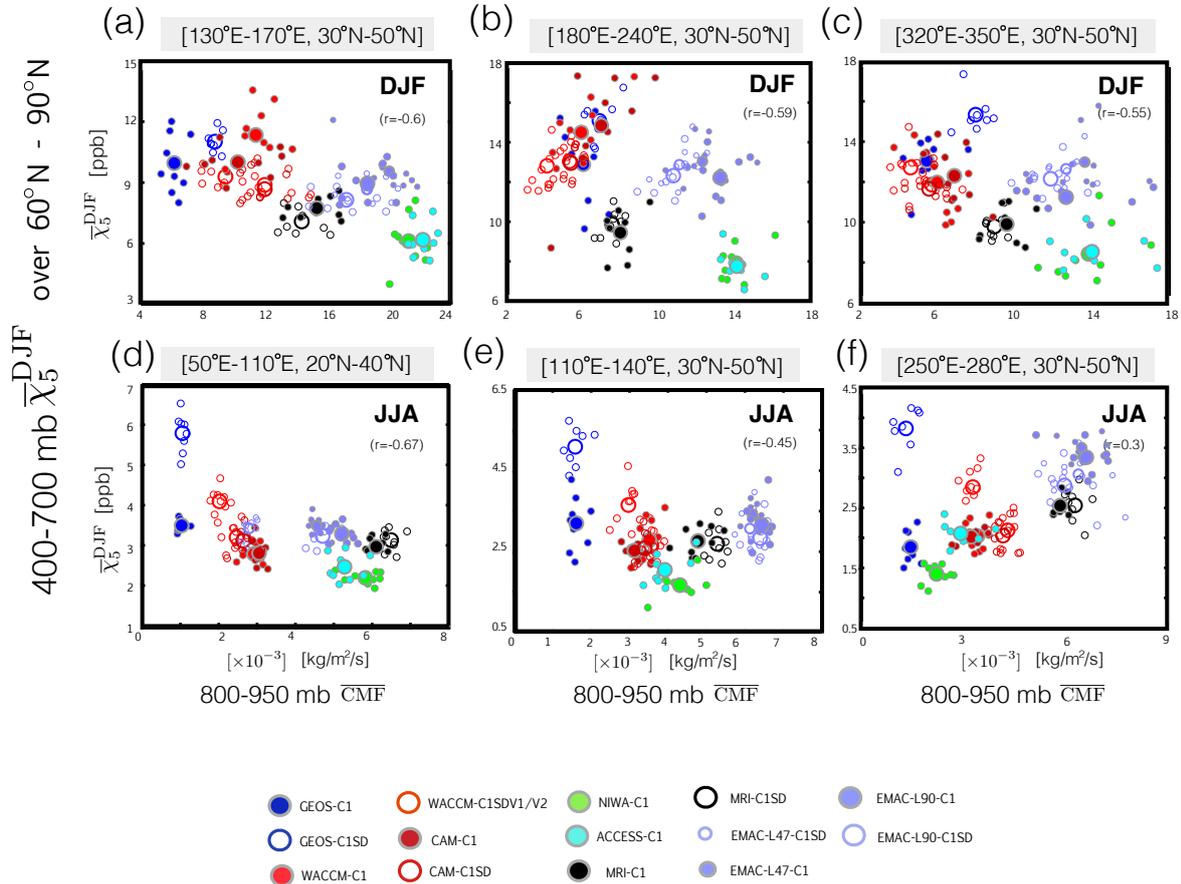

**Figure 6.** Maps of the 700-900 hPa averaged multi-model mean convective mass flux (a,c) and zonal winds (d,e) for DJF (a,b) and JJA (c,d). The multi-model seasonal mean Intertropical Convergence Zone, calculated as the latitude of maximum surface convergence, is shown in the thick black lines in the left panels. Black boxes denote the midlatitude convection regions over which the scatterplots in Figures 8 are evaluated. The thick dark lines in the right panels correspond to the regions where the potential temperature surfaces that span the middle and high latitude upper troposphere intersect the NH midlatitude surface, as shown in Figure 1.

DJF (Top) and JJA (Bottom)  
Convective Mass Flux (CMF) Profiles over NH Midlatitudes

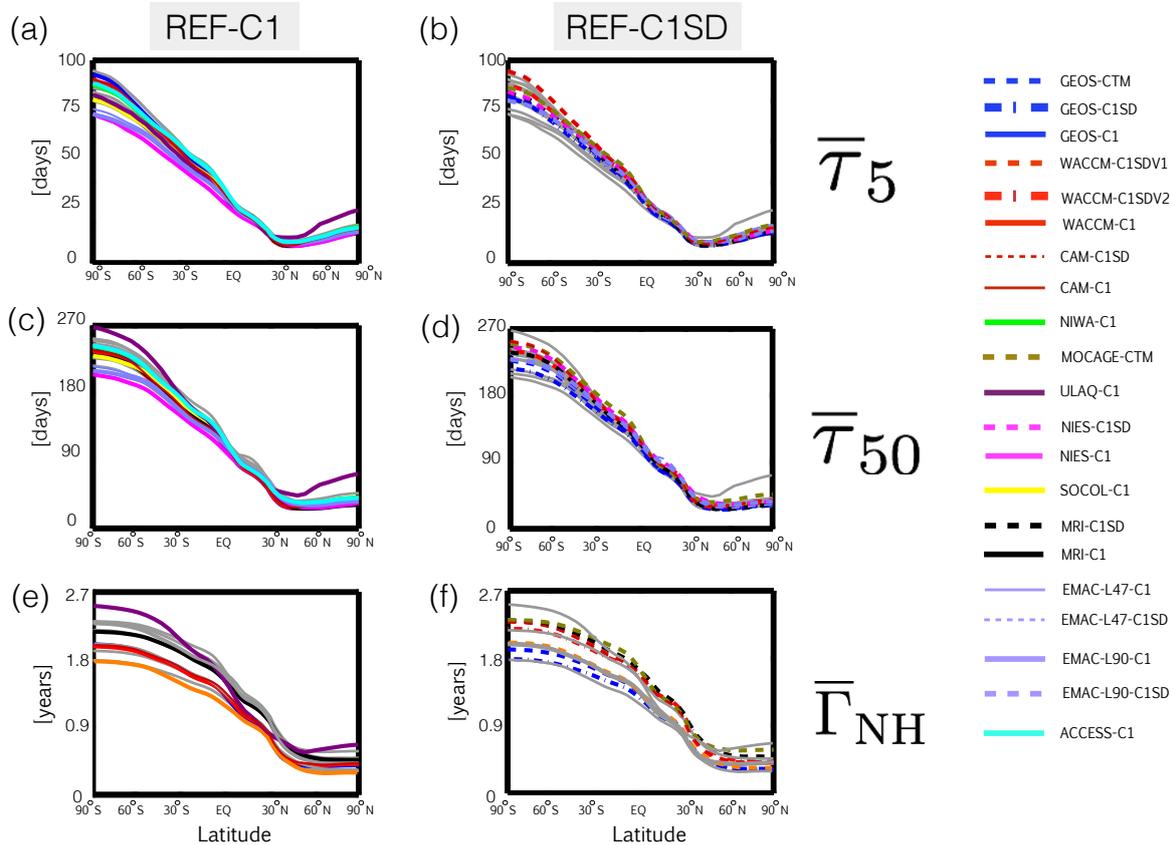

**Figure 7.** Vertical profiles of the convective mass flux evaluated over regions of strong midlatitude convection (black boxes in Figure 6) during DJF (a-c) and JJA (d-f). The dark thick grey line represents the multimodel mean and dashed lines correspond to the REF-C1SD simulations, while solid lines correspond to the free-running REF-C1 simulations

## Seasonal Mean Correlations of Arctic 5-Day Loss Tracer Concentrations ( $\chi_5$ ) and Midlatitude Convection (CMF)

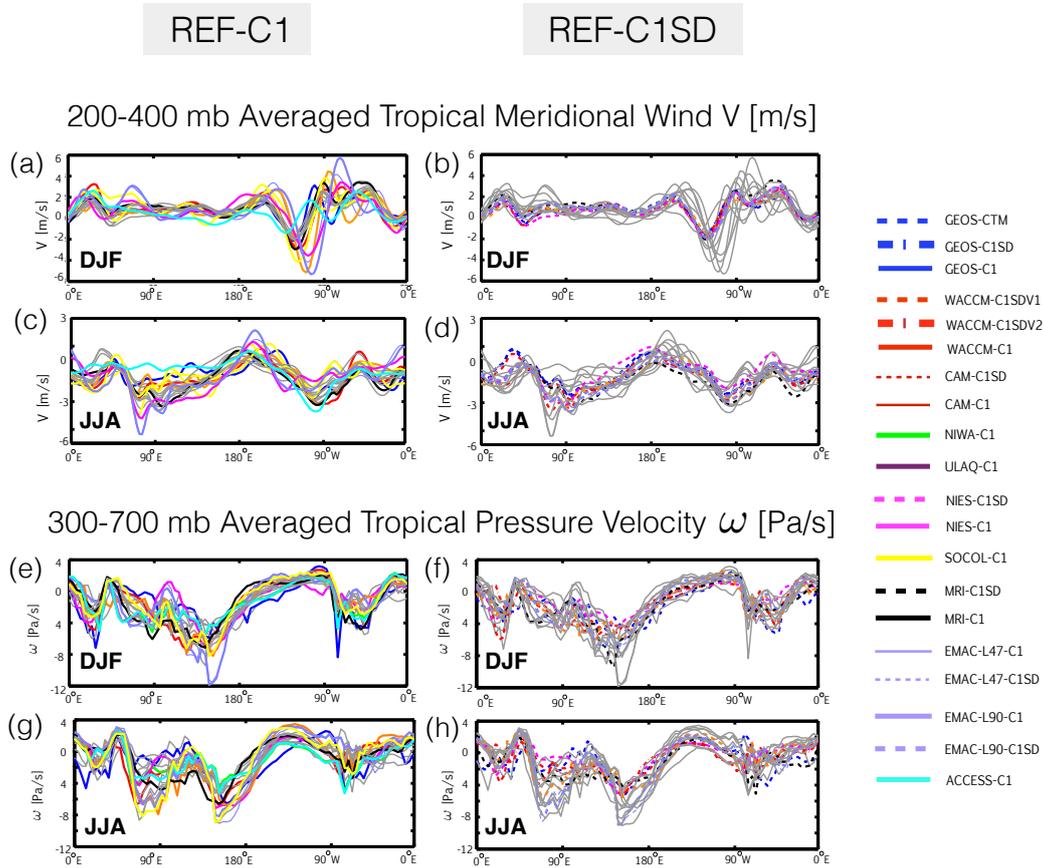

**Figure 8.** Scatterplots showing negative correlations between the strength of parameterized convection in the midlatitude lower troposphere, represented by the 800-950 hPa averaged convective mass flux ( $\overline{CMF}$ ), and mid-tropospheric (400-700 hPa) concentrations of the 5-day idealized loss tracer averaged poleward of 60°N. The convection regions coincide with black boxed regions shown in Figure 6. The different colors correspond to the different simulations, with open circles denoting REF-C1SD simulations and closed circles corresponding to REF-C1 (grey outline) simulations. Small circles correspond to individual years within the 2000-2009 climatological mean period, while large circles denote the climatological mean.

## 400-700 mb Annual Mean 5-Day and 50-Day Tracer Ages ( $\bar{\tau}_5$ and $\bar{\tau}_{50}$ ) and the NH Midlatitude Mean Age ( $\bar{\Gamma}_{NH}$ )

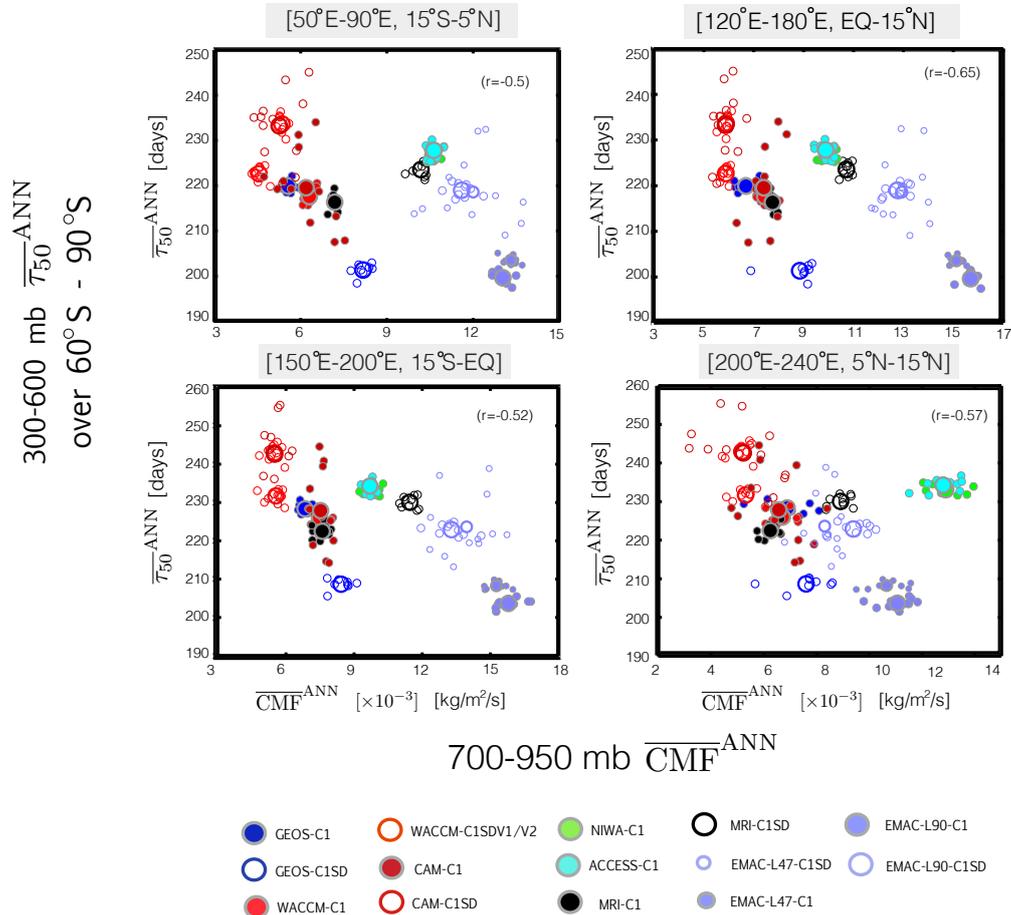

**Figure 9.** Meridional profiles of the annual mean 5-day loss and 50-day loss tracer ages,  $\bar{\tau}_5$  (a-b) and  $\bar{\tau}_{50}$  (c-d), as well as the annually averaged mean transit time since air was last at the NH midlatitude surface  $\bar{\Gamma}_{NH}$  (e-f). Left and right panels show the tracer ages for the REF-C1 and REF-C1SD simulations, respectively. The grey lines denote the C1SD(C1) simulations in the left (right) panels in order to provide a sense for the ensemble spread.

**Figure 10.** Comparisons of the upper tropospheric meridional wind  $V$  (a-d) and 300-700 hPa averaged pressure velocity  $\omega$  (e-h) among the simulations. The REF-C1 and REF-C1SD simulations are shown in the left and right panels, respectively. The grey lines denote the C1SD (C1) simulations in the left (right) panels in order to provide a sense for the ensemble spread.

## Annual Mean Correlations of Southern Pole 50-Day Loss Tracer Age ( $\bar{\tau}_{50}$ ) and Tropical Convection ( $\overline{\text{CMF}}$ )

**Figure 11.** Scatterplots showing negative correlations between the strength of parameterized convection in the tropics, represented by the 700-900 hPa averaged convective mass flux ( $\overline{\text{CMF}}$ ), and mid-tropospheric (300-600 mb) values of the 50-day idealized loss tracer age,  $\bar{\tau}_{50}$ , evaluated over the Southern Pole. The different colors correspond to the different simulations, with open circles denoting REF-C1SD simulations and closed circles corresponding to REF-C1 free-running simulations. Small circles correspond to individual years within the 2000-2009 climatological mean period, while large circles denote the climatological mean.

**Figure 12. Table 1** Details of the model integrations, where columns 3-6 correspond to the horizontal resolution, number of vertical levels and model top, source of meteorological fields and reference for the model's convective parameterizations. T21 and T42 correspond to quadratic grids of approximately to  $\sim 5.6^\circ \times 5.6^\circ$  and  $\sim 2.8^\circ \times 2.8^\circ$ , respectively. Two types of model experiments are examined: the REF-C1SD and REF-C1 simulations. Both REF-C1 and REF-C1SD are constrained with observed sea surface temperatures (SSTs) and sea ice concentrations (SICs). Whereas the REF-C1 experiment use internally generated (or free-running) meteorological fields, however, the C1SD or C1 "Specified Dynamics" simulations is constrained with (re)analysis meteorological fields. Note that both CTMs and nudged simulations are included in the REF-C1SD suite of model simulations (see column 6). In cases where individual modeling agencies performed multiple C1SD simulations (e.g. NASA and NCAR) we append a "V1/V2" to the simulation name.

## Idealized Tracers

Tracer ( $\chi$ )	Boundary Condition ( $\chi_\Omega$ )	Source (S)
5-Day NH-Loss ( $\chi_5$ )	1 over $\Omega_{\text{MID}}$	$-\chi/\tau_c$ ( $\tau_c = 5$ days, entire atmosphere)
50-Day NH-Loss ( $\chi_{50}$ )	1 over $\Omega_{\text{MID}}$	$-\chi/\tau_c$ ( $\tau_c = 50$ days, entire atmosphere)
Tropospheric Mean Age ( $\Gamma_{\text{NH}}$ )	0 over $\Omega_{\text{MID}}$	1 year/year
Stratospheric-Loss ( $\chi_{\text{STE}}$ )	200 ppbv above 80 hPa	$-\chi/\tau_c$ ( $\tau_c = 25$ days, troposphere only)
Global Source Decay (e90)	100 ppbv in first model level	$-\chi/\tau_c$ ( $\tau_c = 90$ days, entire atmosphere)

**Figure 13. Table 2** Table of idealized tracers,  $\chi$ , integrated in the simulations. All tracers ( $\chi$ ) satisfy the tracer continuity equation,  $(\partial_t + \mathcal{T})\chi(\mathbf{r}, t|\Omega) = S$  in the interior of the atmosphere (that is, outside of  $\Omega$ ), where  $\mathcal{T}$  is the linear advection-diffusion transport operator and  $S$  denotes interior sources and sinks. For the first three tracers (rows 2-4)  $\Omega$  is taken to be the NH midlatitude surface,  $\Omega_{\text{MID}}$ , which is defined throughout as the first model level spanning latitudes between  $30^\circ\text{N}$  and  $50^\circ\text{N}$ . The last two tracers, referred to throughout as the global source tracers, include the stratospheric tracer  $\chi_{\text{STE}}$ , which is set to 200 ppbv for pressures less than and equal to 80 hPa, and decays uniformly in the troposphere at a loss rate  $\tau_d = 25 \text{ days}^{-1}$  (row 5). The e90 tracer is uniformly emitted over the entire surface layer and decays exponentially at a rate of  $90 \text{ days}^{-1}$  such that concentrations greater than 125 ppb tend to reside in the lower troposphere and concentrations less than 50 ppb reside in the stratosphere (row 6).

\*incorrectly implemented

**Figure 14. Table 3** List of the model simulations for which the idealized tracers ( $\chi_5$ ,  $\chi_{50}$ ,  $\Gamma_{NH}$ ,  $\chi_{STE}$  and e90) and dynamical fields ( $U$ ,  $V$ ,  $\omega$ ,  $T$  and parameterized convective mass fluxes (CMF)) were available. Asterisks denote fields that were output in simulations, but were not correctly implemented.
