11 Abstract

12 Laboratory-based studies have shown that combustion sources emit volatile organic compounds that can be photo-oxidized in
13 the atmosphere to form secondary organic aerosol (SOA). In some cases, this SOA can exceed direct emissions of primary
14 organic aerosol (POA). Jathar et al. (2017) recently reported on experiments that used an oxidation flow reactor (OFR) to
15 measure the photochemical production of SOA from a diesel engine operated at two different engine loads (idle, load), two fuel
16 types (diesel, biodiesel) and two aftertreatment configurations (with and without an oxidation catalyst and particle filter). In
17 this work, we used two different SOA models, the volatility basis set (VBS) model and the statistical oxidation model (SOM),
18 to simulate the formation and composition of SOA for those experiments. Leveraging recent laboratory-based
19 parameterizations, both frameworks accounted for a semi-volatile and reactive POA; SOA production from semi-volatile,
20 intermediate-volatility and volatile organic compounds (SVOC, IVOC and VOC); multigenerational gas-phase chemistry; and
21 kinetic gas/particle partitioning. Both frameworks demonstrated that for model predictions of SOA mass to agree with
22 measurements across all engine load-fuel-aftertreatment combinations, it was necessary to model the kinetically-limited gas-
23 particle partitioning in OFRs as well as account for SOA formation from IVOCs, which were found to account for more than
24 90% of the model-predicted SOA. Accounting for IVOCs however resulted in an under-prediction of a factor of two for OA
25 atomic O:C ratios. Model predictions of the gas-phase organic compounds (resolved in carbon and oxygen space) from the
26 SOM compared favorably to gas-phase measurements from a Chemical Ionization Mass Spectrometer (CIMS), substantiating
27 the semi-explicit chemistry captured by the SOM. Model-measurement comparisons were improved on using vapor wall-loss
28 corrected SOA parameterizations. As OFRs are increasingly used to study SOA formation and evolution in laboratory and field
29 environments, models such as those developed in this work can be used to interpret the OFR data.

31 1 Introduction

32 Combustion-related aerosols are an important contributor to urban and global air pollution and have impacts on climate
33 (Pachauri et al., 2014) and human health (Anderson et al., 2012). While direct particle emissions from combustion sources are
34 dominated by primary organic aerosol (POA) and black carbon (Bond et al., 2004), these sources also emit more volatile
35 organic compounds (VOCs) that can photochemically react in the atmosphere to form secondary organic aerosol (SOA)
36 (Robinson et al., 2007). SOA production from combustion emissions is poorly understood and not very well represented in
37 models in terms of its precursors, gas-particle partitioning, composition, and properties (Fuzzi et al., 2015). Atmospheric
38 models frequently under-predict SOA mass concentrations during strong photochemical episodes in urban areas (Jathar et al.,
39 2017b), which likely highlights the challenge in modeling the SOA contributions from urban, combustion-related emissions
40 (Ensberg et al., 2014).

42 Diesel-powered sources, which are an important source of air pollution at urban and regional scales, emit precursors that form
43 SOA in the atmosphere (Gentner et al., 2016). Robinson et al. (2007) found that photochemical processing of exhaust
44 emissions from a small off-road diesel engine led to SOA production and doubled the primary aerosol mass over a few hours in
45 a chamber. Chirico et al. (2010) and Gordon et al. (2014) performed similar chamber experiments on tailpipe emissions from
46 in-fleet, on-road diesel vehicles run on chassis dynamometers. Both found SOA production that was roughly consistent with
47 the findings from Robinson et al. (2007). They additionally found that the use of aftertreatment devices (diesel oxidation
48 catalysts and diesel particulate filters) substantially reduced SOA production (mimicking the reduction in primary aerosol
49 emissions) but observed some SOA production during cold starts and/or regeneration events when the proper functioning of the
50 aftertreatment devices was limited. Furthermore, Gordon et al. (2014) found negligible differences in the SOA formation
51 between diesel and biodiesel fuel. To access longer equivalent photochemical aging timescales compared to typical chamber
52 experiments, Tkacik et al. (2014) measured SOA formation using an oxidation flow reactor (OFR) from air sampled from a
53 highway tunnel in Pittsburgh, PA used by both on-road gasoline and diesel vehicles. OFRs use high concentrations of
54 atmospheric oxidants, e.g. hydroxyl radicals, to achieve long exposures on short actual timescales; further discussion is
55 provided below. Tkacik et al. (2014) measured much stronger SOA formation compared to chambers (SOA: POA was 10:1)
56 over photochemical exposures equivalent to 2 to 3 days, but found that the SOA was lost, or destroyed, as the mixture
57 continued to age over the timescale of a week. Recently, Jathar et al. (2017a) performed experiments using an oxidation flow
58 reactor to measure the photochemical production of SOA from an off-road diesel engine operated at various engine load, fuel,
59 and aftertreatment configurations. Jathar et al. (2017a) found that efficient combustion at higher engine loads and removal of
60 SOA precursors by aftertreatment systems reduced SOA production by factors of 2 to 10. The only exception was that the
61 aftertreatment system did not seem to reduce SOA production at idle loads possibly because the exhaust temperatures were low
62 enough to limit removal of SOA precursors in the oxidation catalyst. Overall, these studies indicate that diesel exhaust
63 contributes to atmospheric SOA production, although the precise production of SOA varies across dimensions of
64 photochemical age, engine duty cycle, use of alternative fuels, and aftertreatment devices.

65

66 Oxidation flow reactors are being used to study the photochemical production of SOA from both anthropogenic (e.g., Ortega et
67 al. (2016)) and natural (e.g., Palm et al. (2016)) sources. Most OFRs used for SOA studies are 10 to 15 L, flow-through metal
68 reactors with lamps that can produce high concentrations of atmospheric oxidants to simulate photochemical processing (e.g.,
69 Lambe et al. (2011)). Flows through an OFR allow for residence times between one and three minutes, but given the high
70 oxidant concentrations OFRs can simulate up to two weeks of photochemistry. OFRs have three distinct advantages over
71 environmental chambers. First, OFRs are smaller in size and easier to operate than environmental chambers, which allows for
72 shorter experiments and makes them ideal for field deployments (Palm et al., 2016; Simonen et al., 2017). Second, production
73 of high oxidant concentrations in OFRs allows for much longer photochemical exposures (~factor of 10) than those possible
74 with chambers (Lambe et al., 2011). Third, due to their flow-through nature, OFRs have shorter residence times than
75 conventional chambers (~1-3 minutes) and hence are less susceptible to gas and particle losses that can influence SOA
76 formation (Zhang et al., 2014; Krechmer et al., 2016). Despite those advantages, there are concerns that the accelerated
77 chemistry and limitations to gas/particle partitioning may affect the formation and composition of SOA in OFRs, which calls
78 into question their relevance in understanding SOA formation in the real atmosphere (Palm et al., 2016; Jathar et al., 2017a).
79 For example, short residence times and/or small condensation sinks from preexisting aerosol may not allow for complete
80 condensation of SOA vapors (Lambe et al., 2015). Similarly, high oxidant concentrations in OFRs may lead to molecules
81 undergoing a greater number of reactions in the gas-phase before condensing, including reactions that lead to fragmentation

82 and formation of higher volatility products (Kroll et al., 2009). Both effects will typically suppress SOA production. With the
83 increased use of OFRs, there is a need to develop and use modeling tools that can account for fragmentation reactions and
84 kinetic gas/particle partitioning. This will allow for a more accurate interpretation of OFR data and facilitate translation of OFR
85 results to the real atmosphere.

86

87 Models used to simulate the photochemical production of SOA from VOCs in combustion emissions have traditionally used
88 the two-product (Odum et al., 1996) or the more generalized n-product volatility basis set (VBS) framework (Donahue et al.,
89 2006a). In this framework, VOC oxidation products are lumped into volatility bins based on their effective saturation
90 concentrations (C^*) and where the saturation concentration determines the partitioning of the products between the gas and
91 particle phases (Pankow, 1994). This framework has been widely used in both box (Dzepina et al., 2009; Hodzic et al.,
92 2010; Jathar et al., 2014a; Hayes et al., 2015) and three-dimensional (Murphy and Pandis, 2009; Tsimpidi et al., 2009; Jathar et
93 al., 2011; Ahmadov et al., 2012; Kononov et al., 2015) models to simulate the chemistry and gas/particle partitioning of SOA.
94 While this framework offers a simple and computationally efficient scheme to model SOA formation, the use of volatility
95 alone neither tracks the molecular composition, nor informs the continued multi-generational chemistry that will determine the
96 atmospheric evolution and properties of SOA. As a result, volatility-based models have been challenged in leveraging
97 observations of the elemental composition of SOA (e.g., atomic O:C ratios) that have become possible through the use of the
98 aerosol mass spectrometer (AMS) to constrain parameterizations or test model predictions. Further, most volatility-based
99 models have employed *ad hoc* parameterizations to model multi-generational chemistry that do not account for fragmentation
100 reactions (Robinson et al., 2007) and possibly double count SOA formation (Jathar et al., 2016). Therefore, there is a demand
101 to develop models that can provide an improved representation of the chemistry that governs the formation, composition, and
102 properties of SOA.

103

104 Previously, volatility-based SOA models have been used to predict photochemical production of SOA from motor vehicle
105 exhaust (Robinson et al., 2007; Jathar et al., 2014b; Tkacik et al., 2014). These modeling studies have shown that speciated SOA
106 precursors such as long alkanes (C_{6-12}) and single-ring aromatics (e.g., benzene, toluene) explain less than 20% of the observed
107 SOA and have argued that the remainder of the SOA (~80%) arises from the photooxidation of typically unspciated organic
108 compounds. These unspciated compounds, also referred to as intermediate volatility organic compounds (IVOCs), are likely
109 species with carbon numbers larger than 12 and appear as an unresolved complex mixture on using traditional gas
110 chromatography mass spectrometry (GC-MS) techniques (Presto et al., 2011). Early estimates of IVOC emissions and their
111 SOA potential have significantly improved predictions of the SOA formed from diesel exhaust (Jathar et al., 2014b) and have
112 broadly improved OA model performance in three-dimensional large-scale models (Murphy and Pandis, 2009; Pye and
113 Seinfeld, 2010; Jathar et al., 2011; Tsimpidi et al., 2009). Consider as an example that Zhao et al. (2015)₂ using a thermal
114 desorption GC-MS to provide detailed speciation of the carbon-number resolved linear, branched, and cyclic alkane IVOCs in
115 diesel exhaust, found that these species accounted for up to 60% of the non-methane organic gas emissions. While IVOCs have
116 been recognized as an important class of SOA precursors for diesel (and even for gasoline and biomass burning) sources,
117 updated emissions and speciation estimates from Zhao et al. (2015) have not yet been used to explain observations of
118 photochemically produced SOA from diesel exhaust.

119

120 Recently, several model frameworks have been developed to improve the representation of SOA formation, considering
121 dimensions of SOA beyond just volatility. The statistical oxidation model (SOM) developed by Cappa and Wilson (2012) is

122 one such example, although volatility remains an important consideration. The SOM is a semi-explicit, parameterizable
123 mechanism that uses a two-dimensional carbon-oxygen grid to simulate the multigenerational chemistry and gas/particle
124 partitioning of organic compounds. Although the SOM does not explicitly track or specify the product species composition
125 (e.g., functional groups), the carbon- and oxygen-number representation provides adequate detail to represent many key
126 atmospheric processes, e.g., reactions with oxidants, formation of functionalized products, scission of carbon backbones or
127 fragmentation, surface and condensed-phase chemistry and gas/particle partitioning. The SOM has been used to interpret
128 chamber experiments (Zhang et al., 2014;Cappa et al., 2013;Cappa and Wilson, 2012) and was recently integrated into a
129 chemical transport model (Jathar et al., 2015) to examine the influence of multigenerational aging (Jathar et al., 2016) and
130 chamber-based vapor wall losses (Cappa et al., 2016) on ambient concentrations and properties of OA. The two-dimensional
131 VBS (2D-VBS) of Donahue et al. (2011) and the carbon-polarity grid of Pankow and Barsanti (2009) are examples of similar
132 frameworks. These more sophisticated models (SOM, 2D-VBS, carbon-polarity grid) have not yet been employed to study
133 SOA formation from complex mixtures such as combustion emissions.

134

135 To summarize, combustion sources such as diesel-powered sources emit precursors that can photooxidize in the atmosphere to
136 produce SOA. This SOA production is dependent not only on the precursor composition (that could vary by combustion mode
137 and fuel type) and photochemical age, but also experimental artifacts (e.g., short condensation timescales) introduced by
138 oxidation flow reactors. Hence, there is a need to develop and apply sophisticated, yet computationally efficient, numerical
139 models to simulate and study SOA formation from combustion emissions. In this work, we applied two SOA model
140 frameworks that vary in sophistication (VBS and SOM) to simulate the photochemical production of SOA in an OFR from
141 diesel exhaust. The models were evaluated by comparing model predictions (OA and O:C) to the recent measurements made
142 by Jathar et al. (2017a), where SOA production was quantified for different photochemical ages under varying engine loads,
143 fuels, and aftertreatment devices. The model-measurement comparison, along with sensitivity simulations, highlights the
144 importance of modeling the kinetic gas/particle partitioning of SOA in OFRs, the contribution of IVOCs to the total SOA
145 production, and the ability of the SOM to accurately track the composition of SOA.

146

147 **2 Methods**

148 **2.1 Experiments and Data**

149 Jathar et al. (2017a) performed photooxidation experiments using an OFR to measure SOA production from the exhaust of a
150 4.5L, John Deere diesel engine. The stock engine met Tier 3 emissions standards for off-road diesel engines. The OFR used
151 therein was described in detail by Friedman et al. (2016) and the experimental setup and OA measurements from these
152 experiments were described in detail by Jathar et al. (2017a). We briefly summarize the experimental setup, measurements, and
153 findings from Jathar et al. (2017a). Diesel exhaust was diluted by a factor of 45-110 before entering the OFR. The intensity of
154 the mercury lamps (at wavelengths of 185 and 254 nm) inside the OFR was varied to produce different hydroxyl radical (OH)
155 concentrations and simulate different photochemical exposures. A suite of instrumentation was used to measure gas- (CO₂, CO,
156 total hydrocarbons, NO_x, O₂, oxygenated organic compounds) and particle- (aerosol size and composition) phase
157 concentrations. A total of fourteen experiments (see Table 1 for more details) were performed at varying engine loads and with
158 varying fuels and aftertreatment configurations. The OH exposure was varied between 0 and a maximum of 9.2×10^7
159 molecules-hr cm⁻³ (equivalent to 2 days of photochemical aging at an OH concentration of 1.5×10^6 molecules cm⁻³). On
160 average, each experiment included measurements at six to seven different photochemical exposures. The mass concentrations
161 and elemental composition of the POA (measured when OFR lights were off) and SOA (at varying OH exposures) were

162 measured by a high-resolution aerosol mass spectrometer (HR-AMS). In addition to the measurements reported by Jathar et al.
163 (2017a), the gas-phase concentrations of oxygenated organic compounds were measured by an acetate reagent ion-based
164 chemical ionization mass spectrometer (CIMS) (Link et al., 2016). At all engine configurations, SOA production exceeded the
165 POA emissions after the equivalent of a few hours of atmospheric photochemical aging. SOA production was particularly
166 strong at idle (or less fuel-efficient) engine loads and/or when exhaust temperatures were low and proper functioning of the
167 aftertreatment devices was limited. Further, POA emissions and SOA production were nearly identical between diesel and
168 biodiesel fuels. A synopsis of the THC (which includes all SOA precursors), POA, SOA, O:C, OH, and size distribution data
169 are presented in Table 1.

170

171 2.2 Organic Aerosol Models

172 In this work, we used two different OA models to predict the mass concentrations and chemical composition of SOA and
173 compare predictions against the SOA measurements from Jathar et al. (2017a) and Friedman et al. (2017). In this section, we
174 briefly describe the two model frameworks, namely the Volatility Basis Set (VBS) and the Statistical Oxidation Model (SOM),
175 used to simulate the coupled chemistry, thermodynamic properties, and kinetic gas/particle partitioning of OA. The VBS model
176 was chosen as it is widely used in contemporary air quality models; the SOM was chosen to examine the influence of improved
177 representation of OA processes (e.g., fragmentation reactions) on model predictions.

178

179 2.2.1 Volatility Basis Set

180 The Volatility Basis Set model, developed by Donahue et al. (2006b), is a parameterizable model that allows for a volatility-
181 based representation of the coupled chemistry, thermodynamic properties, and gas/particle partitioning of OA. The VBS uses
182 logarithmically spaced so-called basis sets based on the effective saturation concentration (C^*); C^* of a species determines the
183 partitioning between the gas and particle phases (Pankow, 1994). In the VBS model, precursor VOCs were allowed to react
184 with OH to yield a unique product distribution in C^* space that represented stable first-generation products. Subsequent multi-
185 generational gas-phase oxidation, or so-called ‘aging,’ of the VBS products was modeled using the scheme of Robinson et al.
186 (2007). In this scheme the product species are allowed to react with OH and yield a product with a C^* that was an order of
187 magnitude lower than the direct precursor, to a lower limit C^* of $10^{-1} \mu\text{g m}^{-3}$. This scheme did not consider fragmentation
188 reactions. The following equations were used to represent the precursor VOC oxidation (equation 1) and subsequent reaction
189 and formation of products from VOC oxidation and aging reactions (equation 2):

$$190 \frac{dV}{dt} = -k_{OH}[V][OH] \quad (1)$$

$$191 \frac{dC_j^{g+p}}{dt} = \alpha_j k_{OH}[V][OH] + \beta k_{OH,aging}[C_{j+1}^g][OH] - \gamma k_{OH,aging}[C_j^g][OH] \quad (2)$$

192 where V is the gas-phase concentration of a generic VOC precursor ($\mu\text{g m}^{-3}$; here, VOC includes VOCs, IVOCs and SVOCs),
193 k_{OH} is the reaction rate constant between the VOC and OH ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$), C_j^{g+p} is the gas + particle-phase concentration
194 in the j^{th} bin ($\mu\text{g m}^{-3}$), α_j is the mass yield of the first-generation oxidation product of the j^{th} bin (Table 2), $k_{OH,aging}$ is the reaction
195 rate constant ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) to represent multi-generational aging of the oxidation products, and β and γ are the mass
196 yields associated with the production and loss terms from multi-generational aging. For the j^{th} bin, the second term in equation
197 (2) represents the formation of oxidation products from the $j+1^{\text{th}}$ volatility bin and the third term in equation (2) represents the
198 loss of precursor from the j^{th} bin. β and γ are assumed to have a value of 1 (meaning no fragmentation) but β is zero for the last
199 bin and γ is zero for the first bin.

200

201 Volatility-resolved mass yields for eighteen different VOCs for C^* bins ranging from 10^{-1} to $10^3 \mu\text{g m}^{-3}$ were adopted or refit
 202 based on parameterizations published in the literature; VOCs, their VBS mass yields, and the relevant references are listed in
 203 Table 2. Some of these parameterizations accounted for vapor wall losses and have been accordingly marked in Table 2. Each
 204 SOA precursor in the exhaust emissions was assigned a surrogate from Table 2 to model SOA formation in the VBS model.
 205 Branched and cyclic alkanes were assigned surrogates based on equivalent linear alkanes, following the work of Lim and
 206 Ziemann (2009) and Tkacik et al. (2012). A C_X branched alkane was assigned a C_{X-2} linear alkane as a surrogate and a C_X
 207 cyclic alkane was assigned a C_{X+2} linear alkane as a surrogate. Since we only fit alkanes up to *n*-heptadecane, we considered *n*-
 208 heptadecane as a surrogate for alkanes C_{17} - C_{22} . The mass transfer (condensation/evaporation) of the VBS products to the
 209 particle phase was assumed to be kinetically-limited in the OFR (Palm et al., 2016; Jathar et al., 2017a); Section 2.3 describes
 210 the mass transfer equation used to model kinetic gas/particle partitioning.

211

212 2.2.2 Statistical Oxidation Model

213 The Statistical Oxidation Model (SOM), developed by Cappa and Wilson (2012) is a semi-explicit, parameterizable model that
 214 allows for a statistical representation of the coupled chemistry, thermodynamic properties, and gas/particle partitioning of OA.
 215 The SOM uses a 2-dimensional carbon-oxygen grid to track gas- and particle-phase precursors and products from VOC
 216 oxidation. Each cell in the SOM grid represents a model organic species with a molecular weight defined by the formula
 217 $C_xH_yO_z$. A SOM species reflects the average properties (e.g. C^* , reactivity) of all actual species with the same number of
 218 carbon (N_C) and oxygen (N_O) atoms that are produced from a given precursor class (e.g., benzene, alkanes). In the SOM, all
 219 gas-phase species are assumed to be reactive towards OH and the OH reactivity (k_{OH}) is calculated using equation 3 as follows:

$$220 \log(k_{OH}) = A_1 + A_2 \times (N_C^{A_3}) \times \exp\left(-1 \times \frac{E_a}{8.314 \times T}\right) \times \left[1 + \frac{b_1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{1(\ln(N_O+0.01)-\ln(b_2))^2}{2\sigma^2}\right)\right] \quad (3)$$

$$221 \sigma(N_C \leq 15) = 0.0214 \times N_C + 0.5238$$

$$222 \sigma(N_C \geq 15) = -0.115 \times N_C + 2.695$$

$$223 b_1 = -0.2583 \times N_C + 5.8944$$

$$224 b_2(N_C \leq 15) = 0.0314 \times N_C + 0.9871; b_2(N_C > 15) = 0.25 \times N_C - 2.183$$

225 where $A_1=15.1$, $A_2=3.94$, and $A_3=0.797$. k_{OH} for a specified N_C and N_O is assumed to be the same for species in all the SOM
 226 grids.

227

228 The reactions with OH lead to either functionalization or fragmentation, resulting in movement through the carbon-oxygen
 229 grid. Six precursor-specific adjustable parameters are assigned for each SOM grid: four parameters that define the molar yields
 230 of the four functionalized, oxidized products ($p_{O,k}$, $\sum p_{O,k}=1$ and hence one out of the four parameters is determined by mass
 231 balance), one parameter that determines the probability of functionalization or fragmentation (P_{Frag} , $P_{Func}=1-P_{Frag}$) and one
 232 parameter that describes the change in C^* associated with the addition of one oxygen atom (ΔLVP). Equation 4 represents the
 233 evolution of species in the SOM grid:

$$234 \frac{d[C_X O_Z]}{dt} = -k_{OH}^{X,Z} [OH][C_X O_Z] + [OH] \sum_{k=1}^4 k_{OH}^{X,Z-k} P_{Func}^{X,Z-k} p_{O,k} [C_X O_{Z-k}] +$$

$$235 [OH] \sum_{j=1}^{j_{max}} \sum_{k=0}^{k_{max}-Z} k_{OH}^{X+j,Z-1+k} \frac{P_{Frag}^{X,Z-1+k}}{N_{Fragments}^{X,Z}} [C_X O_{Z-1+k}] \quad (4)$$

236 where $C_X O_Z$ is the gas + particle-phase concentration of the SOM species with *X* carbon atoms and *Z* oxygen atoms ($\mu\text{g m}^{-3}$)
 237 and $N_{Fragments}$ is the number of possible products from fragmentation. The probability of fragmentation is modeled using

238 equation 5 as a function of the O:C ratio because higher O:C ratio compounds are expected to have a higher probability of
 239 fragmentation (Chacon-Madrid and Donahue, 2011):

$$240 \quad P_{frag} = \binom{N_O}{N_C}^{m_{frag}} \quad (5)$$

241 The C^* for each SOM species was calculated using equation 6 as follows:

$$242 \quad \log_{10} C^* = -0.337 MW_{HC} + 11.56 - (N_O \times \Delta LVP) \quad (6)$$

243 where MW_{HC} (g mole⁻¹) is the molecular weight of the hydrocarbon backbone (accounting only for the carbon and hydrogen
 244 atoms).

245

246 The parameters used to model SOA formation were based on those published in Cappa et al. (2016) and are listed in Table 3.

247 These parameter sets were developed by fitting the SOM predictions to chamber measurements of SOA mass concentrations
 248 and include corrections to account for vapor wall losses (Zhang et al., 2014). Each SOA precursor in the exhaust emissions was
 249 assigned a surrogate from Table 3 to account for the oxidation chemistry associated with oxidation of that species. For
 250 example, pentadecane used the parameterization developed by fitting *n*-dodecane. The difference in the initial number of
 251 carbons and oxygens, and thus the volatility, between the surrogate compound and the precursor compound of interest was
 252 accounted for, with consequent impact on the SOA yield. In other words, unlike the VBS where the SOA mass yield of the
 253 SOA precursor and surrogate is identical, the surrogate in the SOM only informed the statistical trajectory for multi-
 254 generational oxidation of a given precursor, and the surrogate and actual compound of interest can have different SOA mass
 255 yields. Similar to the VBS model, the mass transfer (condensation/evaporation) of the SOM products to the particle phase was
 256 assumed to be kinetically-limited in the OFR (Palm et al., 2016; Jathar et al., 2017a) and Section 2.3 below describes the mass
 257 transfer equation used to model kinetic gas/particle partitioning.

258

259 2.3 Kinetic Gas/Particle Partitioning

260 Palm et al. (2016) and Jathar et al. (2017a) have argued that the short residence times and small condensation sinks in the OFR
 261 may not permit all low-volatility products formed from VOC oxidation to condense onto preexisting aerosol. Hence, unlike
 262 earlier work that has assumed equilibrium partitioning to model SOA in OFRs (Tkacik et al., 2014; Chen et al., 2013), we
 263 modeled the kinetic gas/particle partitioning of OA using equation 7 (Zhang et al., 2014):

$$264 \quad \frac{dC_i^p}{dt} = 2\pi D_i D_p N_p F_{FS} (C_i^g - \frac{C_i^p C_i^*}{C_{OA}}) \quad (7)$$

265 where C_i^p is the particle-phase mass concentration for the i^{th} organic species ($\mu\text{g m}^{-3}$), D_i is the gas-phase diffusion coefficient
 266 of the i^{th} organic species ($\text{m}^2 \text{s}^{-1}$), D_p is the number mean particle diameter (m), N_p is the total particle number concentration
 267 (m^{-3}), F_{FS} is Fuchs-Sutugin correction for non-continuum mass transfer, C_i^g is the gas-phase mass concentration of the i^{th}
 268 organic species ($\mu\text{g m}^{-3}$), C_i^* is the effective saturation concentration of the i^{th} organic species, and C_{OA} is the total OA mass
 269 concentration ($\mu\text{g m}^{-3}$). The i^{th} organic species refers to the organic compounds tracked in the VBS bins and the SOM grids.
 270 The gas-phase diffusion coefficient was calculated for each organic species as follows:

$$271 \quad D_i = D_{CO_2} \frac{MW_{CO_2}}{MW_i} \quad (8)$$

272 where D_{CO_2} is the gas-phase diffusion coefficient of CO₂ ($1.38 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$), MW_{CO_2} (g mole⁻¹) is the molecular weight of CO₂,
 273 and MW_i (g mole⁻¹) is the molecular weight of the i^{th} organic species. In the VBS model where we do not track the molecular
 274 composition of the SOA species, we assumed all condensing species to have a molecular weight of 200 g mole⁻¹. The Fuchs-
 275 Sutugin correction was calculated as follows:

$$276 \quad F_{FS} = \frac{0.75\alpha(1+Kn)}{Kn^2 + Kn + 0.283 \cdot Kn \cdot \alpha + 0.75\alpha} \quad (9)$$

$$277 \quad Kn = \frac{2\lambda_i}{D_p} \quad (10)$$

$$278 \quad \lambda_i = \frac{3D_i}{C_j} \quad (11)$$

$$279 \quad C_i = \sqrt{\frac{8N_A kT}{\pi M W_i}} \quad (12)$$

280 where Kn is the Knudsen number, α is the mass accommodation coefficient, λ_i is the mean free path of the i^{th} organic species in
281 air (m), C_i is the root mean square speed of the gas (m s^{-1}), N_A is Avogadro's number (molecules mole^{-1}), k is the Boltzmann
282 constant ($\text{m}^2 \text{kg s}^{-2} \text{K}^{-1}$), and T is the temperature (K).

283

284 2.4 Model Inputs

285 2.4.1 Semi-Volatile and Reactive POA

286 Previous work has shown that much of combustion-related POA is semi-volatile and exists in an equilibrium with gas-phase
287 vapors (Robinson et al., 2007; Huffman et al., 2009; May et al., 2013c, b; May et al., 2013a). Jathar et al. (2017a) measured
288 emissions of POA at no OH exposure and these measured concentrations were used to initialize the seed OA available for
289 partitioning in the OFR and to calculate the mass concentrations of vapors in equilibrium with the POA. The mass
290 concentrations of the POA vapors were determined based on the normalized, volatility-resolved distribution of primary organic
291 compounds estimated by May et al. (2013b) for emissions from a suite of on- and off-road diesel vehicles. The volatility
292 distribution of May et al. (2013b) for diesel primary organic compounds is listed in Table 4(a). For the SOM, we assumed that
293 the primary organic compounds could be represented using a distribution of n -alkanes and we refit the volatility distribution in
294 Table 4(a) to develop a carbon-number resolved distribution of n -alkanes; this distribution is listed in Table 4(b). The POA and
295 POA vapors estimated for the VBS and SOM models for all the experiments are listed in the supplementary information
296 (Tables S1 and S2).

297

298 2.4.2 SOA Precursors

299 Jathar et al. (2017a) did not speciate the THC or SOA precursor emissions from the diesel engine and hence we have developed
300 our own emissions profiles based on previously published literature to speciate the THC emissions. In this work, we used two
301 different emissions profiles listed in EPA SPECIATE version 4.3 that are commonly used to speciate THC emissions from
302 diesel engines for emissions inventories used in atmospheric modeling (EPA, 2013): Profiles #3161 (Diesel Exhaust- Farm
303 Equipment) and #8774 (Heavy Duty Diesel Exhaust). Profile #3161 best matched the diesel engine source and diesel fuel used
304 by Jathar et al. (2017a) and was used as the baseline emissions profile to speciate the THC emissions; we examined the
305 sensitivity of using Profile #8774 on model predictions. We were unable to find a comprehensive emissions profile for THC
306 emissions from the use of straight biodiesel fuel in the literature, and have relied on emissions profiles that were determined for
307 biodiesel-diesel blends. Profile #4777 (30% Biodiesel Exhaust - Light Duty) was used as the baseline emissions profile to
308 speciate THC emissions for experiments performed using the biodiesel fuel. All three emissions profiles (3161, 8774, and
309 4777) are listed in Tables S1 through S3.

310

311 Prior work in studying SOA formation has revealed that traditional speciation of THC emissions does not include emissions of
312 high molecular-weight organic compounds, such as IVOCs, that are important SOA precursors (Jathar et al., 2014b). In Profile
313 #3161 such compounds are partially accounted for in the 'unknown' species category (13.76% by mass of THC). Zhao et al.

314 (2015) recently estimated the magnitude of IVOCs in THC emissions from a suite of on- and off-road diesel engines and
315 provided a semi-explicit speciation of the IVOC emissions as a carbon-number distribution of linear, branched and cyclic
316 alkanes. To account for these IVOC emissions, we assumed that the baseline emissions profiles contained 60% IVOCs on a
317 mass-basis, based on the median estimate in Zhao et al. (2015), and had the same chemical speciation as that proposed by Zhao
318 et al. (2015) for an off-road engine (transportation refrigeration unit). We performed sensitivity simulations using IVOC
319 fractions of 0% (assuming that the THC emissions contained no IVOCs) and 13.76% (based on the ‘unknown’ category in
320 Profile #3161), on a mass-basis. Addition of IVOCs to the baseline emissions profile meant that the VOC species (e.g.
321 benzene, toluene, short alkanes) had to be renormalized to accommodate the IVOCs. Table 5 lists the renormalized baseline
322 emissions profiles for SOA precursors used for diesel and biodiesel exhaust with 60% IVOCs along with the reaction rate
323 constants with OH (k_{OH}) and surrogates (or model compound) used to model SOA formation for the VBS and SOM models.
324 Concentrations for each species were determined by multiplying the experiment-specific THC mass concentrations with the
325 renormalized emissions profile.

326

327 2.4.3 Particle Size and Particle Number Concentrations

328 For numerical simplicity, we used a monodisperse aerosol, the properties of which (number mean diameter (D_p) and number
329 concentration (N_p)) were initialized from the measured particle size distribution data when modeling kinetic gas/particle
330 partitioning. For experiments performed without the DPF+DOC, the initial particle number concentrations and condensational
331 sinks were high ($>3 \times 10^5 \text{ # cm}^{-3}$ and $>0.5 \text{ min}^{-1}$) and hence the monodisperse aerosol was initialized based on data at no
332 photochemical exposure. For experiments performed with the DPF+DOC where the initial particle number concentrations were
333 relatively low ($<1000 \text{ # cm}^{-3}$ and $<0.003 \text{ min}^{-1}$), photochemical aging resulted in formation and growth of new particles and
334 provided a substantial increase in the surface area ($>$ factor of 100) available for condensation. In these experiments, we
335 initialized the monodisperse aerosol using an average of the data at no photochemical exposure and after photochemical
336 exposure (Palm et al., 2016). Averaging the data allowed for a more realistic estimate of the condensational sink. In each
337 simulation, the condensing SOA mass was used to calculate the change in particle size but the number concentration was
338 conserved. The number mean diameter and the number concentration data - representing the initial condensational sink - for all
339 experiments are listed in Table 1.

340

341 New particle formation and growth was observed for most experiments at or near the highest photochemical ages (at or >1 OH
342 day), which presumably influenced the condensational sink at the beginning of the experiment. Therefore, we performed
343 sensitivity simulations to investigate the influence of new particle formation on model predictions. We performed simulations
344 with each model (VBS and SOM) with four different initial condensational sinks. The first three simulations used measured
345 data to calculate the initial condensational sink inputs: (i) number mean diameter and measured number concentration at no OH
346 exposure (equivalent to the default for non-DPF+DOC experiments), (ii) number mean diameter and measured number
347 concentration at the given OH exposure, and (iii) average of (i) and (ii) (default for DPF+DOC experiments). The fourth
348 simulation (iv) assumed that the OFR nucleated 1 nm particles at the beginning of the experiment where the number
349 concentration of these particles was equal to that measured at the end of the experiment.

350

351 2.5 Model Simulations and Model Code

352 The VBS and SOM models were run separately for each photochemical exposure simulated for each experiment listed in Table
353 1. In the VBS simulations, POA was tracked in one basis set while products from each SOA precursor were tracked in separate

354 basis sets, allowing us to distinguish between POA and SOA. In the SOM simulations, all precursor molecules with the same
355 surrogate (e.g., all *n*-alkanes) were tracked in the same SOM grid. Model simulations were performed in phases to answer
356 specific questions and inform model inputs for later simulations:

- 357 1. To provide a general overview of the model predictions and model-measurement comparison, and to orient the reader
358 to the results thereafter, we performed simulations with the VBS and SOM models using the base set of inputs for one
359 of the Idle-Diesel-None experiments. Our base case included: Profile #3161 for VOC emissions, 60% IVOC mass
360 fraction, kinetic gas/particle partitioning with a mass accommodation coefficient of 0.1, and monodisperse aerosol
361 inputs based on measured data at no photochemical exposure.
- 362 2. Models used to simulate SOA production in environmental chambers and OFRs have typically assumed instantaneous
363 equilibrium partitioning (e.g., Chen et al. (2013)). To examine the validity of assuming instantaneous equilibrium
364 partitioning, we performed simulations with the VBS and SOM models using instantaneous or kinetic gas/particle
365 partitioning for one of the Idle-Diesel-None and the Idle-Diesel-DPF+DOC experiments. Kinetic partitioning was
366 modeled using three values of the mass accommodation coefficient ($\alpha=0.01, 0.1, 1$) to capture the uncertainty in its
367 true value. To examine the influence of an increased initial condensational sink from new particle formation on kinetic
368 partitioning, we performed additional simulations using four different initial condensational sinks (see Section 2.4.3)
369 on one of the Idle-Diesel-None and the Idle-Diesel-DPF+DOC experiments.
- 370 3. Previous work has shown that combustion-related IVOCs are important precursors of SOA (e.g., Jathar et al. (2014b)).
371 To investigate the importance of IVOCs, we performed simulations with the VBS and SOM models at three different
372 assumed IVOC mass fractions (0%, 13.76%, and 60%), as discussed above when discussing the THC profiles, at all
373 photochemical exposures and for all the experiments listed in Table 1. We performed additional simulations with
374 different emissions profiles and SOA parameterizations on one of the Idle-Diesel-None experiments to further
375 investigate uncertainties linked to the composition and SOA potential of IVOCs.
- 376 4. Additional simulations were performed to examine the sensitivity of model predictions to the following processes:
377 multi-generational aging, vapor wall losses, residence time distributions, spatial heterogeneity in OH concentrations,
378 and low NO_x SOA parameterizations.

379 The numerical codes for the VBS were developed in Matlab while those for the SOM were developed in IGOR (WaveMetrics
380 Inc.). These codes will be made available on request. The simulations were performed on an Intel i5 processor (1.7 GHz) and
381 required ~10 s to perform a VBS simulation and ~500 s to perform a SOM simulation at a single photochemical exposure.

382

383 3. Results

384 3.1 General Model Results Using the Base Case

385 We compare predictions of OA from the VBS and SOM models using the base case to the measurements in Figure 1 for the
386 Idle-Diesel-None experiment. Figures 1(a) and 1(b) compare predictions to the measurements in units of $\mu\text{g m}^{-3}$ and g kg-fuel^{-1} ,
387 respectively; hereafter we present all mass predictions in units of g kg-fuel^{-1} . For this experiment, the VBS and SOM models
388 over-predicted the OA mass by a factor of ~3 at the lower photochemical exposures (0.06 and 0.17 OH days). For higher
389 photochemical exposures (>0.5 OH days), both models performed very well in reproducing the OA evolution with little
390 difference between the VBS and SOM models. Although our base case seemed to offer a reasonable model-measurement
391 comparison for this specific experiment, the model performance did vary across the suite of experiments, which is discussed in
392 more detail in Section 3.3. The VBS and SOM models predicted that the OA at the maximum photochemical exposure was
393 dominated by SOA produced from VOC and IVOC oxidation (94%), which agreed well with the measured composition (see

394 Figure 1(c)). For the measurements, POA was defined as fresh OA while SOA was defined as OA formed in addition to the
395 POA. Furthermore, both models suggested that most of the SOA emanated from the oxidation of IVOCs with only about 3-4%
396 resulting from the oxidation of aromatic VOCs and less than 1% resulting from alkane VOCs smaller than a C_{12} . This
397 dominance of IVOCs in explaining the photochemically produced SOA is in line with previous OFR and chamber studies that
398 have modeled SOA formation from diesel exhaust (Tkacik et al., 2014; Zhao et al., 2015; Jathar et al., 2014b).

399

400 3.2 Kinetic Gas/Particle Partitioning

401 In Figure 2, we plot predictions from the VBS and SOM models for the Idle-Diesel-None and Idle-Diesel-DPF+DOC
402 experiments assuming instantaneous and kinetic gas/particle partitioning. The two different experiments were deliberately
403 chosen to highlight the role instantaneous partitioning plays at the extremities. We found that for the Idle-Diesel-None
404 experiment, the use of instantaneous partitioning produced the same result as kinetic partitioning with α values of 0.1 and 1 and
405 that all these predictions resulted in roughly the same model-measurement comparison. The kinetic partitioning simulations
406 (except for that with an α of 0.01) produced the same result as the instantaneous partitioning simulation most likely because the
407 initial condensational sink was large enough (1.12 min^{-1}) in this experiment that there were no kinetic limitations to
408 partitioning. The increase in the condensational sink through condensation of SOA (10 min^{-1} at the highest photochemical
409 exposure) tended to further reduce any differences in the predictions between the kinetic and instantaneous partitioning
410 simulations. However, for the Idle-Diesel-DPF+DOC experiment, the instantaneous partitioning simulation predicted
411 substantial SOA production at the lower photochemical exposures (0.04 and 0.12 OH days) compared to the kinetic
412 partitioning simulations, specifically a factor of 10 to 100 larger for the VBS model and a factor of 3 to 4 larger for the SOM.
413 The instantaneous partitioning simulations predicted a lot more SOA because all condensable products of VOC oxidation were
414 allowed to condense instantaneously (according to their respective volatilities) while the kinetic partitioning simulations
415 predicted little SOA production because the initial condensational sink was quite small (0.002 min^{-1}). Predictions from the
416 instantaneous and kinetic partitioning simulations were nearly identical at the higher photochemical exposures because the
417 SOA formed had grown the condensational sink enough to reduce limitations to partitioning (10 min^{-1} at the highest
418 photochemical exposure). These results imply that the condensation of SOA in OFRs, at least to some extent, could be
419 kinetically-limited and that instantaneous partitioning may result in models over-predicting the condensation and formation of
420 SOA.

421

422 We make two additional observations based on the results in Figure 2. First, the initial condensational sink for the Idle-Diesel-
423 None experiment was large (1.12 min^{-1}) compared to condensational sinks one would encounter in the real atmosphere. For
424 example, $5 \mu\text{g m}^{-3}$ of aerosol in a representative rural or remote environment will have a condensational sink $<0.05 \text{ min}^{-1}$
425 (Seinfeld and Pandis, 2006). Therefore, modeling ambient applications of the OFR will need to be even more mindful of the
426 instantaneous partitioning assumption while predicting SOA formation. Second, for the kinetic partitioning results, predictions
427 from both models were relatively insensitive to α values between 0.1 and 1 but were dramatically lower (factor of ~ 4) for an α
428 value of 0.01. Given the reasonable model-measurement comparison at an α value of 0.1 and 1, we argue that the SOA
429 condensation needs to be represented by an α value larger than 0.1 for the OFR experiments in this work. This α value for
430 diesel exhaust SOA is consistent with prior estimates of the α value of α -pinene SOA estimated from chamber and aerosol
431 heating experiments (Karnezi et al., 2014) (Lee et al., 2011; Saleh et al., 2013) but significantly higher than that observed
432 recently for toluene SOA under dry conditions (Zhang et al., 2014). Model results presented hereafter include a kinetic
433 treatment of gas/particle partitioning and assumed an accommodation coefficient of 0.1.

434

435 Results from model simulations performed using different initial condensational sink inputs, some of which captured the
436 influence of new particle formation, are plotted in Figure 3. We found that the initial condensational sink had no influence on
437 the OA predictions from both models for the Idle-Diesel-None experiment, despite substantial differences in the initial
438 condensational sink between the different cases. This was because the amount of SOA formed ($875 \mu\text{g m}^{-3}$ at the highest
439 photochemical exposure) was sufficient to grow the condensational sink enough that the initial condensational sink did not
440 matter. In contrast, for both models we found large differences between the model predictions of OA for the Idle-Diesel-
441 DPF+DOC experiment. The use of inputs based on the measurements at no OH exposure, where the aftertreatment system
442 significantly reduced number concentrations (910 cm^{-3}) and hence the available condensational sink (0.0018 min^{-1}), produced
443 much less SOA (factor of ~ 3 lower) and poorer agreement with the measurements (see curve (i) in Figure 3). Initial
444 condensational sinks that captured the influence of new particle formation resulted in better agreement of the model predictions
445 with measurements. The DPF+DOC results also suggest that calculating an initial condensational sink using data from before
446 and after photochemical exposure could be used as an input to model OFR data.

447

448 3.3 Influence of IVOCs on SOA Formation

449 In Figure 4(a), we compare predictions of SOA concentrations from the SOM against measurements for all the experiments
450 listed in Table 1 and at all photochemical exposures. For visual clarity, we do not present results from the VBS model as both
451 models had nearly identical predictions with a few exceptions; see Figure S1 where we compare VBS model predictions to
452 SOM predictions for all experiments at all photochemical exposures for the base case. The three panels in Figure 4(a) show
453 model-measurement comparisons assuming three different fractions of IVOCs: 0%, 13.76% and 60%; statistical metrics of
454 fractional bias, fractional error, and R^2 for the comparison for both models are listed in Table S4. The model-measurement
455 comparison and the model skill was very poor when no IVOCs were included (fractional bias = -135%, fractional error =
456 146%, and $R^2 = 0.79$); this model reflects the treatment of diesel-powered sources in most traditional emissions inventories and
457 large-scale models. The model performance improved with 13.76% IVOCs (fractional bias = -60%, fractional error = 108%,
458 and $R^2 = 0.92$) and 60% IVOCs (fractional bias = 46%, fractional error = 87%, and $R^2 = 0.92$). The optimal model performance
459 that produced the lowest fractional bias and fractional error was realized at an IVOC mass fraction of 40% (fractional bias = -
460 10%, fractional error = 97%, and $R^2 = 0.9$) (not shown). For predictions with an IVOC mass fraction of 40%, 59% and 68% of
461 the model predictions were within a factor of 1.5 and 2 of the measurements. These comparisons indicate that it is critical that
462 IVOCs be included when modeling the SOA formation from diesel exhaust and also validate the IVOC emissions and
463 composition estimates made by Zhao et al. (2015) for IVOCs.

464

465 We further investigated the IVOC species that contributed the most to SOA formation. Cyclic alkane IVOCs accounted for
466 45% of the THC emissions and contributed 40 to 75% of the SOA formation across the different experiments. We should note
467 that the speciation of cyclic alkane IVOCs in Zhao et al. (2015), while robust in quantifying the carbon number, did not include
468 any specificity in terms of the molecular structure, i.e., their methods would not be able to distinguish between a pure C_{10}
469 cyclic alkane and a cyclohexane with a 4-carbon branch. Further, the parameterizations to model SOA formation from cyclic
470 alkane IVOCs for both models were based on the behavior of particular compounds. In the VBS model, the surrogate for a
471 cyclic alkane IVOC was determined through equivalence with a straight alkane IVOC while in the SOM the cyclic alkane
472 IVOCs were tied to parameterizations for hexylcyclohexane. (The observed SOA yield and derived SOM parameterization for
473 hexylcyclohexane is actually quite similar to that for cyclododecane for low- NO_x conditions, but not for high- NO_x conditions

474 (Cappa et al., 2013).) This lack of specificity in the speciation and the SOA parameterizations made the SOA predictions from
475 the oxidation of cyclic alkane IVOCs relatively uncertain. To examine the sensitivity of the model predictions to uncertainties
476 in the model treatment of cyclic alkane IVOCs, we performed simulations with both models for one of the Idle-Diesel-None
477 experiments where the cyclic alkane IVOCs were treated as branched alkane IVOCs; results from these simulations are shown
478 in Figure 5(a). The use of branched alkane IVOCs to model cyclic alkane IVOCs reduced OA predictions at the highest
479 photochemical exposure by 33% and 11% for the VBS and SOM models respectively, suggesting that the model predictions
480 were modestly sensitive to the SOA parameterization used for cyclic alkane IVOCs. We recommend that future work focus on
481 more detailed speciation of cyclic alkane IVOCs in combustion emissions as well as on chamber and OFR experiments on
482 those speciated compounds to improve quantification of their SOA mass yields.

483

484 As there were no direct measurements of any SOA precursors in the study of Jathar et al. (2017a), we have used previously
485 published emissions profiles for diesel exhaust to determine initial concentrations of the SOA precursors. We examined the
486 sensitivity of model predictions to two different emissions profiles from the EPA SPECIATE (version 4.3) database: Profile
487 #3161 (included in the base case) and Profile #8774 that represents emissions from ‘Heavy Duty Diesel Exhaust’; the
488 speciation for both profiles is provided in Tables S1 and S2. Both profiles only included speciation for VOC emissions and in
489 these simulations we assumed an IVOC mass fraction of 60%. The results captured in Figure 5(b) for one of the Idle-Diesel-
490 None experiments show that the choice in the emissions profile had very little influence on the OA evolution, which was
491 expected given that most of the SOA was formed from IVOC, rather than VOC, oxidation. This further demonstrates that
492 IVOCs, not VOCs, play an important role in controlling the SOA formation from diesel exhaust emissions and it is important
493 that future studies work towards better understanding the IVOC speciation.

494

495 The IVOC speciation of Zhao et al. (2015) included 37 unique species, each of which required a unique surrogate to model the
496 SOA formation from that species. Tracking these many IVOC species in an atmospheric model (e.g., global climate model)
497 may be intractable and hence, there is a need to develop simplified parameterizations to efficiently model SOA formation from
498 IVOCs. We note that species using the same surrogate in the VBS model (e.g., a C₁₅ linear alkane, C₁₇ branched alkane, and
499 C₁₃ cyclic alkane are all parameterized using *n*-pentadecane) could be lumped together to reduce the number of precursors and
500 products tracked and that there are no penalties for a precursor type (e.g., *n*-alkanes) to include additional precursor and
501 product species once a SOM grid is setup. Nonetheless, to investigate the possibility of developing a simplified
502 parameterization, we modeled SOA from IVOCs assuming that all the IVOCs could be modeled together as a single linear C₁₃,
503 C₁₅, or C₁₇ alkane; a similar strategy was employed by (Jathar et al., 2014b) to model SOA formation from unspciated organic
504 compounds in combustion emissions. Results from these simulations are shown in Figure 5(c) for one of the Idle-Diesel-None
505 experiments. For the VBS model, the use of a linear C₁₅ and C₁₇ alkane parameterization for IVOCs reproduced the
506 measurements well. For the SOM, the use of a linear C₁₇ alkane parameterization produced good agreement with
507 measurements. Differences in the VBS and SOM predictions with different alkane parameterizations point to inherent
508 differences in the coupled representation of multigenerational aging and gas/particle partitioning. Results from these
509 simulations indicate that in cases where computational efficiency is demanded, the SOA formation from IVOCs in diesel
510 exhaust could be modeled using a surrogate linear alkane, possibly a C₁₅ or a C₁₇ linear alkane.

511

512 3.4 Elemental Composition

513 The SOM tracks both the carbon and oxygen number of the oxidation products, which allowed us to predict the O:C ratio of

514 the OA. The O:C of the OA was calculated by combining the measured O:C of the POA with the modeled O:C of the SOA. We
515 compare predictions of the O:C of OA from the SOM against measurements for all the experiments listed in Table 1 and at all
516 photochemical exposures in Figure 4; statistical metrics of fractional bias, fractional error, and R^2 for the comparison are listed
517 in Table S5. Model predictions for the no IVOC case, where the O:C of the OA was dominated by the O:C of the aromatic
518 SOA, compared well with measurements (fractional bias = -3%, fractional error = 29%, and $R^2 = 0.80$). However, the poor OA
519 mass predictions with no IVOCs suggests that the good O:C performance was purely coincidental. Both the 13.76% and 60%
520 IVOC cases under-predicted the OA O:C, on average, by about a factor of two although the 13.76% IVOC case offered a
521 slightly better model performance than the 60% IVOC case (fractional bias = -41%, fractional error = 43%, and $R^2 = 0.75$ for
522 the 13.76% IVOC case versus fractional bias = -55%, fractional error = 57%, and $R^2 = 0.49$ for the 60% IVOC case). For both
523 the 13.76% and 60% IVOC cases, the model skill in predicting the O:C was much better for the non-DPF+DOC experiments
524 ($R^2 = 0.83$ and 0.50 respectively) than for the DPF+DOC experiments ($R^2 = 0.02$ and 0.29 respectively). Measurements and
525 model predictions of the OA O:C ratio from the 0% and 60% IVOC case as a function of photochemical age are presented in
526 Figure S2.

527

528 The under-prediction in O:C ratios was confounding when compared to earlier applications of the SOM and in light of the
529 reasonable model-measurement comparison found in this work in predicting OA mass. We note that the low O:C in the 13.76%
530 and 60% IVOC cases stems from the dominance of product species that have high carbon numbers and low oxygen numbers.
531 We explored several lines of reasoning for this under-prediction. First, Cappa et al. (2013) found good agreement between the
532 SOM-predicted and observed O:C for chamber experiments conducted using individual linear, branched and cyclic C_{12} alkanes.
533 Also, general predictions of the dependence of O:C on the carbon number of the parent hydrocarbon (cf. Fig. 2b in Cappa and
534 Wilson (2012)) show good agreement with observations (cf. Fig. 2a in Tkacik et al. (2012)), both in terms of absolute values
535 and shape. This suggests that uncertainties in the SOM parameters may not be the dominant reason for the under-prediction. A
536 possible reason for the under-prediction then is that the compounds identified by Zhao et al. (2015) as IVOCs are structurally
537 different than the alkanes used to model them in this work. Second, it is possible that we incorrectly assumed, based on the
538 measured VOC:NO_x ratio (1.9 and 4.1 ppbC ppbN⁻¹ for the Idle experiments and 0.06–0.55 ppbC ppbN⁻¹ for the Load
539 experiments), that the SOA was formed under high NO_x conditions and that we would need to use SOM parameters developed
540 from high NO_x experiments. In an OFR, high oxidant loadings (OH and O₃) could rapidly reduce NO_x at the OFR inlet and
541 result in most of the SOA being formed at low NO_x conditions (Peng and Jimenez, 2017). We performed simulations to
542 examine the sensitivity of model predictions to the use of SOM parameters developed from low NO_x experiments. We found
543 that the SOM resulted in an average increase of only 5% in O:C predictions but an average increase of 65% in OA mass across
544 all experiments at the highest photochemical exposure. A better understanding of the NO_x chemistry inside the OFR (Peng and
545 Jimenez, 2017) might provide insight on the parameterizations needed to model SOA formation in OFRs. Third, the gas-phase
546 chemistry in the OFR might be inherently different than that in a chamber. For example, kinetic limitations to gas/particle
547 partitioning may result in gas-phase oxidation of low-volatility products having high O:C that typically would have partitioned
548 to the particle phase in a chamber experiment but instead are fragmented (Palm et al., 2016). As to why the chamber-based
549 SOM parameters then offer good model performance on OA mass remains unclear. One way in which this issue could be
550 addressed in the future is by developing SOM parameters exclusively based on OFR data, as and when they become available.
551 And finally, the SOM used here did not include surface/heterogeneous and particle-phase reactions that might influence the OA
552 composition and O:C ratio. When heterogeneous reactions of OA were included assuming an OH uptake coefficient of 1 (the
553 product distribution from the oxidation reaction was kept the same as the gas-phase reactions), SOA production at the highest

554 photochemical exposure for all the experiments was reduced, on average, by 10% from fragmentation reactions within the
555 particle phase, but the O:C ratio was only marginally increased (average of 1%).

556

557 To understand the O:C under-prediction better, we compared model predictions of normalized gas-phase species
558 concentrations from the SOM to normalized gas-phase measurements made by Friedman et al. (2017) using a chemical
559 ionization mass spectrometer (CIMS). The CIMS detects an array of oxygenated organic species and the high resolution of the
560 time-of-flight mass spectrometer enables identification of the elemental composition of each detected peak. The CIMS data
561 were aggregated by carbon and oxygen number to facilitate comparison with the SOM data. The comparison was performed on
562 a normalized basis because the CIMS did not provide absolute concentrations for every detected peak. The SOM-CIMS
563 comparisons for the Idle-Diesel-None and Load-Diesel-None experiments at the highest photochemical exposure are shown in
564 Figure 6, which highlight four findings of note. First, the CIMS measured species larger than a carbon number of 12 that are
565 presumably products from oxidation of higher molecular weight organic compounds, although the possibility of dimer
566 formation in the instrument cannot be entirely ruled out. Nonetheless, this provides additional evidence for the presence of
567 IVOC oxidation products in diesel exhaust emissions. Second, the CIMS measured organic compounds with high O:C ratios
568 (e.g., C₆O₆, C₇O₇). This implies that the reaction chemistry in OFRs rapidly adds functional groups to the carbon backbone,
569 although larger, less oxidized compounds could be simultaneously functionalized and fragmented in the CIMS to lead to the
570 appearance of highly oxidized species having only 6 carbon atoms. Third, the SOM offered a reasonable correlation against the
571 CIMS measurements for both experiments across a majority of the carbon-oxygen combinations that spanned more than four
572 orders of magnitude. Qualitatively, this finding validates the statistical evolution of organic compounds tracked through the
573 generalized SOM mechanism, although certainly some differences are evident. Finally, compared to the Idle-Diesel-None
574 experiment, the SOM over-predicted the fractional contribution of low-oxygen number species (O₀ to O₃, factor of 5) and
575 under-predicted some of the high oxygen number species (O₅ to O₇, factor of 2) in the Load-Diesel-None experiment. This
576 under-prediction of the high oxygen number species might potentially explain why the SOM may be under-predicting the OA
577 O:C ratio. The SOM-CIMS comparison is preliminary and we intend to explore the implications of this comparison in future
578 work.

579

580 3.5 Other Model Sensitivities

581 We performed sensitivity analyses to examine the influence of other key processes on predictions from both the VBS and SOM
582 models. When examining the sensitivity to each process, all the other inputs were kept the same as those listed in the base case.
583 We only present sensitivity results for the Idle-Diesel-None experiment performed on June 5, as the results for this experiment
584 were generally representative of all experiments (Figure 7). For completeness, we performed simulations for all the
585 experiments at the highest photochemical exposure since each of the processes explored below manifested the strongest
586 response at the highest photochemical exposure. The results from these simulations are presented as a change in the model
587 predictions relative to that offered by the base case.

588

589 **Multi-generational Aging.** One of the key differences between the VBS and the SOM models is how they represent the multi-
590 generational aging of gas-phase products. SOA parameters for the VBS model represent stable product distributions at the end
591 of the chamber experiments and therefore already include the influence of multi-generational aging reactions encountered
592 during the chamber experiment. Additional multi-generational aging in the VBS model, based on the scheme of Robinson et al.
593 (2007), is simulated as a continuous decrease in product volatility, which does not account for fragmentation reactions and has

594 not been constrained against experiments. The SOM framework explicitly models multi-generational aging that includes
595 treatment of fragmentation reactions and constrains the aging reactions based on the chamber experiments to an extent that is
596 determined by the length (in OH exposure space) of the experiment. To test the influence of multi-generational aging, we
597 performed model simulations with aging turned off for the VBS and SOM models and plot the results in Figure 7(a). We found
598 that aging had no influence on model predictions from the VBS model, most likely because the high SOA and OA mass
599 concentrations resulted in a substantial fraction of the organic species to be partitioned to the particle phase. This left very little
600 of the organic species in the gas-phase to participate in multi-generational aging; we calculated that less than 1% by mass of
601 the product species in this experiment was in the gas-phase at the OA mass concentration at the highest photochemical
602 exposure, implying that the SOA mass yields at these OA mass concentrations approached 100%. In contrast, the absence of
603 aging resulted in a 46% decrease in the OA mass for the SOM. The decrease was mainly because the first generation oxidation
604 product with the highest yield (i.e., C_xO_1) was too volatile to partition to the particle phase and needed to be aged further to
605 form condensable products. As noted earlier, the term aging is defined differently for the VBS and SOM models and the results
606 presented here need to take the definitional issues into account when examining the influence of aging. Compared to the base
607 case, no aging resulted in an average decrease of <1% and 27% in OA mass for the VBS and SOM models respectively for all
608 experiments at the highest photochemical exposure. These simulations suggest that aging of the oxidation products, at least for
609 the SOM, is as important as the contribution of first generation products to SOA formation.

610

611 **Vapor Wall Losses.** Prior work has highlighted the influence vapor wall losses exert on the calculation of SOA mass yields
612 from chamber experiments (Zhang et al., 2014; Krechmer et al., 2016). Cappa et al. (2016), based on the chamber work of
613 Zhang et al. (2014), recently published parameter sets for the SOM that accounted for no vapor wall losses and two different
614 vapor wall loss rates (1×10^{-4} and $2.5 \times 10^{-4} \text{ s}^{-1}$) assuming an equivalent OA mass of the chamber walls of 10 mg m^{-3} (the base
615 case used the parameter sets for a vapor wall loss rate of $2.5 \times 10^{-4} \text{ s}^{-1}$). We performed model simulations with SOM using
616 parameters that were either not corrected for vapor wall losses or that were corrected for vapor wall losses using either the low
617 (1×10^{-4}) or high (2.5×10^{-4}) estimates proposed by Cappa et al. (2016). The results plotted in Figure 7(b) show that correcting
618 for vapor wall losses slightly increased model predicted OA mass (by 8% and 27% for the low and high cases respectively at
619 the highest photochemical exposure) and provided the best performance for the high estimate for vapor wall losses. Across all
620 experiments and at the highest photochemical exposure, accounting for vapor wall losses using the high estimate resulted in an
621 average increase of 36% over no accounting for vapor wall losses. These comparisons suggest that it is important to use SOA
622 parameterizations in which vapor wall losses in chambers have been accounted for when interpreting SOA experiments.
623 Furthermore, we also simulated the influence of vapor losses to the OFR walls on model predictions. We assumed reversible
624 uptake of vapors to the walls and used a vapor wall loss rate of $2.5 \times 10^{-3} \text{ s}^{-1}$ (factor of ~ 10 larger than that for a chamber) based
625 on the work of Palm et al. (2016) and an equivalent OA mass concentration of 10 mg m^{-3} for the OFR walls. The results plotted
626 in Figure 7(b) show that the loss of vapors to the OFR walls had a small influence on model predictions: a 9% decrease for this
627 experiment and an average decrease of 12% across all experiments at the highest photochemical exposure. Increasing the
628 equivalent OA mass concentration for the OFR walls to 100 and 1000 mg m^{-3} seemed to have no influence on model
629 predictions. These findings imply that vapor wall losses in the presence of sufficient seed aerosol might not be of concern for
630 OFRs (Lambe et al., 2015).

631

632 **Residence Time Distributions.** Model simulations performed in this work assumed that the OFR operated as a plug flow
633 reactor with a constant residence time. Experimental studies by Lambe et al. (2011) and fluid dynamics simulations by Ortega

634 et al. (2016) have shown that OFRs, particularly like the one used in this work, exhibit heterogeneity in residence times. We
635 performed simulations to explore the sensitivity of varying residence times on model predictions. These simulations were
636 performed based on a discretized version of the residence time distribution measured by Lambe et al. (2011) for SO₂ that
637 yielded an average residence time of 100 seconds (same as that used by Jathar et al. (2017a)). The discretized version included
638 six parcels with volume fractions of 0.23, 0.36, 0.24, 0.11, 0.05, and 0.01 with residence times of 45, 65, 100, 200, 300, and
639 500 seconds respectively. Each parcel experienced the same OH concentration but the varying residence times resulted in
640 different OH exposures for each parcel. The parcels were combined after photochemical exposure without repartitioning the
641 OA between the six parcels. Similar to the findings of Peng et al. (2015) for calculating OH exposure, our results in Figure 7(c)
642 show that using a residence time distribution had very little influence on the OA mass evolution compared to use of an
643 effective average time. Compared to the base case, the residence time distribution resulted in an average decrease of 3% and
644 7% in OA mass for the VBS and SOM models respectively for all experiments at the highest photochemical exposure.

645

646 ***Spatial Heterogeneity in OH.*** In addition to the influence exerted by a distribution of residence times, spatial heterogeneity in
647 the gas-phase chemistry inside the OFR (e.g., from radial variation in light intensity) could lead to spatial heterogeneity in OH
648 concentrations and result in a distribution of OH exposures for the sample being aged. We performed simulations to explore the
649 sensitivity of a varying OH exposure on model predictions. These simulations were performed where we split the sample
650 coming into the OFR into two parcels and treated the parcels to different OH exposures. Each experiment was repeated for all
651 combinations (six total) of three different parcel splits ($\frac{1}{4}$ - $\frac{3}{4}$, $\frac{1}{3}$ - $\frac{2}{3}$, $\frac{1}{2}$ - $\frac{1}{2}$) and two different OH exposure splits ($\frac{1}{3}$ -X, $\frac{2}{3}$ -X); X
652 was determined by conserving the total OH exposure reported by Jathar et al. (2017a). For instance, the first simulation was
653 performed by splitting the OFR air parcel into $\frac{1}{4}$ and $\frac{3}{4}$ fractions by volume and exposing the $\frac{1}{4}$ volume to $\frac{1}{3}$ the OH exposure.
654 The parcels were combined after photochemical exposure without repartitioning the OA between the two parcels. The results in
655 Figure 7(d) show that the simulated spatial heterogeneity always reduced the OA mass although the maximum reduction (12%
656 for the VBS and 15% for the SOM models) at the highest photochemical exposure was well within the measurement
657 uncertainty. Compared to the base case, the spatial heterogeneity in OH resulted in a maximum decrease of 12% and 14% in
658 OA mass for the VBS and SOM models respectively for all experiments at the highest photochemical exposure.

659

660 4. Summary and Discussion

661 Recently, Jathar et al. (2017a) reported on experiments performed using the oxidation flow reactor (OFR) to measure the
662 photochemical production of secondary organic aerosol (SOA) from diesel exhaust under varying engine loads, fuel types, and
663 emissions control systems. These data present an opportunity to not only test SOA models but also use these models to
664 interpret OFR data and determine their relevance for the real atmosphere. In this work, we applied two different SOA model
665 frameworks (VBS and SOM) to simulate the photochemical production of SOA in an OFR from diesel exhaust and evaluated
666 those model frameworks using the data from Jathar et al. (2017a). The volatility basis set (VBS) model is a parameterized
667 model that allows for a volatility-based representation of OA while the statistical oxidation model (SOM) is a semi-explicit
668 parameterized model that uses a carbon-oxygen grid to track OA. Both simulated the coupled chemistry, thermodynamic
669 properties, and gas/particle partitioning of OA and accounted for: (i) semi-volatile and reactive emissions of primary organic
670 aerosol (POA), (ii) SOA production from IVOCs and VOCs, (iii) multi-generational aging, and (iv) kinetic gas/particle
671 partitioning.

672

673 Model predictions suggest that the instantaneous gas/particle partitioning assumption may over-predict SOA formation in

674 OFRs when the initial condensational sinks are low and the condensation of SOA is likely kinetically limited. Hence, SOA
675 formation in OFRs needs to be modeled/interpreted through an explicit treatment of kinetic gas/particle partitioning.
676 Differences in model predictions between instantaneous and kinetic partitioning will depend on the rate at which condensable
677 SOA mass is produced in the OFR (depends on the initial precursor concentrations and photochemical exposure), residence
678 time in the OFR, properties of the condensing species (e.g., diffusion coefficient, molecular weight), and parameters relevant
679 for partitioning (e.g., accommodation coefficient, seed aerosol surface area). To explore the relative importance of
680 instantaneous and kinetically-limited partitioning in an OFR, we used the SOM to simulate SOA formation from diluted diesel
681 exhaust using instantaneous and kinetic partitioning assumptions for varying amounts of SOA formed ($0.1\text{--}1000\ \mu\text{g m}^{-3}$) and
682 initial condensational sinks ($0.001\text{--}10\ \text{min}^{-1}$). The calculations were performed for two different particle sizes (10 and 100 nm)
683 since the condensation of SOA mass would grow the initial condensational sink for the two particles at different rates, i.e. for
684 the same starting initial condensational sink, smaller particles would experience quicker growth in the condensational sink
685 compared to larger particles for the same amount of condensing mass. We assumed a residence time in the OFR of 100 s and
686 an accommodation coefficient of 0.1. The results plotted in Figure 8 show the ratio of SOA predicted through kinetic
687 partitioning to that predicted through instantaneous partitioning as a function of the initial condensational sink and the SOA
688 formed under an instantaneous partitioning assumption. We found that the SOA formation in the OFR was kinetically-limited
689 over most of input ranges explored and approached the SOA formed under the instantaneous partitioning assumption either
690 when the initial condensational sink was very large ($>5\ \text{min}^{-1}$) or when a large amount of condensable SOA was produced in
691 the OFR ($\geq 1000\ \mu\text{g m}^{-3}$ for the 10 nm particles and $\gg 10000\ \mu\text{g m}^{-3}$ for the 100 nm particles). Our finding implies that
692 ambient applications of the OFR, where initial condensational sinks are typically smaller ($\sim 0.005\text{--}0.5\ \text{min}^{-1}$) and the maximum
693 SOA produced is typically less than $20\ \mu\text{g m}^{-3}$, will only produce a small fraction (1–30%) of the intended SOA. Although
694 these simulation results need to be verified experimentally, they do suggest that it might be challenging to operate the OFR in
695 conditions where instantaneous or atmospherically-relevant partitioning is applicable, further complicating the coupled
696 atmospheric simulation of chemistry and thermodynamics in OFRs.

697

698 Upon including IVOCs as SOA precursors, both the VBS and SOM models were able to reasonably predict the OA mass
699 evolution reported by Jathar et al. (2017a) across different engine loads, fuel types, and emissions control systems. Model
700 predictions suggest that 40% of the unburned hydrocarbon emissions are likely IVOCs and that these IVOCs (regardless of the
701 emissions profiles used to determine non-IVOC emissions) would account for most ($>90\%$) of the SOA formed from diesel
702 exhaust. These findings are consistent with prior work from chamber experiments (Jathar et al., 2014b) and modeling studies
703 (Zhao et al., 2015). Simulations performed using single surrogates suggest that the complex mixture of IVOCs in diesel
704 exhaust could be well represented using a linear C_{15} or C_{17} alkane. These offer a computationally-efficient strategy to model
705 SOA formation from IVOCs in large-scale three-dimensional models. The SOM tracks the carbon and oxygen numbers of the
706 oxidation products and hence model predictions were used to calculate atomic O:C ratios for OA, which were then compared to
707 measurements. While the inclusion of IVOCs allowed for good model-measurement comparisons on OA mass, the SOM
708 under-predicted the O:C ratio of OA by a factor of two, possibly highlighting the limitations in modeling the IVOCs as alkanes
709 and/or extrapolating chamber-based parameterizations to OFR experiments. Model predictions of the gas-phase organic species
710 compared favorably to those measured using a chemical ionization mass spectrometer (CIMS), which qualitatively validates
711 the statistical evolution of organic compounds tracked through the generalized SOM mechanism.

712

713 As OFRs are increasingly used to study SOA formation and evolution in laboratory and field environments, there is a need to

714 develop models that can be used to interpret OFR data. This work suggests that multi-generational aging (in case of the VBS
715 model), residence time distributions, and spatial heterogeneity in OH concentrations produced sensitivities that were well
716 within the measurement uncertainty and were not a concern for the model system studied. However, model predictions did
717 appear to be more sensitive to multi-generational aging (in case of the SOM) and influence of vapor wall losses, highlighting
718 that these processes be included in OFR models. While the conclusions from this work may be relevant for other laboratory
719 and ambient studies, their relative importance may vary. There are several instances where the model development was
720 insufficient and will likely be addressed in future work. For example, the model could benefit from the use of a polydisperse
721 size distribution to treat new particle formation and growth and improve predictions of the evolution of the aerosol size
722 distribution. Similarly, the model needs to be rigorously tested against other laboratory (e.g., Lambe et al. (2012)) and ambient
723 (e.g., Palm et al. (2016)) OFR data.

 931

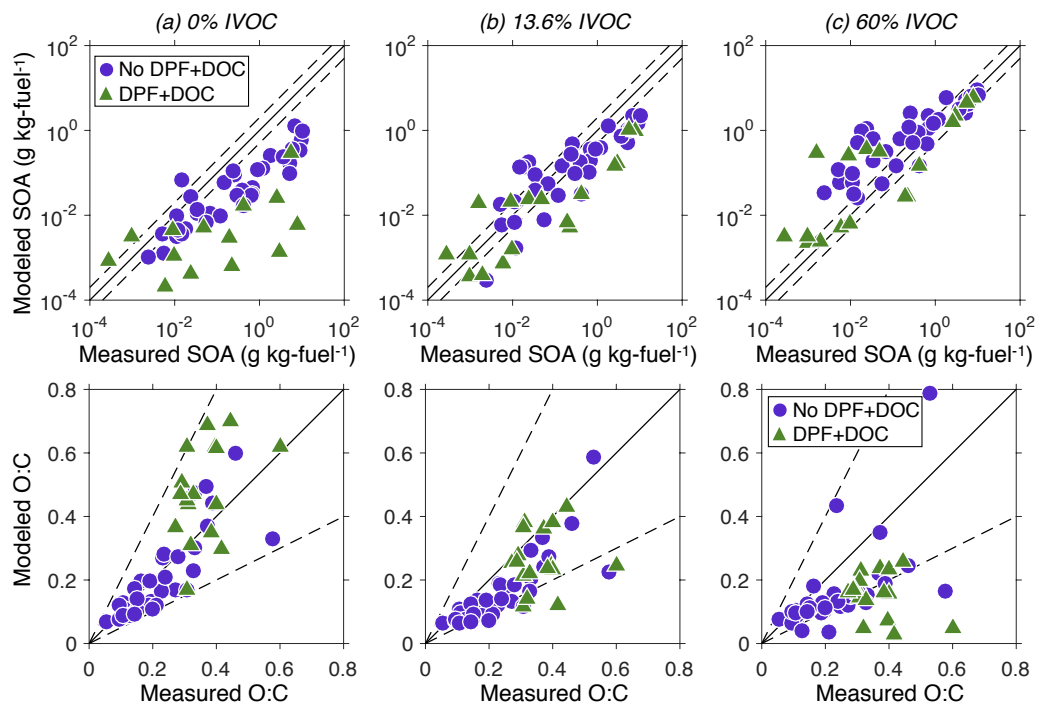

932
 933 *Figure 1: VBS and SOM model predictions of OA compared to measurements from the experiment performed on June 5 (Idle-*
 934 *Diesel-None) as a function of photochemical age. Inputs for both models have been specified in the text. Panel (a) has*
 935 *comparisons in $\mu\text{g m}^{-3}$ and panel (b) has comparisons in g kg-fuel^{-1} . Panel (c) shows the modeled and measured OA*
 936 *composition at the highest photochemical exposure.*
 937

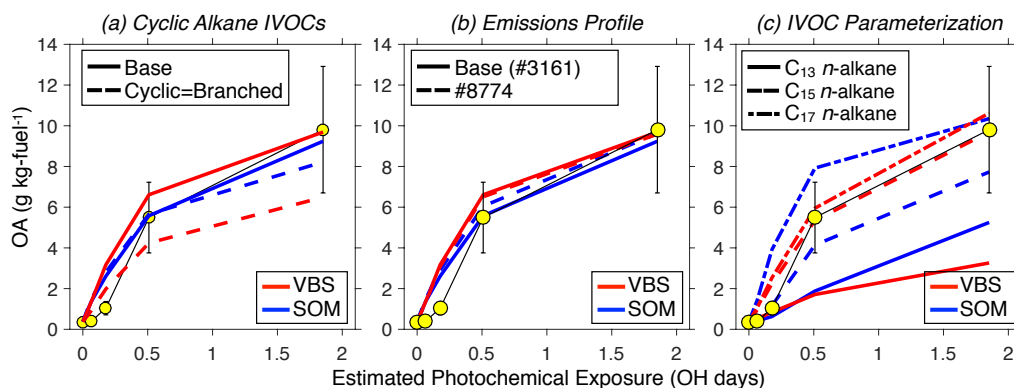

938
 939 *Figure 2: VBS model predictions of OA compared to measurements from the experiment performed on June 5 (Idle-Diesel-*
 940 *None) as a function of photochemical age assuming instantaneous equilibrium partitioning and kinetic gas/particle*
 941 *partitioning run at three accommodation coefficients, $\alpha = 1$ (dash-dot), 0.1 (dash) and 0.01 (solid).*
 942

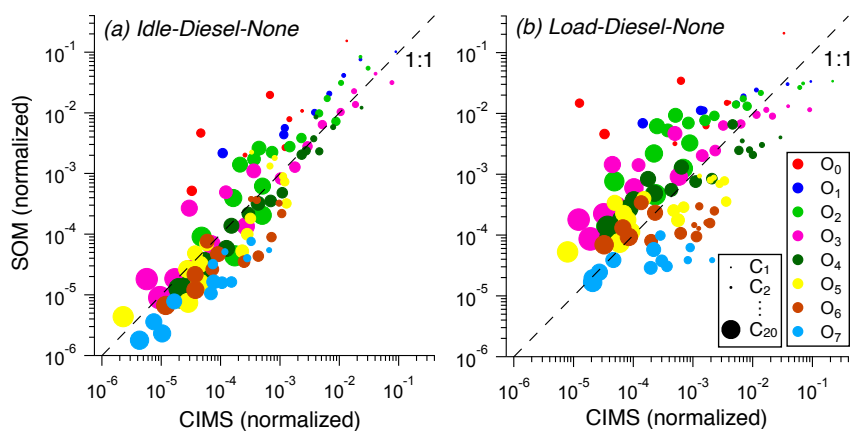

943
 944 *Figure 3: VBS and SOM model predictions of OA compared to measurements from the experiments performed on (a) June 5*
 945 *(Idle-Diesel-None) and (b) June 11 (Idle-Diesel-DPF+DOC) as a function of photochemical age for four different particle size*
 946 *distribution inputs: (i) number mean diameter and measured number concentration at no OH exposure (solid), (ii) number*
 947 *mean diameter and measured number concentration at the given OH exposure (dash), (iii) average of (i) and (ii) (dash-dot),*
 948 *and (iv) nucleation of 1 nm particles (dot).*
 949

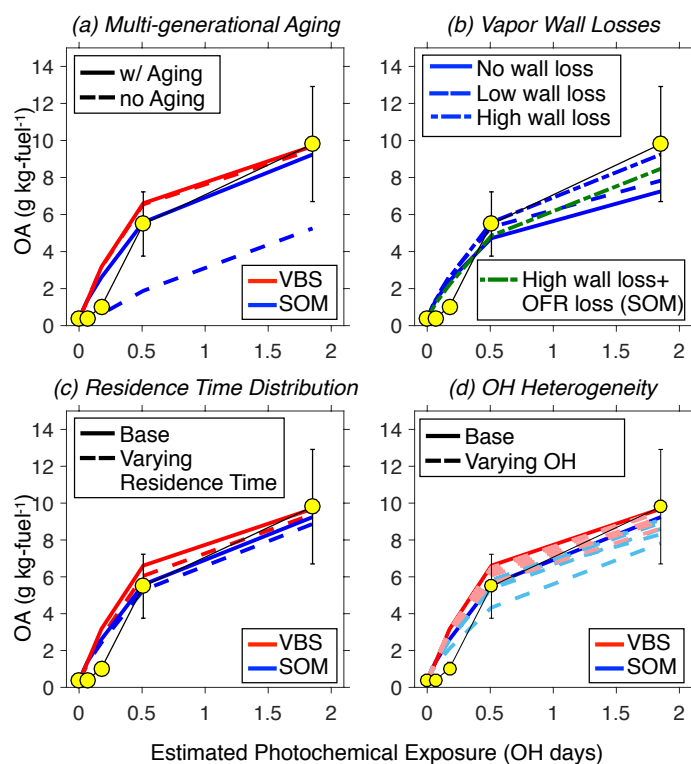

950
 951 *Figure 4: Scatter plot comparing SOM predictions of OA mass and O:C to measurements from all experiments at all*
 952 *photochemical ages at three different IVOC mass fractions: (a) 0%, (b) 13.76%, and (c) 60%.*
 953

954
 955 *Figure 5: VBS and SOM predictions of OA compared to measurements from the experiment performed on June 5 (Idle-Diesel-*
 956 *None) as a function of photochemical age. Panel (a) examines uncertainty in model treatment of cyclic alkanes, panel (b)*
 957 *examines uncertainty in the VOC emissions profile, and (c) explores suitability of using a single surrogate linear alkane to*
 958 *model SOA formation from all IVOCs.*
 959

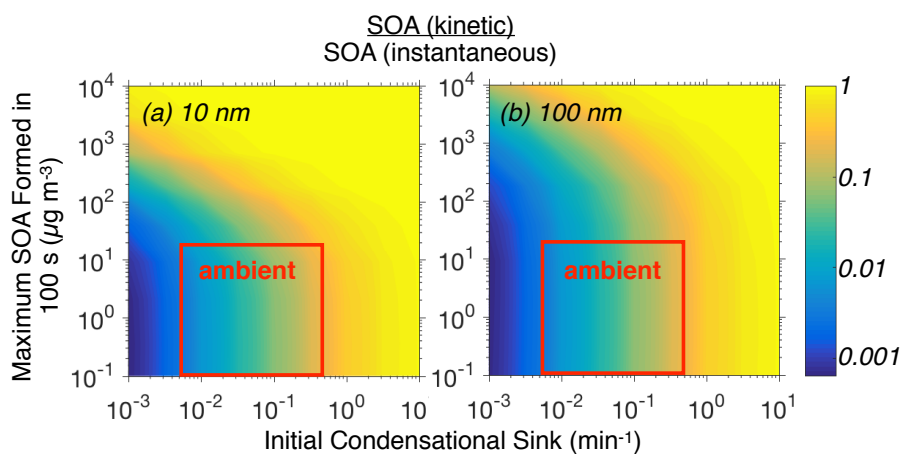

960
 961 *Figure 6: Normalized gas-phase concentration predictions from the SOM model for the Idle-Diesel-None and Load-Diesel-*
 962 *None experiments performed on June 5 and compared to normalized gas-phase concentrations measured by the CIMS.*
