11 **Abstract.**

12 Mean age of stratospheric air can be derived from observations of sufficiently long lived trace
13 gases with approximately linear trends in the troposphere. Mean age can serve as a tracer to
14 investigate stratospheric transport and long term changes in the strength of the overturning
15 Brewer-Dobson circulation of the stratosphere. For this purpose, a low-cost method is required
16 in order to allow for regular observations up to altitudes of about 30 km. Despite the desired
17 low costs, high precision and accuracy are required in order to allow determination of mean
18 age. We present balloon borne AirCore observations from two mid latitude sites: Timmins in
19 Ontario/Canada and Lindenberg in Germany. During the Timmins campaign five AirCores
20 sampled air in parallel with a large stratospheric balloon and were analysed for CO₂, CH₄ and
21 partly CO. We show that there is good agreement between the different AirCores (better than
22 0.1%) especially when vertical gradients are small. The measurements from Lindenberg were
23 performed using small low-cost balloons and yielded very comparable results. We have used
24 the observations to extend our long term data set of mean age observations at Northern Hemi-
25 sphere mid latitudes. The time series now covers more than 40 years and shows a small, statis-
26 tically not significant positive trend of 0.15 ± 0.18 years/decade. This trend is slightly smaller
27 than the previous estimate of 0.24 ± 0.22 years/decade which was based on observations up to
28 the year 2006. These observations are still in contrast to strong negative trends of mean age as
29 derived from some model calculations.

1 Introduction

2 Mean age of stratospheric air is the average time it takes for the atmosphere to transport air
3 from the tropospheric source region to a given place in the stratosphere. The concept of mean
4 age was first developed by Kida (1983) and has since been refined and discussed in several high
5 quality reviews (Hall and Plumb, 1994; Waugh and Hall, 2002). In brief, the concept divides an
6 air parcel into irreducible fluid elements which are irreversibly mixed during transport in the
7 stratosphere. Each such fluid element has a separate transport time and transport path associated
8 with it. The distribution of the statistical probability associated to the different transit times is
9 called the age spectrum and represents a probability density function (pdf) for individual transit
10 times to this air parcel. The first moment of the age spectrum is called the mean age of air.
11 While the age spectrum cannot be measured, mean age can be derived from observations of
12 inert trace gases under certain conditions. In case of an inert tracer with a perfectly linear trend
13 in the atmosphere, the time lag between the occurrence of a given mixing ratio of a tracer in the
14 troposphere and the occurrence of the same mixing ratio at some place in the stratosphere would
15 be the mean age of air. The two tracers which have been used most widely for this purpose are
16 CO₂ and SF₆. Neither of these gases increases completely linearly with time, so the shape of
17 the age spectrum needs to be taken into account in deriving mean age.

18 Mean age has been identified as a valuable tracer to investigate stratospheric transport time
19 scales, e.g. by comparing model derived mean age with observations. Long term trends in mean
20 age have been used to investigate long term changes in the overall overturning circulation of
21 the stratosphere (Brewer-Dobson circulation, BDC). An increase in the strength of the BDC is
22 expected from model calculation with increasing greenhouse gas concentrations (Austin and
23 Li, 2006; Butchart et al., 2006; Butchart, 2014). This is reflected in overall shorter transit times,
24 thus also lower mean age values in the models.

25 The experimental data base of mean age observations for the verification of such changes is
26 sparse. It relies mainly on very sporadic balloon borne observations of CO₂ and SF₆ dating back
27 to 1975 (Engel et al., 2009) and on satellite observations of SF₆ (Stiller et al., 2012; Haenel et
28 al., 2015). The balloon borne observations used in Engel et al. (2009) were taken in a region
29 between 24 and 35 km where the vertical gradient in mean age at Northern Hemisphere mid
30 latitudes was found to be very small, leading to little variability in this region. The balloon data
31 was limited to a total of 28 flights and showed a positive trend of 0.24 years per decade for this
32 region, which was however estimated to be non-significant. Satellite observations of SF₆ used

1 in Stiller et al. (2012) and Haenel et al. (2015) were limited to the lifetime of the Envisat satellite
2 of about 10 years. They show an uneven distribution of trends with positive trends in the middle
3 stratosphere of the northern Hemisphere but negative trends in the Southern Hemisphere. Mod-
4 elling work by Garny et al. (2014) showed that mixing has a strong influence on mean age and
5 that enhanced mixing leads to higher mean ages in large parts of the stratosphere (“aging by
6 mixing”). Ploeger et al. (2015) then showed that trends in mean age are to a large degree also
7 influenced by trends in mixing and not only in residual transport. Overall, it has become clear
8 that the interpretation of changes in mean age as changes in residual circulation is inadequate,
9 but rather that it represents a combination of changes in mixing and in residual transport.

10 The experimental investigation of changes in mean age of stratospheric air is to a large degree
11 restricted by the availability of observations. The balloon borne data set presented in Engel et
12 al. (2009) relies to a large part on samples collected in the stratosphere using large and heavy
13 cryogenic whole air samplers. These instruments require large and expensive balloons to carry
14 them to altitudes above 25 km. The use of these large balloons involves a large operational team
15 and is very expensive. The uncontrolled parachute descent of such large payloads after the
16 flights further presents a large operational constraint due to safety regulations. These safety
17 regulations make it virtually impossible to fly such large payloads in densely populated areas
18 as Central Europe. Due to these operational constraints and in order to create a larger and more
19 representative data base, an easy to launch and cheap technique to allow for the measurement
20 of age tracers would be required. AirCore, a new technique to sample air which has been sug-
21 gested by Karion et al. (2010) may provide such an opportunity. In brief, this technique relies
22 on collecting air in a previously evacuated, long stainless steel tube. When deploying AirCore
23 on a balloon, the tube, which is open on one side and closed on the other side, is filled with a
24 fill gas (FG) which has different chemical characteristics from the ambient air to be sampled.
25 The tube is emptied during ascent of the balloon due to the decreasing pressure with altitude.
26 Upon descent of the balloon, ambient air is pushed into the AirCore. Due to the length of the
27 tube and the laminar flow during the collection, the air is only partially mixed and the infor-
28 mation on the vertical distribution is retained for a while before eventually being mixed due to
29 molecular diffusion. After collection, the sampled air can then be analysed by pushing it out of
30 the tube with a push gas (PG), which must again be well distinguishable from ambient air.

31 A very light weight AirCore developed at University Frankfurt for deployment on small, cheap
32 and easy to launch balloons as used for launching of e.g. ozone sondes is presented in section
33 2 together with the analytical set-up for measurements of the AirCore and the data retrieval. In

1 section 3 we present observations from two mid latitude campaigns, the first one in Timmins,
2 Ontario in 2015 and the second one in Lindenberg, Germany in 2016. Results from a first test
3 campaign in Timmins, Ontario in 2014 have been published in Membrive et al. (2016). Due to
4 technical problems the results from the campaign in 2014 cannot be used to derive mean age.
5 The mean ages calculated from the observations in 2015 and 2016 are presented in section 4
6 together with an updated long term evolution of mean age. Summary and conclusions are given
7 in section 5.

8 **2 University Frankfurt AirCore**

9 The AirCore used by University of Frankfurt was developed under two main aspects. The first
10 aspect is that the instrument should be sufficiently light to allow for flights under simple bal-
11 loons at mid latitudes in Europe. The second aspect is that the AirCore should be optimised to
12 allow measurements at high altitudes with an optimal resolution. The AirCore is currently used
13 for measurements of CO₂, CH₄ and CO.

14 **2.1 Overall concept**

15 As explained above, the University Frankfurt AirCore is designed to provide optimum resolu-
16 tion in the stratosphere while keeping the weight sufficiently low for use under a small balloon.
17 The vertical resolution, which can be achieved by AirCore measurements, will generally de-
18 pend on the geometry of the AirCore itself, on the effective volume of the analyser deployed
19 and on the storage time between collection of the sample and the analysis. The target of our
20 AirCore is to derive mean age from CO₂. As the loss of CH₄ in the stratosphere results in the
21 production of CO₂, CH₄ needs to be measured simultaneously. We therefore decided to use a
22 Picarro G2401 analyser for this, which is able to measure CO₂, CH₄, CO and H₂O with a tem-
23 poral resolution of about 2-3 seconds and very high precision, which is better than 0.01% for
24 CO₂ and 0.05% for CH₄ over a 5 sec period under typical ambient conditions. Typical repro-
25 ducibilities observed during field operations showed in precisions of 0.025 ppm of CO₂ and 0.2
26 ppb of CH₄. For CO, which was mainly used to distinguish between ambient air and PG, typical
27 precision was 5 ppb.

28 Molecular Diffusion is described by Fick's first law of diffusion, which states that the diffusive
29 flux J is proportional to the concentration gradient $\frac{\partial c}{\partial x}$ and the Diffusion-constant D .

$$J = -D \times \frac{\partial c}{\partial x}$$

1
2 The same amount of air stored in a short tube with large inner diameter will be stretched out
3 over a much shorter distance than in a narrow and longer tube. The diffusive flux is thus lower
4 when using a longer and thinner tube. As the amount of sample collected by AirCore is propor-
5 tional to the ambient pressure, very little air is collected at high altitudes. In order to minimize
6 loss of vertical resolution with altitude, it is thus desirable to have thin and long tubes for the
7 storage of stratospheric air. On the other hand, the absolute amount of air collected by the Air-
8 Core is limited by the total volume of the tube, which is low for tubing with small inner diam-
9 eter. We have therefore decided to construct an AirCore from different diameter tubes in such
10 a way that the high altitude air is stored in the thin diameter tubing part of the AirCore while
11 the overall volume is provided by wider diameter tubing in which the lower altitude air will
12 eventually be stored. The AirCore operated at University Frankfurt is thus composed of 20 m
13 of 8mm O.D. tubing, and 40 m each of 4 and 2 mm outer diameter tubing. The thinnest walled
14 tubing we could identify were 0.2 mm wall thickness for 8 mm and 4 mm outer diameter tube.
15 A 2 mm outer diameter tube with an 0.12 mm wall thickness is available. The volume per
16 weight is highest for the large outer diameter tubing. All tubings were custom produced for the
17 production of our AirCores. The tubes are joined by solder and light weight adaptors. As sug-
18 gested in Karion et al. (2010), all tubes were silanized prior to soldering them together. The
19 AirCore is closed during flight on the 2 mm side, while the 8 mm O.D. tube is the open ended.
20 The calculated weight of the AirCore based on the specifications of the tubes is 1.4 kg for the
21 100 m long tube. The final weight of the tube was, however, slightly higher due to the wall
22 thickness being on the high side of the specified tolerance. An automated closure valve (Chen
23 et al., 2017) is added on the closed side and a sample dryer is mounted on the open end. The
24 drier is based on $\text{Mg}(\text{ClO}_4)_2$ filled in a $\frac{1}{2}$ " O.D. tube of 50 mm length containing a total of 4cm^3
25 of $\text{Mg}(\text{ClO}_4)_2$. The AirCore is mounted in a Styrofoam box for thermal insulation and mechan-
26 ical protection. As the temperature of the AirCore during the collection determines the amount
27 of air, which can be sampled, we monitor this temperature with a minimum of three temperature
28 sensors. The automatic closure valve (Chen et al., 2017) closes the AirCore after landing. This
29 valve is controlled by a light weight electronics package which also includes the data logger for
30 the temperature sensors and was developed at University Groningen (Chen et al., 2017). The
31 overall weight of the AirCore in flight mode and using the University Groningen electronics
32 package and closure valve is about 2.5 kg including a protective housing.

1 **2.2 Estimated vertical resolution**

2 The vertical resolution of the derived mixing ratio profiles is influenced by sampling, storing
3 and measurements procedures. The principal procedure to estimate vertical resolution has been
4 outlined by Karion et al. (2010). Resolution is lost due to molecular diffusion during the storage
5 of the sampled air in the AirCore and due to mixing during the sampling and analysis process.
6 Molecular diffusion can be calculated using Fick's law. The mixing process is essentially in-
7 fluenced by two parameters: (i) Taylor dispersion during the collection and analysis of the sam-
8 ples and (ii) the effective cell volume of the analyser, which has to be flushed. Mixing processes
9 are species independent, while the first effect (molecular diffusion during storage) is species
10 dependent, each species having a different molecular diffusion coefficient. The cell volume of
11 the analyser is not an intrinsic limitation of the resolution of the AirCore itself, but will be
12 included in the derived resolution based on the Picarro G2401 analyser used for our analysis.
13 As molecular diffusion is a function of time and molecule, the resolution of our AirCore is also
14 a function of time and will deteriorate with time and differ for each molecule. As explained
15 above, molecular diffusion will lead to more loss of resolution in a wider tube. Therefore, our
16 AirCore loses resolution much faster at lower altitudes during storage, where the sampled air is
17 in the wider tube. We have applied the same parameters as described in Karion et al. (2010) to
18 derive the vertical resolution for our AirCore. Figure 1 compares the vertical resolution of our
19 AirCore to other AirCore systems (Karion et al., 2010; Membrive et al., 2016). The calculation
20 is based on the assumption of sampling air down to 1000 hPa. At the upper altitudes, the reso-
21 lution is dominated in these calculation by the effective volume of the analyser cell, while mo-
22 lecular diffusion is the dominant term at low altitudes. The overall vertical resolution of the
23 measurements is better than 1 km below 24 km altitude and increases to about 2.5 km at 30 km
24 altitude (Fig. 1). For comparison, the HR-AirCore described by Membrive et al. (2016) achieves
25 a vertical resolution which is better than 300 m below 15 km and better than 500 m below 22
26 km, however using much longer tubing resulting in a higher weight.

27 **2.3 Operation and analytical setup**

28 Before the flight the AirCore is checked for leak tightness and cleanliness. As a first test, a gas
29 of known concentration is measured either directly or by passing it through the AirCore and the
30 measurements are compared. As a further test, the AirCore is filled with a gas of known con-
31 centration and analysed again after a storage time of 24 hours. Only if the CO₂ and CH₄ readings
32 from both values agree within the uncertainties, the AirCore is considered as clean and leak

1 tight. It is then filled with a fill gas (FG) of known CO₂, CH₄ and CO concentration no longer
2 than 24 hours before flight. Before flight the automatic valve mounted on the inlet side of the
3 AirCore is opened.

4 The AirCore should be analysed as quickly after the flight as possible as molecular diffusion
5 decreases the achievable vertical resolution. During the flight in Timmins, Ontario, this oc-
6 curred about 4 hours after the ~300 km flight, while the analysis started within an hour after
7 landing during the flights launched from Lindenberg. In order to achieve this fast analysis, the
8 analytical setup consisting of a Picarro analyser and a gas control system must be deployed in
9 the field. For this purpose, we mounted the analytical system in a car when operating from
10 Timmins and inside our laboratory bus during flights from Lindenberg. The setup also included
11 a battery-operated inverter allowing to run the Picarro for up to 6 hours, which also allowed the
12 instrument to remain heated and under constant flow while driving to the predicted landing
13 area. We use the same gas as Fill Gas (FG) and Push Gas (PG). This gas-mixture contains
14 typical atmospheric CO₂ values, typical CH₄ values expected around 30 km altitude and signif-
15 icantly higher CO values than observed either in the troposphere or in the stratosphere. Based
16 on the CO values, it is thus possible to distinguish between the sampled atmospheric air, the PG
17 and the FG, which is left in the tube.

18 The gas flow system used for the analysis of AirCore is shown in Figure 2. This system allows
19 the two lines, which are needed to connect the AirCore for the analysis, to be flushed with a
20 standard gas (Cal Gas) or the push gas used for the analysis (connection and flushing, upper
21 panel in Figure 2). During the connection all dead volumes of the connectors can be flushed,
22 minimizing the contamination from ambient air. During the connection the Picarro is flushed
23 with push gas. The pressure of the PG is regulated to slightly above ambient pressure (typically
24 1030 hPa) and the flow through the Picarro is regulated to 40 ml/min. Once all lines are flushed
25 and connected and the Picarro gives a stable reading of the expected value for the PG, the two-
26 position position valve can be switched. PG regulated at 1030 hPa is then flushed through the
27 AirCore with a flow of 40 ml/min. The stratospheric (upper altitude) air is flushed out first.
28 Before stratospheric air arrives at the Picarro analyser, the standard gas that was used for flush-
29 ing the connection lines will arrive first, followed by the remaining FG from the AirCore. The
30 amount of FG left will depend on the lowest pressure reached during flight and on the temper-
31 ature of the AirCore during that phase (see section data retrieval). A typical example of the raw
32 analytical results from the measurements of two AirCores embarked simultaneously on board
33 the flight from Timmins in 2015 (see section 3.1) is shown in Figure 3. Figure 4 shows a zoom

1 on the CO measurements shortly after switching the rotary valve. The PG with its high CO
2 values close to 1.4 ppm is measured. Then the CO values drop due to the lower values of the
3 calibration gas with which the connection line was flushed. This is then followed by the FG
4 remaining in the tube. Note that during this flight the amount of FG left was not sufficient for
5 the Picarro to arrive at its expected value of close to 1.4 ppm. After the passing of the peak with
6 high CO from the FG, the values drop sharply showing much lower CO values. These lower
7 CO values are expected in the middle stratosphere (Toon et al., 1999;Engel et al., 2006b) due
8 to the photochemical balance between production of CO from oxidation of CH₄ and the break-
9 down of CO due to oxidation with the OH radical. The transition from high CO (remaining FG)
10 to low CO thus marks the beginning of the sampled air at the upper part of the profile. In a
11 similar way, the transition from rather low tropospheric CO to high CO marks the time when
12 all the sampled air has been pushed out of the AirCore and the PG used to push the air out of
13 the AirCore is seen by the analyser.

14 **2.4 Data retrieval**

15 The Picarro analyser will deliver a time series of mixing ratios as a function of measurement
16 time. The absolute values of the Picarro analyser are transferred to the WMO scale (X2007
17 scale for CO₂ and X 2004a scale for CH₄) based on a calibration function derived from absolute
18 values of 4 gas bottles with a range of CO₂ values between 390 and 416 ppm of CO₂ and 1.07
19 to 1.91 ppm of CH₄ (only 3 gas bottles). The mixing ratios determined by the Picarro analyser
20 have to be matched to the altitude at which the air was sampled by the AirCore during the flight.
21 The basis of this altitude attribution is the ideal gas law and the molar amount sampled at each
22 altitude during the flight. This matching is achieved in a 4 stage process. First (i) the amount of
23 remaining Fill Gas is determined, then (ii) the sampling of air based on the ideal gas law is
24 calculated. In the third step (iii) the start and end times of AirCore in the analyser time series
25 are determined and finally (iv) the sampling and the analysis can be matched based on the molar
26 amount.

27 **2.4.1 Determination of remaining Fill Gas**

28 In the case of slow vertical displacement of the balloon, pressure equilibrium between the Air-
29 Core and the surrounding air can be assumed. Under this assumption of an instantaneous pres-
30 sure equilibrium, the molar amount n of an ideal gas stored in volume V at pressure p and
31 temperature T is according to the ideal gas law:

$$n = \frac{p \cdot V}{R \cdot T}$$

where R is the general gas constant. The temperature in this aspect is not the ambient temperature but the temperature of the coil, as we assume an instantaneous equilibrium between temperature of the air inside the AirCore with the coil temperature. In the (i) first step the amount of FG remaining in the AirCore at the top of the profile is then calculated by searching for the minimum in $\frac{p}{T}$.

As noted above, the assumptions about pressure equilibrium between air inside the AirCore and outside air needs to be made in this calculation. While this is certainly a valid assumption for a slow descent of the balloon, it will be less valid the faster the descent of the balloon. In the case of a rubber balloon which will burst while still ascending and then immediately start to descend the situation is even more difficult, as the pressure inside the AirCore will actually be higher than the outside pressure during the beginning of the descent, because a non-equilibrium will exist both for the emptying of the tube during ascent and the re-filling of the tube during the descend. The size of this non-equilibrium effect will depend on the geometry of the AirCore but also on the filling of the sample dryer. In particular, this latter may provide a significant flow restriction if the $\text{Mg}(\text{ClO}_4)_2$ is packed very densely. The amount of FG left in the AirCore is thus expected to differ significantly from the equilibrium amount calculated before based on the minimum in $\frac{p}{T}$. We have taken particular care to have a short and loosely packed dryer providing minimal flow restriction. As the FG used in our case differs significantly in CO values from ambient air and from the calibration gas used, it is possible to determine the amount of remaining FG by integrating the CO peak observed during the measurement of the AirCore (Chen et al., 2017) as illustrated in Figure 4. When switching from the bypass to the measurements mode, the gas inside the Picarro measurement cell is first replaced by the calibration gas, which was used to flush the transfer line to the AirCore during the connection. The calibration gas (Cal Gas) is then replaced by the FG which remained in the AirCore and then by ambient stratospheric air. All of these gases are partially mixed and all of them contain some CO. In order to separate the amount of CO due to PG and Cal Gas from the signal due to remaining FG, we performed a measurement in a similar set-up but with our AirCore filled with pure nitrogen, which contained no detectable amounts of CO. The CO in this set-up is thus not due to remaining FG and can be used to correct the offset due to PG and Cal Gas when integrating the CO peak from the remaining FG. Using the known mixing ratio of CO in the FG, the molar amount of remaining FG can be determined. In the case of the two fast descent profiles from

1 Lindenber (see section 3), the pressure of remaining FG was determined to be 17.2 hPa and
2 7.3 hPa, respectively, while the corresponding pressures derived from the minimum in $\frac{p}{T}$ was
3 slightly lower at 15.2 hPa and 7 hPa, respectively. The differences are rather small, correspond-
4 ing to altitude differences of a km or less, as the flow restriction of our AirCore is low due to
5 the large inner diameter of the 8 mm tube (which carries the largest part of the volume) and the
6 carefully packed sample dryer. In the following we have therefore only corrected this effect by
7 adopting the upper sampling pressure during the Lindenber flights to the value calculated from
8 the integration of the CO peak of the remaining FG.

9 **2.4.2 Sampling of ambient air with AirCore**

10 In the second step, we determine the amount of moles sampled during every time step of the
11 balloon trajectory. Again in case of slow descent the assumption of pressure equilibrium be-
12 tween the tube and the sampled ambient air is justified. Starting at the molar amount determined
13 during step 1 and adding up over the pressure and coil temperature measured during the descent
14 of the balloon results in a matrix linking ambient pressure and altitude to sampled molar
15 amount. In the case of a faster descent, the assumption of pressure equilibrium is not completely
16 valid, but as shown in section 2.4.1. the effect is small. To a first order this is compensated by
17 starting the summing at the molar amount determined from integration of the CO peak as de-
18 scribed in section 2.4.1.

19 The approach of summing up the amount of moles in the AirCore during the flight will also
20 take into account that air from the AirCore can be lost again, if the pressure of ambient air is
21 below that of the AirCore, e.g. in case the balloon ascends (which can occur for large strato-
22 spheric balloons) or if the AirCore heats up after landing without being closed. The procedure
23 is thus integrated in time until the moment that the AirCore is closed either manually or via an
24 automatic closure valve.

25 **2.4.3 Matching AirCore and Picarro data**

26 In the third step we determine the starting and ending point in the measurements of the air mass
27 sampled and stored in the AirCore with the Picarro (see Figure 2). This is achieved by fitting a
28 Gaussian curve to the CO peak from the remaining FG (see Figure 4). In case that there is so
29 much FG left that the CO peak reaches a plateau the left and right side of the remaining CO
30 from FG are fitted separately using only one side of the Gaussian for fitting. The time when the
31 peak reaches half its height is chosen as the start time. The time derived for the rising CO peak

1 is then taken as the start time of the FG, the time derived for the descending part of the peak is
2 taken as the start of the AirCore, i.e. ambient stratospheric air. We chose to use this second
3 point as the starting point and associate it with the amount of remaining FG determined in sec-
4 tion 2.4.1. The determination of starting and ending point of the AirCore analysis in the Picarro
5 time series is critical in the correct assignment of the measured mixing ratio to the sampling
6 location and altitude. Especially the starting point of the AirCore is a critical parameter as an
7 offset of 1 hPa will result in a significant shift in altitude in the stratosphere. The fourth step is
8 then to calculate the molar amount of air passing through the Picarro and linking this to the
9 molar amount sampled with the AirCore. The link between the molar amount and the time of
10 measurement is straight forward, as the flow through the Picarro is regulated to be constant (in
11 our case 40 ml/min) and also temperature and pressure of the measurement cell of the Picarro
12 analyser are controlled

13 **2.4.4 Correction of mixing ratios for mixing between AirCore and fill-** 14 **gas**

15 In order to keep the effect of mixing between FG and ambient stratospheric air small, the FG
16 had mixing ratios close to those expected in the middle stratosphere. The FG, which is also used
17 as PG, has a mixing ratio of about 407.75 ppm of CO₂ and 1228.6 ppb of CH₄. On the other
18 hand, the PG has much higher CO (about 1400 ppb) in order to allow a clear distinction from
19 both tropospheric and stratospheric air. Especially stratospheric air has much lower CO mixing
20 ratios, which are on the order of 20 ppb (Engel et al., 2006b; Toon et al., 1999). Our measure-
21 ments showed a gradual decrease of CO values from the high FG values to the significantly
22 lower stratospheric mixing ratios. Values as low as 20 ppb were only observed sporadically,
23 with values around 100 hPa pressure altitude typically being in the 30 ppb range. This enhance-
24 ment could either be caused by CO production from the reaction of ozone with the tubing or it
25 could be a measurement artefact as the Picarro is not well suited for such low CO mixing ratios.
26 This gradual decrease from the FG values to stratospheric values is due to a combination of
27 mixing and diffusion. While mixing is similar for all species, molecular diffusion depends on
28 the diffusion coefficient and is different for each gas. The upper part of the profile is stored in
29 the 2 mm O.D. tube. In this tube molecular diffusion only leads to a very gradual mixing of the
30 two gases (FG and ambient air). Most of the gradient is due to mixing during the analysis (the
31 limiting part is the volume of the analyser cell). Therefore, this gradient can be treated as a
32 gradient caused by mixing and not diffusion, and the mixing should be similar for all species.
33 We will thus use the large difference in CO to characterise the fraction of FG in the analysis

1 and correct the observed mixing ratios of CH₄ and CO₂ for the remaining impact of FG. In order
2 to determine the fraction of remaining FG an assumption on the expected stratospheric mixing
3 ratio of CO must be made. As we expect that the correction should approach zero once the cell
4 has been flushed a few times, we have chosen to use the average CO value observed between
5 80 and 100 hPa as the expected value. Using this target value the fraction of FG is calculated
6 from the difference between the measured and the expected CO mixing ratios and the observed
7 mixing ratio from the Picarro measurements is corrected accordingly.

8 **3 Atmospheric observations**

9 The AirCore developed at University Frankfurt is sufficiently light to be flown with a small
10 balloon. However, we performed our first test flights using large stratospheric balloons
11 launched by CNES from Timmins in Ontario. Two such test flights were performed in order to
12 compare our results with those of other groups. The first test flights were performed in 2014.
13 The results from the first flight in 2014 is reported by Membrive et al. (2016). Due to a balloon
14 trajectory which was not adapted to AirCore measurements (long ceiling and long float of the
15 balloon around 20 km altitude) the profiles obtained for CO₂ from AirCore could not be used
16 to derive mean age, as the AirCore showed unrealistically low values of CO₂ around the float
17 altitude, possibly due to an interference with the sample dryer (Membrive et al., 2016). These
18 data are therefore not discussed in this paper. During a second flight of the same payload as
19 reported in Membrive et al. (2016), the vertical velocities were much better adapted and we
20 could derive profiles of CO₂, CO and CH₄. These are presented in section 3.1. In section 3.2.
21 we present the first results from our AirCore measurements at mid latitudes using a small and
22 easy to launch rubber balloon of similar type as used for ozone soundings.

23 **3.1 Timmins 2015**

24 The payload launched from Timmins in the year 2015 was very similar to the one described in
25 Membrive et al. (2016). It consisted of a combination of two AirCores by University Frankfurt,
26 one high-resolution AirCore (Membrive et al., 2016) and two light weight AirCores by the
27 Laboratoire de Meteorologie Dynamique (LMD). In contrast to the Picarro G2401 used by
28 University Frankfurt, the LMD team used a G2301 analyser, which lacks the capacity to meas-
29 ure CO. The payload also included two pico-SDLA spectrometers (Ghysels et al., 2014;Durry
30 and Hauchecorne, 2005) for measurements of CO₂ and CH₄, which are based on in-situ infrared

1 absorption measurements. Results from these latter measurements were perturbed due to ther-
2 mal drifts in laser emission wavelength and are not available at the time of writing. The balloon
3 was launched from Timmins, Ontario, on August 22, 2015 and reached a minimum pressure of
4 about 11 hPa. In order to reach a zone where a safe landing was possible, the balloon was left
5 to drift westwards and a slow descent of the balloon was started in the early morning of August
6 23 (8:30 U.T.). The payload was separated from the balloon just below 100 hPa pressure and
7 the payload landed at about 10:40 U.T. The recovery team was able to recover the payload such
8 that the analysis could be started about 4 hours after landing.

9 Figures 5-7 show the vertical profiles of CO, CH₄ and CO₂ as measured with the Picarro ana-
10 lyser for both AirCores by GUF and in comparison to the LMD AirCores (only for CH₄ and
11 CO₂). The altitude attribution is based on the CO peak as described in section 2.4. One of the
12 AirCores (AC-2) was operated with the automatic closure valve and thus did not lose any air
13 while warming up on the ground after landing. The profile from this AirCore extends to the
14 ground, while other profile (AC-3) ends higher up due to the loss of air. First of all, two peaks
15 in CO are observed in the troposphere, which are found at the same altitude for both AirCores.
16 These could have been caused by biomass burning from wildfires occurring over western Can-
17 ada during the period of observations. Lowest values of CO in the stratosphere are on the order
18 of 10-20 ppb, in agreement with expected steady state values (Toon et al., 1999;Engel et al.,
19 2006b). AC-3, which was measured after AC- 2 shows an increase in CO mixing ratios above
20 20 km, which is most probably due to the longer storage time, resulting in more diffusive mixing
21 with remaining Fill Gas.

22 Figure 6 shows the vertical profiles of CH₄ derived from the 5 independent AirCores all
23 mounted on the same gondola. A remarkably good agreement is observed, as already shown for
24 observations in 2014 (Membrive et al., 2016). As also discussed in (Membrive et al., 2016) it
25 is obvious that the AirCore-HR is able to capture fine scale vertical structures which are not
26 present in the profiles derived from the light weight AirCore of University Frankfurt nor from
27 the light weight AirCore of LMD, which have a similar vertical resolution in the troposphere
28 but less vertical resolution in the stratosphere. The vertical profile of the light weight LMD
29 AirCore is only derived up to about 23 km altitude. Above 19 km altitude the light weight LMD
30 AirCore shows some deviations from the High Resolution AirCore and the University Frankfurt
31 AirCores. The University Frankfurt AirCore on the other hand is capable of capturing some
32 local structure around 21-22 km altitude, although the two local minima from the High Reso-
33 lution AirCore are smeared out to one broader minimum. Above 23 km altitude there seems to

1 be a small altitude mismatch between the University Frankfurt and the High Resolution Air-
2 Core, which is however less than 1 km. This altitude discrepancy is explained by the uncertainty
3 in matching the Picarro measurements to the AirCore sampling, which is also treated slightly
4 differently in the LMD and the University Frankfurt retrieval. In order to compare the values
5 of the different AirCores, we binned the data into 1 km intervals and then calculated averages
6 for each AirCore in these bins. In the troposphere (values between 3 and 13 km altitude) the
7 standard deviation between these 1 km bins is 1.4 ppb, or 0.08%. In the stratosphere the devia-
8 tions are higher due to the large vertical gradient. Absolute deviations are on average (between
9 15 and 24 km altitude) 11 ppb or 0.75%. The agreement of the two University Frankfurt Air-
10 Cores is much better (0.17 ppb or 0.001% in the troposphere and 3.8 ppb or 0.25% in the strat-
11 osphere), as is that of the two light weight LMD AirCores (0.28 ppb or 0.0015% in the tropo-
12 sphere and 1.6 ppb or 0.1% in the stratosphere).

13 The CO₂ measurements from the five AirCore are compared in Figure 7. The overall shapes of
14 the profiles from the different AirCores show good agreement. In particular, also rather small
15 scale phenomena are resolved and observed in all AirCores. For instance the small scale struc-
16 ture at around 13 km is observed in all AirCores, again showing that the sampling and the
17 altitude attribution gives consistent results. As already discussed by Membrive et al. (2016),
18 CO₂ measurements seem to show more deviations. However, it should be noticed that the range
19 shown for CO₂ is much smaller than for CH₄. In contrast to CH₄ the deviations in the tropo-
20 sphere and the stratosphere are very similar, as the vertical gradient is similar. In absolute terms,
21 the deviations are typically 0.35 ppm or about 0.09%. This deviation is thus on a very similar
22 level as observed for CH₄ in the troposphere. Overall, this agreement is very good, taking into
23 account that the different AirCores partly use different data retrieval algorithms and have dif-
24 ferent geometries and thus also different vertical resolutions. As in the case of CH₄, we note
25 that the agreement between the two University Frankfurt AirCores is much better (0.04 ppm or
26 0.01% in the troposphere and 0.17 ppm or 0.04% in the stratosphere), as is the agreement be-
27 tween the two light weight LMD AirCores (0.05 ppm or 0.015% in the troposphere and 0.07
28 ppm or 0.02% in the stratosphere). This shows that the differences are systematic and must be
29 related to the geometries of the different AirCores and the related uncertainties in the altitude
30 attributions.

1 **3.2 Lindenberg 2016**

2 A first test campaign to study the use of our AirCore using small balloons was conducted from
3 the Lindenberg Meteorological Observatory, Germany. AirCores were launched on May 20,
4 2016 and May 25, 2016. The balloon used for the first flight was a TA 1500 balloon. A larger
5 balloon (TA 3000) was used for the flight on May 25, which reached a higher ceiling altitude.
6 Ceiling pressures were 15.2 and 7 hPa, respectively. Large parachutes were used in order to
7 slow down the descent speed and minimize the effects due to non-equilibrium of pressure inside
8 of the AirCore and outside pressure. For both measurement flights we were able to recover the
9 AirCore very fast and start the analysis within an hour after landing. The retrieval procedure
10 was similar to the one for the flight from Timmins in 2015 with the exception that we derived
11 the pressure at which sampling began not from the measurements of ambient pressure but from
12 the integration of the CO peak as described in section 2.4.1. (diploma thesis Markus Ullrich,
13 University Frankfurt, Dec. 2016).

14 Figures 8 to 10 show the vertical profiles of CO, CH₄ and CO₂ from the two flights conducted
15 in May 2016. For CO the general agreement between both flights is very good, even though
16 they are five days apart. CO values are higher than observed in Timmins in 2015. This could
17 either be due to the use of a different Picarro analyser (note that these values are close to the
18 detection limits of CO) or to enhanced CO in early spring e.g. due to descending mesospheric
19 air during the polar winter. For all species there is a distinct change at the tropopause, which is
20 observed around 10.4 km altitude on May 20 and 10.9 km on May 25. . The decrease in tracer
21 mixing ratios, especially for CO, is observed at the same altitude as the thermal tropopause,
22 showing that the altitude attribution as explained in section 2 yields realistic results.

23 For CH₄ and CO this is due to the chemical loss in the stratosphere, whereas CO₂ is very long
24 lived in the stratosphere. The decrease in CO₂ values above the tropopause is mainly caused by
25 the high values of CO₂ in the northern hemisphere troposphere during spring, while the air
26 above the tropopause partly entered through the tropical tropopause and partly during late sum-
27 mer of the preceding year when tropospheric CO₂ values were lower due to the seasonal cycle
28 (Boenisch et al., 2009). Both CH₄ and CO₂ show some fine structures in the stratosphere during
29 both flights. There is a local maximum in CO₂ and CH₄ at around 21 km altitude on May 20
30 and a similar local maximum is observed on May 25 at about 20.5 km altitude. The maxima
31 and minima in CO₂ and CH₄ are collocated at the same altitude. Therefore, this is clearly a
32 dynamical feature where CO₂ rich (younger) air (see section 4) is advected which at the same
33 time has higher CH₄ mixing ratios. Such air masses would be expected to occur in the tropics

1 or subtropics. As the dynamical interpretation of the profiles is not the focus of this paper, this
2 is not investigated further e.g. by using meteorological data.

3 **4 Age of air from AirCore**

4 The main aim of our AirCore activities is to determine mean age of air and use this to extend
5 our long time series of mean age from balloon observations (Engel et al., 2009). The two tracers
6 most commonly used to derive mean age are CO₂ and SF₆. As shown in Engel et al. (2009), the
7 vertical gradient of mean age becomes rather small at pressures below 30 hPa (approximately
8 altitudes above 24 km). The mean value of mean age above this altitude has been used to in-
9 vestigate long term changes in mean age and in the stratospheric circulation (Engel et al., 2009).
10 An ideal tracer for the derivations of mean age should have neither sinks nor sources in the
11 middle atmosphere and show a monotonous, linear trend in the lower atmosphere (Hall and
12 Plumb, 1994; Waugh and Hall, 2002). Neither CO₂ nor SF₆ completely fulfil these requirements
13 (Engel et al., 2009) leading to uncertainties in the mean age values derived from observations.
14 In the case of CO₂ there are three specific issues which need to be considered: (i) the source of
15 CO₂ in the middle atmosphere due to the oxidation of CH₄, (ii) the seasonal cycle of CO₂ and
16 (iii) the deviation of the deseasonalized long term trend of CO₂ in the troposphere from linearity.
17 The procedure to calculate mean age and how to take these issues into account is the same as
18 in Engel et al. (2009) and only briefly summarized here. As CH₄ is oxidised in the stratosphere
19 and thus provides a source for CO₂ in the stratosphere, the amount of CO₂ produced from the
20 oxidation has to be subtracted from the observed CO₂ mixing ratio. The CO₂ produced in the
21 stratosphere is derived from the observed CH₄ by taking the difference to the deseasonalized
22 tropospheric CH₄ at the time of measurements. In this procedure the fact that CH₄ has a tropo-
23 spheric trend and takes some time to propagate to the stratosphere is ignored. The error in mean
24 age due to this simplification is less than half a month. CO₂ has a seasonal cycle in the tropo-
25 sphere which can propagate into the lower stratosphere (Andrews et al., 2001a; Andrews et al.,
26 2001b; Hints et al., 1998; Boenisch et al., 2009; Engel et al., 2006a). Rosenlof et al. (1997) found
27 that the seasonal cycle in water vapour is observable up to potential temperatures of about 450
28 K and termed this region the tropically controlled transition layer. In the stratospheric overworld
29 (above 450 K potential temperature) short term influences e.g. due to seasonal cycles in the
30 troposphere or tropopause region are much smaller. CO₂ can thus only be used as an age tracer
31 for air at potential temperatures above 450 K where the mixing ratios are not influenced by
32 seasonality in the troposphere anymore. Our analysis of mean age is thus restricted to potential

1 temperatures above 450 K. Thirdly, the deseasonalized tropospheric trend of CO₂ in the tropo-
2 sphere deviates from a perfect linear increase. The mean age derived from CO₂ observations
3 will thus depend on the shape of the age spectrum. To compensate for the effects of this devia-
4 tion on the mean age values derived, we again followed the same approach as in Engel et al.
5 (2009). We use a parameterization of the width of the age spectrum Δ as function of mean age
6 Γ as suggested by Hall and Plumb (1994), i.e. $\frac{\Delta^2}{\Gamma} = 0.7 \text{ years}$ with the general shape of the age
7 spectrum being an inverse Gaussian function. We have further adapted the fitting period for the
8 tropospheric trend so as to represent 98% of the air input for each individual data point (i.e.
9 shorter time periods for the fit are applied for younger air), in order to find the best possible
10 description of the tropospheric input time series.

11 The influence on all three effects on the mean age values has been included in the error analysis,
12 again following Engel et al. (2009).

13

14 **4.1 Vertical profile observations**

15 Figure 11 shows the mean age profiles for the two flights from Lindenberg in May 2016 and
16 the two AirCores flown simultaneously in August 2015 from Timmins. The data have been
17 filtered to exclude air masses with potential temperature below 450 K where the CO₂ seasonal
18 cycle is still expected to have a significant impact. As for many other profile observations of
19 mean age (Andrews et al., 2001a; Engel et al., 2009; Schmidt and Khedim, 1991) an increase of
20 mean age with altitude is observed up to about 23-24 km altitude, above which the vertical
21 gradient becomes very small. Mean age values above this layer are on the order of 5 years, in
22 very good agreement with other long term data sets. The observations from Timmins in August
23 2015 show slightly higher mean age values than the observations in May 2016 from Lindenberg
24 in Germany. This could be explained by the seasonal cycle in mean age derived from MIPAS
25 Envisat observations of SF₆, showing youngest air in the northern hemisphere mid latitudes
26 above 25 km during winter and oldest air during summer (Stiller et al., 2012). The younger
27 spring measurements from Lindenberg could thus still be influenced from the lower mean age
28 values during winter, while the older observations from Timmins in August 2015 should be
29 during the maximum of the seasonal cycle. Note that the accuracy of the mean age values de-
30 termined here is not limited by the analytical precision of the Picarro analyser, which is typically
31 0.025 ppm, which is less than a week when translated into mean age. .

1 **4.2 Extension of long term time series**

2 As explained above, we want to use AirCore observation to extend our long time series of
3 stratospheric mean age observations (Engel et al., 2009). The calculation of a temporal trend in
4 mean age is complicated by the sparsity of the data set in combination with a vertical gradient
5 in mean age. As the AirCore observations, in agreement with other balloon data, only show a
6 very small vertical gradient above an altitude of 23-24 km, corresponding to about 30 hPa, we
7 have adopted the same procedure as used in Engel et al. (2009), i.e. we average all data between
8 30 hPa and 5 hPa and calculate an average value of mean age for this region of the strato-
9 sphere.

10 The last data point in Engel et al. (2009) was from the year 2005. There is thus a gap of 10 years
11 between these last measurements and the new AirCore data. Overall the mean values derived
12 from the AirCore data are in very good agreement with the values published in Engel et al.
13 (2009). The mean values for mean age above 30 hPa from the Timmins flights are 4.9 ± 1 and
14 5.3 ± 1 years, while the Lindenberg flights yield slightly lower mean age values at 4.7 ± 1 and
15 4.8 ± 1 years. Note that the uncertainty ranges include uncertainties in the estimated representa-
16 tiveness, the derivation of mean age and the observations themselves, based on the error assess-
17 ment given in Engel et al. (2009). Using all the data available, we derive a new estimate of the
18 long term trend in mean age for the mid latitude stratosphere of the Northern Hemisphere be-
19 tween 30 and 5 hPa. The time period covered is now more than 40 years (1975-2016), albeit
20 with a very restricted number of profile observations. The updated trend is now calculated to
21 be 0.15 ± 0.18 years/decade. This trend is smaller than the previous estimate (0.24 ± 0.22
22 years/decade), but agrees within the uncertainty range. The positive trend is not significant
23 within the one sigma uncertainty range. Due to the reduced uncertainty of the new estimate, the
24 largest negative trend which would be compatible with our data within the two sigma uncer-
25 tainty range remains nearly unchanged (-0.21 years/decade instead of -0.2 years /decade).

26 **5 Summary and conclusion**

27 Observations of stratospheric trace gases are well suited to investigate chemical and physical
28 processes in the stratosphere. They are also well suited to investigate long term changes in the
29 stratosphere. In particular, for the investigation of long term changes, high precision and accu-
30 racy are needed in combination with rather low costs (Müller et al., 2016; Moore et al., 2014).
31 Most in-situ measurements in the stratosphere require the use of large and expensive balloons

1 to carry instruments above altitudes of 20 km. The new technique of AirCore (Karion et al.,
2 2010;Membrive et al., 2016) is ideally suited to provide such low cost long term observations.
3 We have thus investigated the usefulness of AirCore for investigations of long term evolution
4 of mean age in order to extend the existing balloon data set used in Engel et al. (2009) and(Ray
5 et al., 2014). University Frankfurt has developed an AirCore system from three different inner
6 diameter tubes, targeted at an optimal vertical resolution in the stratosphere, while still being
7 sufficiently light weight to be deployed on a small balloon. During an intercomparison cam-
8 paign in Timmins, Ontario in August 2015 we compared 5 different AirCores. We have shown
9 that the AirCore technique can be used to derive high precision vertical profiles of CO₂ and
10 CH₄. Both LMD and University Frankfurt measurements are referenced to the same scales, but
11 use independent calibrations. This shows that the results are also of high accuracy. For both
12 trace gases the comparison between the different independent AirCores was better than 0.1%
13 when vertical gradients are small, as is the case for CO₂ in the mid latitude stratosphere above
14 a pressure altitude of 30 hPa (about 24 km altitude) and for tropospheric CH₄. For CH₄ in the
15 stratosphere, where there is a large vertical gradient the typical agreement was still better than
16 1%. The agreement between two similar AirCores, which sampled in parallel was always better
17 than the agreement between different AirCores when sampling in parallel. This shows that the
18 geometry, the analysis system and the data retrieval of the AirCore has a significant impact. We
19 have further performed the first observations from the mid latitude site of Lindenberg in Ger-
20 many using small rubber balloons. Due to careful planning, it was possible to analyse the Air-
21 Cores within one hour after landing. We showed that the CO peak from the remaining Fill Gas
22 in the AirCore can be used to derive the maximum sampling altitude. In the case of the obser-
23 vations from Lindenberg the maximum sampling altitudes were only slightly lower than the
24 maximum pressure altitude of the balloon. This is a good indication that the flow restriction
25 was rather small and that the pressure equilibrium between the tube and outside air is rather
26 fast. This was achieved in particular due to the use of a large inner diameter tube for the main
27 volume of the AirCore and by using a sample dryer which was optimised for minimum flow
28 restriction. Nevertheless, the altitude attribution of the sampled air remains a difficult issue, in
29 particular when descent rates are high. The use of balloon techniques allowing for rather slow
30 descents should thus be considered when setting up AirCore measurements sites.

31 We have used the new observations to calculate mean age of stratospheric air. The results from
32 our AirCore observations are in very good agreement with previous observations using whole
33 air sampling techniques (Engel et al., 2009) with values ranging from 4.7 to 5.3 years of mean
34 age above a pressure altitude of 30 hPa. We have used these data to extend our long term time

1 series of balloon borne mean age observations. This time series now dates from 1975 to 2016,
2 thus spanning a total of more than 40 years. The long term trend of mean age in the northern
3 hemisphere mid latitude stratosphere deduced from this data set is 0.15 ± 0.18 years/decade. This
4 trend is smaller than the previous estimate (0.24 ± 0.22) years/decade but remains well within
5 the uncertainty limit. Based on this analysis, we thus sustain our result that no significant change
6 in mean age of air for the mid latitude stratosphere of the Northern Hemisphere can be derived
7 from our data set. Despite the smaller positive trend derived from this extended data set, large
8 negative changes in mean age in this region can still be excluded, as the uncertainty on the
9 derived trend has been reduced. A negative trend in mean age of more than -0.2 years/decade
10 for the middle stratosphere of the Northern Hemisphere mid latitudes can still be excluded with
11 95% confidence.

12 We conclude that we have shown that AirCore measurements even when using small balloons
13 can be used to derive vertical profiles of CO_2 and CH_4 . These observations are of sufficient
14 quality to derive mean age of air and use this to extend the currently available data set of strat-
15 ospheric mean age observations. We suggest that long term observations using AirCore from a
16 few selected stations covering different latitude bands may provide a useful tool to investigate
17 long term changes in mean age. An extension of the AirCore technique to other tracers gases
18 as suggested by (Moore et al., 2014) may provide a valuable addition as these gases can also be
19 used to study long term changes in the stratosphere. Müller et al. (2016) suggested that a long
20 term network for water vapour measurements in the stratosphere should be set up to monitor
21 this radiatively important trace gas. We suggest that such a network could be complemented by
22 AirCore observations. Such additional AirCore observations would put the observations of
23 changing water vapour into the general context of a changing stratospheric circulation. In addi-
24 tion, if both measurements are performed simultaneously, the observations of Methane from
25 the AirCore instruments and H_2O from the water vapour network could be used to derive the
26 sum of $2 \cdot \text{CH}_4 + \text{H}_2\text{O}$, which has been identified to show much less variability in the strato-
27 sphere than H_2O .

28 **Acknowledgements**

29 The work of University Frankfurt on AirCore has been funded through the ROMIC programme
30 of the German Ministry of Science and Education (Grant Nr. 01LG1221) and the EU Infra-
31 structure Project RINGO (Grant agreement. 730944). We would like to thank the French Space

1 Agency CNES for balloon operations in Timmins and the team of Ruud Dirksen from the Ger-
2 man Weather Service (DWD) in Lindenberg. The support of the workshops and technicians at
3 University Frankfurt is gratefully acknowledged. Special Thanks go to Huilin Chen from Uni-
4 versity of Groningen in the Netherlands for many valuable discussions on AirCore techniques
5 and an introduction to AirCore measurements during measurements from Sodankylä. Olivier
6 Membrive was funded by EIT/Climate-KIC, a body of the European Union.

3 Figure 2: Analytical Setup for the measurement of AirCore. The AirCore including the valves
 4 which are flown is shown in red. In the Bypass/Flushing position (upper panel) the Push Gas
 5 (PG) is measured bypassing the AirCore. The transfer lines to the AirCore can be flushed with
 6 PG or with a calibration standard (Cal Gas), allowing to connect the AirCore to the analytical
 7 system without contamination. For the analysis the transfer lines to the AirCore are closed, the
 8 AirCore valves are opened and the two position valve is switched to the Measurements mode
 9 (lower panel). The PG is passed through the AirCore and pushes the air to the Picarro. Pressure
 10 and flow are controlled allowing for a very constant air flow.

1
 2 Figure 3: raw analytical results for CO₂ from the measurements of the two AirCores flown from
 3 Timmins in 2015. Note that AC 2, which was measured first, contained a closure valve, while
 4 AC 3 was left open until the recovery team was able to reach the instrument. The lowest part
 5 of the AC 3 profile was therefore lost due to the warming of the AirCore on ground. The grey
 6 shaded areas denote the measurements of air from the AirCore. The stratospheric part of the
 7 profiles is always measured first. Before the measurements of AC2, between the measurements
 8 of the AirCores and after the measurement of AC3, PG is measured by the Picarro analyzer.

3 Figure 4: zoom on CO measurements from the flight on May 25, 2016. After switching the two
4 position valves to measurement mode. Before switching, the analyser measures the high CO
5 mixing ratios of the PG, then a decrease in CO is observed, representing the low CO values of
6 the Cal gas used for flushing the transfer lines, and finally the CO peak from the remaining FG
7 (note that PG and FG are taken from the same gas cylinder and thus have identical mixing
8 ratios) is measured. After the remaining PG has passed the analyser, the CO values drop to the
9 expected low stratospheric CO values. The red line shows the CO values measured using the
10 same setup but analyzing an AirCore filled with CO-free nitrogen. The area between the black
11 CO peak and the red baseline represents the amount of FG left in the AirCore.

1

2 Figure 5: Vertical profiles of CO derived for the flight on August 23 2015 from Timmins, On-
 3 tario, Canada. The two peaks with enhanced CO around 5 km altitude are observed in both
 4 AirCores and are probably caused by wild fires occurring in Canada during August 2015. There
 5 are no CO measurements from the LMD AirCores due to the Picarro analyzer used by LMD.
 6 The dashed lines represents the thermal tropopause according to the WMO definition.

1

2 Figure 6: Vertical profiles of CH₄ derived for the flight on August 23 2015 from Timmins,
 3 Ontario, Canada. Excellent agreement is observed between all AirCores. There is a slight high
 4 bias of the light LMD AirCores above 20 km with respect to both the University Frankfurt Air-
 5 Cores (red and blue trace) and the high resolution (HR) AirCore (green trace). The fine struc-
 6 tures observed by the HR AirCore are smeared out in the light weight AirCores by University
 7 Frankfurt and LMD. The dashed lines represents the thermal tropopause according to the WMO
 8 definition.

1

2 Figure 7: Vertical profiles of CO₂ derived for the flight on August 23 2015 from Timmins,
 3 Ontario, Canada. The overall structure are captured very well by all AirCores. Again, more fine
 4 structure is obvious in high resolution AirCore. See text for discussion of the differences be-
 5 tween the different AirCores. The dashed lines represents the thermal tropopause according to
 6 the WMO definition.

7

1
2 Figure 8: Vertical profiles of CO derived for the flights on May 20 and may 25 2016 from
3 Lindenberg in Germany. The flight on May 25 reached higher altitudes due to a larger balloon.
4 The dashed lines represents the thermal tropopause according to the WMO definition.
5

1
2 Figure 9: Vertical profiles of CH₄ derived for the flights on May 20 and May 25 2016 from
3 Lindenberg in Germany. The flight on May 25 reached higher altitudes due to a larger balloon.
4 The dashed lines represents the thermal tropopause according to the WMO definition.

1
2 Figure 10: Vertical profiles of CO₂ derived for the flights on May 20 and may 25 2016 from
3 Lindenberg in Germany. The flight on May 25 reached higher altitudes due to a larger balloon.
4 The dashed lines represents the thermal tropopause according to the WMO definition.

1

2 Figure 11: Vertical profiles of CO₂ derived mean age for the AirCore observations by Univer-
 3 sity Frankfurt in 2015 in Timmins, Canada and 2016 in Lindenberg, Germany.

1

2 Figure 12: Time series of mean age derived from balloon observations. The data prior to 2010
 3 are those presented in Engel et al. (2009). The data from 2015 and 2016 are derived from the
 4 AirCore measurements presented here. Each data point represents the average value of mean
 5 age derived above 30 hPa and up to 5 hPa. The inner error bars represent the variability (error
 6 of the mean), the larger outer error bars include the uncertainty as discussed in Engel et al.
 7 (2009). A non significant trend of $0.15 (\pm 0.18)$ years per decade is derived from these observa-
 8 tions.
