21
22 **Abstract.** We used the GEOS-Chem model and its adjoint to quantify Chinese non-methane volatile
23 organic compound (NMVOC) emissions for the year 2007, using the vertical column concentrations of
24 formaldehyde and glyoxal observed by the Global Ozone Monitoring Experiment-2A (GOME-2A)
25 instrument and the Ozone Monitoring Instrument (OMI) as constraints. We conducted a series of
26 inversion experiments using different combinations of satellite observations to explore the impacts on
27 top-down emission estimates due to different satellite retrievals. Our top-down estimates for Chinese
28 annual total NMVOC emission was 23.4 to 35.4 (average 30.8) Tg C y⁻¹, including 13.5 to 19.7
29 (average 17.0) Tg C y⁻¹ from anthropogenic sources, 8.9 to 14.8 (average 12.6) Tg C y⁻¹ from biogenic
30 sources, and 1.1 to 1.5 (average 1.2) Tg C y⁻¹ from biomass burning. In comparison, the most
31 widely-used bottom-up estimate for Chinese annual total NMVOC emission was 27.4 Tg C y⁻¹,
32 including 15.5 Tg C y⁻¹ from anthropogenic sources, 10.8 Tg C y⁻¹ from biogenic sources, and 1.1 Tg C

33 y^{-1} from biomass burning. The simultaneous use of glyoxal and formaldehyde observations helped
34 distinguish the NMVOC species from different sources and was essential in constraining anthropogenic
35 emissions. Our four inversions consistently showed that the emissions of Chinese anthropogenic
36 NMVOC precursors of glyoxal were larger than the *a priori* estimates. Our top-down estimates for the
37 Chinese annual emission of anthropogenic aromatics (benzene, toluene, and xylene) ranged from 5.0 to
38 7.3 Tg C y^{-1} , 2% to 49% larger than the estimate of the bottom-up inventory (4.9 Tg C y^{-1}). Model
39 simulations using the average of our top-down NMVOC emission estimates showed that surface
40 afternoon ozone concentrations over northern and central China increased 5-12 ppb in June and
41 decreased 5-13 ppb in December relative to the simulations using the *a priori* emissions and were in
42 better agreement with measurements. We concluded that the satellite observations of glyoxal and
43 formaldehyde together provided quantitative constraints on the emissions and source types of
44 NMVOCs over China and improved our understanding on regional chemistry.

45

46 **1 Introduction**

47 Non-methane volatile organic compounds (NMVOCs) are emitted into the atmosphere from surface
48 anthropogenic, biogenic, and biomass burning sources. NMVOCs are precursors to tropospheric ozone
49 and secondary organic aerosols, both of which are climate forcers and major air pollutants. NMVOC
50 also affect the oxidation capacity of the atmosphere, which in turn changes the lifetimes of greenhouse
51 gases and other pollutants (Monks, 2005; Lelieveld et al., 2008). It is thus crucial to quantify NMVOC
52 emissions in order to understand their impacts on atmospheric chemistry and climate on both global
53 and regional scales. Here we used satellite observations and a chemical transport model to constrain
54 NMVOC emissions from China and assessed their impacts on seasonal surface ozone.

55

56 Emissions of trace species are traditionally estimated in a “bottom-up” manner using activity data and
57 emission factors, but these bottom-up estimates are sometimes susceptible to large uncertainties. This
58 is especially true for NMVOC emissions in developing countries such as China, because (1) a wide
59 range of species, source activities, and technologies are involved (Q. Zhang et al., 2009; Kurokawa et
60 al., 2013; Li et al., 2014; Qiu et al., 2014), (2) locally-representative emission factors are often not
61 measured (Wei et al., 2008; Zhao et al., 2011), and (3) reliable activity data are often incomplete,

62 particularly for small-scale industries, residential activities, and agricultural waste burning (Q. Zhang
63 et al., 2009). Table 1 shows bottom-up estimates for Chinese total annual NMVOC emissions for the
64 years 2005 to 2012, which ranged from 21.6 to 51.7 Tg y⁻¹ (Guenther et al., 2006; Bolscher et al., 2007;
65 Bo et al., 2008; Q. Zhang et al., 2009; van der Werf et al., 2010; Cao et al., 2011; Huang et al., 2012;
66 Kurokawa et al., 2013; Li et al., 2014; Wu et al., 2016). The large uncertainties in these Chinese
67 NMVOC emission estimates have led to great difficulty in evaluating their impacts on regional
68 chemistry (Han et al., 2013; Wang et al., 2014).

69

70 A complementary, “top-down” approach of quantifying emissions uses observations of the targeted
71 species or its chemical derivatives, combined with a chemical transport model acting as a transfer
72 function, to invert for the fluxes of the targeted species. In particular, tropospheric column
73 concentrations of formaldehyde (HCHO), retrieved from satellite UV-backscatter observations, have
74 been used to constrain NMVOC emissions. Formaldehyde is produced at high yields during the
75 oxidation of many NMVOC species, as well as emitted directly from anthropogenic and biomass
76 burning activities (Akagi et al., 2011). Early applications of satellite-observed formaldehyde columns
77 mainly focused on areas where the local NMVOC fluxes were dominated by biogenic emissions during
78 the growing season, such as the southeast U.S. (Palmer et al., 2003, 2006; Millet et al., 2006, 2008),
79 Europe (Dufour et al., 2009; Curci et al., 2010), the Amazon (Barkley et al., 2008, 2009, 2013), and the
80 tropical central Africa (Marais et al., 2012, 2014a). These studies showed that the observed high
81 concentrations of formaldehyde over densely-vegetated areas were linearly proportional to the local
82 biogenic isoprene flux during the growing season.

83

84 Later studies constrained NMVOC emissions from multiple sources by analyzing the spatiotemporal
85 variability of the observed formaldehyde columns (Shim et al., 2005; Fu et al., 2007; Stavrou et al.,
86 2009b; Curci et al., 2010; Gonzi et al., 2011; Marais et al., 2014b; Zhu et al., 2014). Fu et al. (2007), a
87 forerunner of this study, analyzed the spatial and seasonal variation of the formaldehyde column
88 observations from the Global Ozone Monitoring Experiment (GOME) over East and South Asia. They
89 showed that, during the early 2000s, Chinese reactive NMVOC fluxes from biogenic, anthropogenic,
90 and biomass burning sources were 3, 1.2, and 8.8 times their respective bottom-up estimates. In
91 particular, Fu et al. (2007) found a large, annually-recurring NMVOC source over the North China

92 Plain (NCP) in June, which they attributed to crop residue burning after the local harvest of winter
93 wheat. However, these top-down studies using only formaldehyde as constraints relied on bottom-up
94 statistics to differentiate between NMVOC source types.

95

96 More recently, satellite measurements of tropospheric glyoxal columns emerged as an additional
97 constraint on NMVOC emissions (Stavrakou et al., 2009a). Like formaldehyde, glyoxal is produced
98 during the oxidation of many NMVOCs (including most importantly isoprene), as well as emitted
99 directly from biomass burning (Fu et al., 2008; Myriokefalitakis et al., 2008). In addition, glyoxal is
100 produced at high yields at the initial ring-cleaving stage during the oxidation of aromatics (Volkamer,
101 2001; Nishino et al., 2010), which are mainly anthropogenic. In contrast, formaldehyde production
102 from the oxidation of aromatics is further downstream and thus spatially diffused (Volkamer, 2001). As
103 such, simultaneous analyses of formaldehyde and glyoxal observations can help differentiate between
104 biogenic and anthropogenic NMVOC emissions. Stavrakou et al. (2009a) pioneered a two-compound
105 inversion using tropospheric glyoxal and formaldehyde column observations from the SCIAMACHY
106 satellite instrument to constrain the global sources of glyoxal. They estimated that the anthropogenic
107 NMVOC fluxes over East Asia for the year 2005 were a factor of 2-3 larger than the bottom-up
108 estimates of the Emission Database for Global Atmospheric Research (EDGAR, v3.3) inventory
109 (Olivier et al., 2001, 2002) and the REanalysis TROpospheric (RETRO) emission inventory (Schultz et
110 al., 2007). In addition, they inferred a large missing source of glyoxal over the global continents, which
111 they attributed to production from an unknown biogenic precursor.

112

113 Over eastern China, Liu et al. (2012) showed that the glyoxal column concentrations observed by
114 SCIAMACHY in August 2007 was more than twice the simulated glyoxal columns using the
115 bottom-up emission inventory developed by Q. Zhang et al. (2009). Over the Pearl River Delta area
116 (PRD) in southern China, the discrepancy was at least a factor of three. They suggested that the
117 missing glyoxal source over eastern China was anthropogenic, on the basis that the anonymous
118 glyoxal columns observed by SCIAMACHY were spatially correlated with anthropogenic NO_x
119 emissions. Their estimated Chinese anthropogenic aromatics emission was 13.4 Tg y⁻¹, which was six
120 times the 2.4 Tg y⁻¹ aromatic flux estimated by Q. Zhang et al. (2009). In contrast, Chan Miller et al.
121 (2016) simulated the formaldehyde and glyoxal column concentrations over the Pearl River Delta area

122 (PRD) in southern China for the years 2006 and 2007 using the same inventory developed by Q.
123 Zhang et al. (2009). They found that their simulated formaldehyde columns were consistent with the
124 OMI formaldehyde observations, while their simulated glyoxal columns were lower than OMI
125 observations by only 40%. They attributed the high anthropogenic aromatics emission estimate by Liu
126 et al. (2012) to a regional high-bias in the SCIAMACHY data, as well as underestimated yields of
127 glyoxal from the oxidation of aromatics.

128
129 One limitation in the use of satellite observations of formaldehyde and glyoxal for constraining
130 NMVOC sources is their inherent uncertainty. Several studies have compared GOME-2A and OMI
131 formaldehyde column observations against aircraft or ground-based measurements at a few locations
132 around the world (De Smedt et al., 2015; Lee et al., 2015; Wang et al., 2017; Zhu et al., 2016). Zhu et
133 al. (2016) compared the GOME-2A-observed formaldehyde column concentrations over the Southeast
134 U.S. in summer 2013 against aircraft measurements and found the satellite measurements to be too
135 low by a factor of approximately 1.7. Chan Miller et al. (2017) found that glyoxal column
136 concentrations observed by OMI were lower than the aircraft measurements over the Southeast U.S. in
137 summer 2013 by a factor of 1.5. Wang et al. (2017) compared the bi-monthly mean GOME-2A and
138 OMI formaldehyde column concentrations retrieved by De Smedt et al. (2012, 2015) against
139 ground-based multi-axis differential optical absorption spectroscopy (MAX-DOAS) measurements at
140 a rural site in eastern China. They found that both satellite retrievals were systematically lower than
141 the ground-based measurements by approximately 20%. These studies highlight the potential impacts
142 on top-down NMVOC emission estimates due to uncertainty associated with satellite retrievals.

143
144 In this study, we used satellite retrievals of both formaldehyde and glyoxal, along with an updated
145 chemical transport model and its adjoint, to constrain NMVOC emissions from China for the year
146 2007. We conducted sensitivity experiments to evaluate the impacts on the top-down estimates due to
147 different satellite retrieval constraints, with the goal of obtaining a most probable range of top-down
148 estimates. Finally, we examined the impacts of our top-down NMVOC emission estimates on surface
149 ozone concentrations over China.

150

151 **2 Model and data**152 **2.1 The GEOS-Chem model and its adjoint**

153 We used the GEOS-Chem global 3D chemical transport model (version 8.2.1) to simulate the emission,
154 transport, chemistry, and deposition of NMVOCs, as well as the resulting formaldehyde and glyoxal
155 column concentrations for the year 2007. GEOS-Chem was driven by the assimilated meteorological
156 data from the NASA Goddard Earth Observing System (GEOS-5) (Bey et al., 2001). To drive our
157 simulations, the horizontal resolution of GEOS-5 data was downgraded from its native $2/3^\circ$ longitude \times
158 $1/2^\circ$ latitude to 5° longitude \times 4° latitude. The number of vertical levels was reduced from 72 to 47 by
159 merging layers in the stratosphere. The lower 2 km of the atmosphere was resolved by 14 levels. The
160 temporal resolution of GEOS-5 data into GEOS-Chem is 3 h for atmospheric variables and 1 h for
161 surface variables.

162

163 We updated the dicarbonyl chemical mechanism in GEOS-Chem developed by Fu et al. (2008), which
164 in turn was originally adapted from the Master Chemical Mechanism (MCM) version 3.1 (Saunders et
165 al., 2003; Bloss et al., 2005). NMVOC precursors of formaldehyde in our mechanism included ethane,
166 propane, $\geq C_4$ alkanes, ethene, $\geq C_3$ alkenes, toluene, xylenes, isoprene, and monoterpenes. NMVOC
167 precursors of glyoxal in our mechanism included propane, alkanes, ethene, $\geq C_3$ alkenes, ethyne,
168 benzene, toluene, xylenes, isoprene, monoterpenes, glycolaldehyde, and 2-methyl-3-bute-2-nol.
169 OH-oxidation of isoprene is a major source of both formaldehyde and glyoxal over China (Fu et al.,
170 2007, 2008; Myriokefalitakis et al., 2008). We replaced the isoprene photochemical scheme with that
171 used in GEOS-Chem v10.1 (Paulot et al., 2009a,b; Mao et al. 2013), where formaldehyde and glyoxal
172 were produced from isoprene oxidation via the RO_2+NO pathway under high- NO_x conditions and via
173 RO_2 -isomerization under low- NO_x conditions. Li et al. (2016) compared the productions of
174 formaldehyde and glyoxal from isoprene oxidation in this updated scheme with those in the MCM
175 version 3.3.1 (Jenkin et al., 2015). They showed that the production pathways and yields of
176 formaldehyde and glyoxal were similar in the two schemes under the high- NO_x conditions typical of
177 eastern China.

178

179 We updated the molar yields of glyoxal from the OH oxidations of benzene (33.3%), toluene (26.2%),
180 and xylenes (21.0%) following the latest literature (Arey et al., 2009; Nishino et al., 2010). These new
181 molar yields were higher than those used in Fu et al. (2008) but still lower than those used by Chan
182 Miller et al. (2016) (75% for benzene, 70% for toluene, 36% for xylenes), which were taken from MCM
183 version 3.2 (Bloss et al., 2005). In MCM version 3.2, more than half of the glyoxal from aromatics
184 oxidation were produced during second- and later-generation photochemistry, but such productions are
185 still uncertain, with limited experimental support (Bloss et al., 2005).

186

187 Formaldehyde and glyoxal in our model were both removed by photolysis, as well as dry and wet
188 deposition (Fu et al., 2008). We updated the Henry's law constant for glyoxal (Ip et al., 2009) and
189 added the dry deposition of formaldehyde, glyoxal, methyglyoxal and glycolaldehyde on leaves (Mao
190 et al., 2013). In addition, we assumed that glyoxal was reactively uptaken by wet aerosols and cloud
191 droplets with an uptake coefficient $\gamma = 2.9 \times 10^{-3}$ (Liggio et al., 2005; Fu et al., 2008). All other physical
192 and chemical processes in our forward model were as described in Fu et al. (2008).

193

194 For the forward model described above, we developed the adjoint by modifying the standard
195 GEOS-Chem adjoint (version 34) (Henze et al., 2007). We used the Kinetic PreProcessor (KPP)
196 (Daescu et al., 2003; Sandu et al., 2003) to construct the adjoint of the updated photochemical
197 mechanism. Adjoint algorithms were updated to include the emission and deposition processes of
198 formaldehyde and glyoxal precursors. The aqueous uptake rate of glyoxal by wet aerosols was a
199 function of the ambient glyoxal concentration and the total wet aerosol surface area (Fu et al., 2008).
200 We linearized this uptake process by archiving the wet aerosol surface areas in the forward simulations
201 for use in the backward integrations.

202

203 We verified the adjoint model mathematically in two ways. Firstly, we used the adjoint to calculate the
204 sensitivities of global glyoxal and formaldehyde burdens to biogenic isoprene and anthropogenic
205 xylenes emissions, respectively, and found that the results reproduced the calculated sensitivities from
206 the forward model (Figure S1 in Supplementary Information). Secondly, we used an *a priori* NMVOC
207 emission inventory (Section 2.2) to drive the forward model and took the resulting global tropospheric
208 formaldehyde and glyoxal column concentrations as pseudo observations. We then used the pseudo

209 observations of formaldehyde and glyoxal, respectively, to successfully optimize back to close to the *a*
210 *priori* NMVOC emission estimates over high-emission areas from an initial emission guess that was
211 five times larger (Figure S2 in Supplementary Information). These experiments demonstrated the
212 usefulness of the adjoint model for the inversion of NMVOCs emissions.

213

214 **2.2 *A priori* emission estimates of Chinese NMVOCs**

215 As a starting point for our inversion, we used the most widely-used NMVOC emission estimates for
216 China as the *a priori*. Table 2 summarizes the annual total of these *a priori* emission estimates and their
217 associated uncertainties.

218

219 The *a priori* biogenic NMVOC emissions from China and from the rest of the world were calculated
220 with the MEGAN algorithm (Guenther et al., 2006) and dependent on temperature, shortwave radiation,
221 and monthly mean leaf area index. The annual total biogenic NMVOC emissions over China for the
222 year 2007 was 10.8 Tg C y⁻¹, including 6.6 Tg C y⁻¹ of isoprene. Previous estimates of Chinese
223 biogenic NMVOC emissions ranged from 5.0 to 11.0 Tg C y⁻¹ (Guenther et al., 2006; Fu et al., 2007;
224 Stavrou et al., 2015). Based on this range, we estimated the uncertainty of the *a priori* biogenic
225 emissions over China to be ±55%.

226

227 The *a priori* emissions for Chinese anthropogenic NMVOCs were from the Multi-resolution Emission
228 Inventory for China (MEIC) inventory (Li et al., 2014), developed for the year 2010 at 0.25° × 0.25°
229 resolution. The MEIC inventory, including emissions from industry, transportation, power generation
230 and residential activities, was compiled using monthly Chinese provincial activity data and a
231 combination of Chinese and western emission factors. The estimated annual Chinese anthropogenic
232 NMVOC emission was 15 Tg C y⁻¹, including 64% from industries, 24% from residential activities, 10%
233 from transportation, and 1% from power generation. The estimated annual Chinese anthropogenic
234 emission of aromatics was 4.9 Tg C y⁻¹, including 73% from industries, 15% from residential activities,
235 9% from transportation, and 3% from power generation. Previous estimates of Chinese anthropogenic
236 NMVOC emissions for the years 2005 to 2012 ranged from 10.7 to 29.8 Tg C y⁻¹, with aromatics
237 emissions ranging from 2.1 to 11.3 Tg C y⁻¹ (Bo et al., 2008; Q. Zhang et al., 2009; Cao et al., 2011;

238 Liu et al., 2012; Kurokawa et al., 2013; Li et al., 2014; Stavrou et al., 2015; Wu et al., 2016). We
239 therefore estimated the uncertainty for the *a priori* Chinese anthropogenic NMVOC emission estimates
240 to be $\pm 200\%$. Anthropogenic NMVOC emissions for the rest of the Asia were from the inventory
241 compiled by Li et al. (2017) for the year 2010. Anthropogenic NMVOC emissions for Europe, U.S.,
242 and the rest of the world were from the European Monitoring and Evaluation Programme (EMEP)
243 inventory (Vestreng, 2003), the U.S. EPA 2005 National Emission Inventory (NEI05) (Brioude et al.,
244 2011; Kim et al., 2011), and the Emission Database for Global Atmospheric Research (EDGAR)
245 inventory (version 2.0) (Olivier et al., 1999), respectively, and scaled to the year 2007 using CO₂
246 emissions (van Donkelaar et al., 2008).

247

248 Post-harvest, in-field burning of crop residue has been recognized as a large seasonal source of
249 NMVOCs in China (Fu et al., 2007; Huang et al., 2012; Stavrou et al., 2016), but this emission has
250 been severely underestimated in inventories based on satellite burnt area observations (Liu et al., 2015).
251 Huang et al. (2012) estimated the Chinese CO emission from crop residue burning to be 4.0 Tg y⁻¹,
252 based on MODIS daily thermal anomalies, Chinese provincial burnt-biomass data, and emission factors
253 from Akagi et al. (2011). We scaled this CO flux using speciated NMVOC emission factors from crop
254 residue burning from the literature (Hays et al., 2002; Akagi et al., 2011) and then multiplied the
255 resulting NMVOC flux estimate by two. The reason for doubling the scaled NMVOC flux was that the
256 emission factors for many NMVOC species were not measured, such that the sum of the speciated
257 NMVOC emission factors was only half of the measured total NMVOC emission factor (Akagi et al.,
258 2011). This difference may partially explain why the top-down study by Stavrou et al. (2016) using
259 satellite observations of formaldehyde found that Huang et al. (2012) underestimated the NMVOC flux
260 from crop fires over the North China Plain (NCP) in June by at least a factor of two.

261

262 Our resulting *a priori* estimate for Chinese annual NMVOC emissions from biomass burning was 1.1
263 Tg C y⁻¹, including 0.86 Tg C y⁻¹ from crop residue burning (obtained by scaling Huang et al., 2012)
264 and 0.24 Tg C y⁻¹ from other types of biomass burning activities (taken from the Global Fire Emissions
265 Database version 3, GFED3) (van der Werf et al., 2010). Previous estimates of Chinese NMVOC
266 emissions from biomass burning for the years 1996 to 2012 ranged from 0.24 to 3.2 Tg C y⁻¹ (Fu et al.,
267 2007; van der Werf et al., 2010; Wiedinmyer et al., 2011; Huang et al., 2012; Liu et al., 2015;

268 Stavrakou et al., 2015, 2016). We therefore assigned an uncertainty of $\pm 300\%$ to the *a priori* Chinese
269 biomass burning NMVOC flux. Biomass burning emissions from the rest of the world were taken from
270 GFED3 (van der Werf et al., 2010).

271

272 Figure 1 (a)-(c) show the spatial distribution of the *a priori* Chinese NMVOC emissions from biomass
273 burning, anthropogenic, biogenic, and total sources, respectively. Biomass burning emissions were
274 highest over the NCP and southwest China, reflecting strong emissions from crop residue burning over
275 the NCP in June and from land-clearing burning over southwest China during February to April,
276 respectively. Chinese anthropogenic and biogenic NMVOC sources both showed a general west-to-east
277 gradient, following population and vegetation densities. Biogenic NMVOC emissions reflected the
278 combined modulation by vegetation densities, temperature, and sunlight. Anthropogenic NMVOC
279 fluxes exceeded $10^3 \text{ kg C km}^{-2} \text{ y}^{-1}$ throughout the industrialized and densely populated eastern China,
280 with the highest fluxes over the NCP and around the Yantze River Delta area.

281

282 Figure 2 shows the seasonal variation of the *a priori* Chinese NMVOC emissions. The *a priori*
283 anthropogenic NMVOC fluxes were higher during the cold months and lower during the warm months,
284 driven by the seasonal strengths of industrial and residential activities (Li et al., 2017). The *a priori*
285 biogenic NMVOC fluxes showed the opposite seasonal pattern, with more than half of the total annual
286 flux emitted in summer. The *a priori* biomass burning NMVOC source was relatively small except
287 when it peaked in June due to the burst of post-harvest burning over the NCP and in spring due to
288 land-clearing over southwest China. As a result, the Chinese NMVOC emissions were predominantly
289 anthropogenic in January but mainly biogenic in June. During the transition months of April and
290 October, the anthropogenic and biogenic contributions to the total NMVOC emissions were
291 comparable.

292

293 **2.3 Formaldehyde and glyoxal column concentrations observed by GOME-2A and OMI**

294 We used the monthly mean tropospheric formaldehyde and glyoxal column concentrations retrieved
295 from the Global Ozone Monitoring Experiment-2A (GOME-2A) instrument and the Ozone
296 Monitoring Instrument (OMI) for the year 2007 to constrain Chinese NMVOC sources. The technical

297 details of these four sets of satellite retrievals are summarized in Table 3.

298

299 The native GOME-2A pixel vertical column densities (VCDs) of formaldehyde and glyoxal were
300 retrieved by De Smedt et al. (2012) and Lerot et al. (2010), respectively, using protocols briefly
301 described below. First, pixel slant column densities (SCDs) of formaldehyde and glyoxal were
302 retrieved in the 328.5–346 nm and 435–460 nm windows, respectively, using the Differential Optical
303 Absorption Spectroscopy (DOAS) technique (Platt et al., 1979). Previous glyoxal SCD retrievals often
304 showed biases over remote tropical oceans due to absorption from liquid water (Vrekoussis et al., 2010;
305 Wittrock et al., 2006; Lerot et al., 2010). This bias was corrected in Lerot et al. (2010) by explicitly
306 accounting for liquid water absorption during the DOAS fitting. Second, pixel SCDs were converted
307 into VCDs using air mass factors (AMF), which was calculated using Linearized Discrete Ordinate
308 Radiative Transfer model (LIDORT) (Spurr, 2008) and trace gas profiles simulated by the IMAGE v2
309 model (Stavrakou et al., 2009b). The native pixel VCDs were gridded to daily means at $0.25^\circ \times 0.25^\circ$
310 resolution (De Smedt et al., 2012; Lerot et al., 2010). We further averaged the daily means to monthly
311 means at 5° longitude \times 4° latitude resolution. The retrieval errors of the spatially-and-temporally
312 averaged VCDs were estimated to be 30%–40% for formaldehyde and 40% for glyoxal, due to a
313 combination of errors associated with the SCD retrievals, the reference sector correction, the *a priori*
314 profile, and the AMFs (De Smedt et al., 2012; Lerot et al., 2010).

315

316 The OMI native pixel VCDs of formaldehyde and glyoxal were retrieved by González Abad et al.
317 (2015) and Chan Miller et al. (2014), respectively. Briefly, formaldehyde and glyoxal pixel SCDs were
318 retrieved by directly fitting the absorption spectra in the 328.5 – 356.5 nm (formaldehyde) and 435 –
319 461 nm (glyoxal) windows, respectively (Chance, 1998; Kurosu et al., 2004, 2007; Chan Miller et al.,
320 2014), and then converted to pixel VCDs using AMF calculated with a linearized vector discrete
321 ordinate radiative transfer model, VLIDORT (Spurr, 2006), and trace gas profiles simulated by the
322 GEOS-Chem model (González Abad et al., 2015). Liquid water absorption was also explicitly
323 calculated for the glyoxal retrieval (Chan Miller et al., 2014). The typical uncertainties of
324 OMI-observed pixel VCDs over polluted areas were estimated to be 30% to 45% for formaldehyde
325 and 104% for glyoxal (González Abad et al., 2015; Chan Miller et al., 2014). The native pixel VCDs
326 were averaged to monthly means at 5° longitude \times 4° latitude resolution. For glyoxal, we further

327 removed VCDs with signal-to-uncertainty ratios less than 100%. We assumed the retrieval uncertainty
328 of monthly mean OMI formaldehyde and glyoxal VCDs at $4^\circ \times 5^\circ$ resolution to be 40% and 100%,
329 respectively.

330

331 To remove globally systematic biases in the satellite observations, we adjusted the global observed
332 monthly mean VCDs by aligning the observed VCDs over remote reference areas to those simulated by
333 the GEOS-Chem model (sampled at satellite overpass time) using the *a priori* NMVOC emissions. The
334 remote Pacific (140° - 160° W, 90° S- 90° N) was chosen as the reference area for formaldehyde (Palmer et
335 al., 2003, 2006; Fu et al., 2007; González Abad et al., 2015). The Sahara desert (20 - 30° N, 10° W- 30° E),
336 where the interference from liquid water absorption was minimal, was chosen as the reference area for
337 glyoxal (Chan Miller et al., 2014). The justification for performing the alignment was two-fold: firstly,
338 the formaldehyde and glyoxal column concentrations over these remote reference areas were small and
339 well simulated by the model (Fu et al., 2008; Chan Miller et al., 2014). The removed biases over the
340 remote areas were less than 20% and 10% of the typical formaldehyde ($>8 \times 10^{15}$ molecule cm^{-2}) and
341 glyoxal ($>4 \times 10^{14}$ molecule cm^{-2}) monthly mean VCDs observed over eastern China, respectively.
342 More importantly, our inversion was performed over China only, assuming that the *a priori* NMVOC
343 emissions for the rest of the world were unbiased. As will be seen in Sections 3 and 4, the optimization
344 of NMVOC sources were predominantly driven by local formaldehyde and glyoxal enhancements
345 produced by relatively short-lived NMVOCs.

346

347 **2.4 Inversion experiments using the GEOS-Chem adjoint**

348 We used the GEOS-Chem model to perform Bayesian inversions on Chinese NMVOC emissions, using
349 satellite observations of formaldehyde and glyoxal over China and the *a priori* emission estimates as
350 constraints. The inversion minimized the cost function $J(\mathbf{x})$ in Eq. (1) (Rodgers, 2000), which we
351 calculated over China:

$$352 \quad J(\mathbf{x}) = \gamma \mathbf{(\mathbf{x} - \mathbf{x}_a)} \mathbf{S}_a^{-1} (\mathbf{x} - \mathbf{x}_a) + (\mathbf{F}(\mathbf{x}) - \mathbf{y}) \mathbf{S}_o^{-1} (\mathbf{F}(\mathbf{x}) - \mathbf{y}) \quad \text{Eq. (1)}$$

353 The first and second terms on the right-hand-side of Eq. (1) represented the penalty error and the
354 prediction error, respectively. \mathbf{x} , which we sought to optimize, was the vector of scale factors (for each

355 NMVOC species from each emission sector) applied to the *a priori* emissions. \mathbf{x}_a was a unit vector
356 applied to the *a priori* NMVOC emission estimates. \mathbf{y} was the vector of satellite-observed monthly
357 mean VCDs of the targeted tracer (formaldehyde and/or glyoxal). $\mathbf{F}(\mathbf{x})$ was the vector of VCDs of the
358 targeted tracer simulated by the forward model \mathbf{F} . \mathbf{S}_a was the *a priori* emission error covariance matrix,
359 which was a diagonal matrix with the uncertainties estimated based on ranges of previous NMVOC
360 estimates (Section 2.2 and Table 1).

361

362 The observation error covariance matrix in Eq. (1), \mathbf{S}_o , was difficult to quantify, as it included
363 contributions not only from the satellite retrieval, but also from the model representation of chemistry
364 and transport. Zhu et al. (2016) and Chan Miller et al. (2017) compared vertical profiles of
365 GEOS-Chem-simulated formaldehyde and glyoxal over the Southeast U.S. in summer against aircraft
366 measurements. They reported that the simulated formaldehyde mixing ratios showed only a small bias
367 ($-3\% \pm 2\%$) in the lower troposphere but were lower than the observations by 41% in the free
368 troposphere, likely due to insufficient deep convection in the model (Zhu et al., 2016). The simulated
369 glyoxal mixing ratios were within 20% of the observations in the mixed layer, but they were too low in
370 the upper troposphere by more than a factor of two, also likely due to insufficient model vertical
371 transport (Chan Miller et al., 2017). It should be noted that these errors assessed by Zhu et al. (2016)
372 and Chan Miller et al. (2017) likely also included the errors associated with precursor emissions.
373 Nevertheless, based on these assessments, we roughly estimated that the model errors for
374 formaldehyde and glyoxal VCDs to be $\pm 80\%$, $\pm 100\%$, respectively. Adding these estimated model
375 errors in quadrature to the satellite retrieval errors (Section 2.3), we estimated that the observation
376 error (\mathbf{S}_o) of formaldehyde and glyoxal to be about $\pm 90\%$ and $\pm 150\%$, respectively.

377

378 The optimization of Eq. (1) was dependent on the relative weighting of the penalty error (\mathbf{S}_a) and the
379 prediction error (\mathbf{S}_o). However, the errors and error correlations within \mathbf{S}_a and \mathbf{S}_o were often
380 incompletely represented. In addition, we found that due to the mathematical formulation of Eq. (1),
381 the cost function $J(\mathbf{x})$ was heavily weighted by grids where the *a priori* estimates were too high, such
382 that the optimization was less effective at increasing emissions where the *a priori* emissions were too
383 low. These issues were empirically addressed in inversion studies by the introduction of a
384 regularization factor, γ , in Eq. (1) to adjust the relative weight of the penalty error. Henze et al. (2009)

385 used the L-curve method (Hansen, 1998) to find an optimized γ value, which minimized the total cost
386 function and balanced the prediction term and the penalty term. We followed that methodology and
387 found a γ value of 0.01 for July, which we applied for all of the warmer months (March to October). An
388 optimized γ value of 0.1 was found for January, and we applied that value to the colder months.

389

390 Table 2 shows the setup of our inversion experiments. We experimented with four different sets of
391 satellite retrievals as constraints, with the goal of bracketing the uncertainties of the top-down estimate
392 of Chinese NMVOC emissions. The first two experiments (IE-1 and IE-2) constrained emissions using
393 the formaldehyde and glyoxal VCDs observations from GOME-2A and OMI, respectively. Several
394 studies showed that GOME-2A formaldehyde VCDs may be low by a factor of 1.3 to 1.7 (Lee et al.,
395 2015; Zhu et al., 2016; Wang et al., 2017). As an “upper bound” constraint, we conducted a third
396 inversion experiment (IE-3), which was constrained by 1.7 times the GOME-2A formaldehyde alone.
397 We conducted a fourth inversion experiment (IE-4) constrained by OMI glyoxal VCDs alone to explore
398 the impacts of glyoxal observations on the inversions of anthropogenic emissions.

399

400 Figure 3 illustrates our protocol for the inversion experiments. For each month, we began by driving
401 the GEOS-Chem forward model with the *a priori* emissions ($\mathbf{x}_{i=1} = \mathbf{x}_a = 1$) to simulate the monthly mean
402 formaldehyde and glyoxal VCDs at satellite-crossing time. The simulated and satellite-observed VCDs
403 were used to calculate the cost function, $J(\mathbf{x})$, and the forcing arrays ($\frac{\partial J(\mathbf{x})}{\partial \mathbf{F}(\mathbf{x})}$). The adjoint of
404 GEOS-Chem was then used to compute the cost function gradient ($\frac{\partial J(\mathbf{x})}{\partial \mathbf{x}}$), and the next guess of the
405 emission scale factor (\mathbf{x}_{i+1}) was calculated using the Quasi-Newton L-BFGS-B algorithm (Byrd et al.,
406 1995; Zhu et al., 1997), subject to the bounds $0.32 \leq \mathbf{x} \leq 10$. These bounds were selected based on the
407 largest uncertainties quoted in the literature on Chinese NMVOC emission estimates (Q. Zhang et al.,
408 2009; Liu et al., 2012). The process was then iterated until the incremental relative reduction of the cost
409 function ($\frac{|J(\mathbf{x})_{i+1} - J(\mathbf{x})_i|}{\max(J(\mathbf{x})_{i+1}, J(\mathbf{x})_i)}$) was less than 1% after at least six iterations. We took \mathbf{x}_{i+1} from the last
410 iteration as the optimized emission scale factor (\mathbf{x}_p) and applied it to calculate the top-down emission
411 estimate.

412

413 **3 Comparison of simulations using the *a priori* emissions against satellite observations and**
414 **ground-based measurements**

415 We first qualitatively compared the formaldehyde and glyoxal VCDs simulated by the GEOS-Chem
416 model (sampled at satellite overpass times) using the *a priori* emissions against those observed by
417 GOME-2A and OMI, as well as ground-based measurements. Figure 4 (a)-(d) show the monthly mean
418 formaldehyde VCDs observed by GOME-2A over China for January, April, June, and October 2007.
419 Observed formaldehyde VCDs over China showed a distinct west-to-east gradient year-round, which
420 was driven by the higher vegetation and population densities in eastern China. Observed formaldehyde
421 VCDs were higher during the warmer months, reflecting the stronger biogenic emissions during the
422 growing seasons. Highest formaldehyde VCDs were observed over the NCP in June, in response to the
423 large emissions from in-field crop residue burning. In April, high concentrations of formaldehyde were
424 also observed near the southwestern border, reflecting the seasonal biomass burning there.

425

426 Figure 4 (e)-(h) show the simulated monthly mean formaldehyde VCDs using the *a priori* emission
427 estimates. The model generally reproduced the observed seasonal contrast and regional patterns. The
428 simulated formaldehyde columns were higher than the GOME-2A observations in January, implying an
429 overestimate of anthropogenic formaldehyde precursors in the *a priori* in January. The simulated
430 formaldehyde columns were lower than the GOME-2A observations over eastern China in June,
431 implying an underestimation of the emissions of formaldehyde precursors in June in the *a priori*.

432

433 A few ground-based measurements of tropospheric formaldehyde VCDs have been made in China
434 using the MAX-DOAS technique (Li et al., 2013; Stavrakou et al., 2015; Wang et al., 2017) (Table S1).
435 Figure 4 also shows the seasonal mean of these ground-based measurements at GOME-2A overpass
436 time. In principle, these ground-based measurements were not directly comparable to the
437 satellite-observed and model-simulated formaldehyde columns due to the different inherent
438 uncertainties and the coarse spatial resolution of our analyses. Nevertheless, the seasonal progression
439 presented by these few ground-based measurements were consistent with both the GOME-2A-observed
440 and model-simulated formaldehyde VCDs.

441

442 Figure 5 shows the monthly mean glyoxal VCDs observed by GOME-2A. Similar to the case of

443 formaldehyde, GOME-2A-observed glyoxal VCDs were highest over eastern China in June, reflecting
444 large emissions of NMVOC species that are precursors to both formaldehyde and glyoxal. During
445 January the eastern China glyoxal enhancement was more evident than formaldehyde. As biogenic
446 emissions were small in winter, this indicated that the glyoxal VCDs were more reflective of
447 anthropogenic source. Figure 5 (e)-(h) shows that the simulated glyoxal VCDs were higher than the
448 GOME-2A observations in January and lower than the GOME-2A observations in June. This suggested
449 an overestimation of anthropogenic sources in January and an underestimation of the biogenic sources
450 in June, which was consistent with the constraints implied by the GOME-2A formaldehyde
451 observations. During the transition months of April and October, when the anthropogenic and biogenic
452 contributions to carbonyl productions were presumably more comparable, the simulated glyoxal VCDs
453 were lower than the GOME-2A observations, while the simulated formaldehyde VCDs were higher
454 than the GOME-2A observations (Figure 4 (e)-(h)). This likely indicated that the *a priori* inventory
455 underestimated the emissions of NMVOC species (e.g. aromatics, ethyne, ethene, and glyoxal) that
456 preferentially produced glyoxal, while it overestimated the emissions of species (e.g. $\geq C_4$ alkanes and
457 $\geq C_3$ alkenes from anthropogenic activities) that preferentially produced formaldehyde during the
458 transition months. Ground-based MAX-DOAS glyoxal measurements at a rural southern China site in
459 July 2006 averaged $6.8(\pm 5.2) \times 10^{14}$ molecules cm^{-2} , higher than both the GOME-2A-observed and
460 simulated glyoxal VCDs. No other ground-based measurements were available to provide spatial and
461 seasonal information.

462

463 Figure 6 (a)-(d) shows the monthly mean formaldehyde VCDs observed by the OMI instrument.
464 Similar to the GOME-2A-observed formaldehyde VCDs, OMI formaldehyde VCDs were higher over
465 Eastern China and enhanced during the warmer months. However, the formaldehyde VCDs observed
466 by OMI were lower than those observed by GOME-2A by approximately 30%, likely due to the
467 different retrieval algorithms (De Smedt et al., 2012; González Abad et al., 2015). The simulated
468 formaldehyde VCDs over China were also lower at OMI overpass time than at GOME-2A overpass
469 time by less than 20% in all seasons. However, the ground-based measurements at the three Chinese
470 surface sites did not consistently show such a diurnal pattern.

471

472 Figure 7 (a)-(d) shows the monthly mean glyoxal VCDs observed by the OMI instrument. Valid OMI
473 glyoxal VCDs observations were relatively sparse over China, especially during colder months. The
474 seasonal and spatial patterns of the glyoxal VCDs observed by OMI were generally consistent with
475 those observed by GOME-2A. However, the glyoxal VCDs observed by OMI were higher than those
476 observed by GOME-2A except in January. MAX-DOAS measurements of glyoxal at a rural southern
477 China site in July 2006 were also higher in the afternoon than in mid-morning. In contrast, the
478 simulated glyoxal VCDs at OMI overpass time (Figure 7 (e)-(h)) were lower than those at GOME-2A
479 overpass time. This discrepancy among the glyoxal diurnal cycles represented by the MAX-DOAS
480 measurements and the model indicated an uncertainty in the local glyoxal budget.

481

482 Figures 6 and 7 also compare the formaldehyde and glyoxal VCDs observed by OMI to those simulated
483 by the model using the *a priori* emission estimates over China. Formaldehyde VCDs observed by OMI
484 were lower than those simulated by the model in all seasons, with the exception of a local hotspot over
485 the NCP in June. However, the glyoxal VCDs observed by OMI were higher than those simulated by
486 the model in all seasons. It thus appeared that the constraints on Chinese NMVOC emissions indicated
487 by the OMI formaldehyde and glyoxal observations were contradictory, even during January and June
488 when the NMVOC emissions over Eastern China were dominated by anthropogenic and biogenic
489 sources, respectively. There may be two explanations for this apparent contradiction indicated by the
490 OMI formaldehyde and glyoxal observations. Firstly, the simulated photochemical budgets of
491 formaldehyde and glyoxal during the local afternoon may be in error. Errors in the model
492 photochemical budget would also explain why the MAX-DOAS measurements of formaldehyde and
493 glyoxal VCDs were both higher in the afternoon than in the morning, while the model showed an
494 opposite diurnal contrast. It is also possible that there were different inherent biases in the OMI
495 formaldehyde and glyoxal retrievals.

496

497 **4 Top-down estimates of Chinese NMVOC emissions**

498 **4.1 *A posteriori* formaldehyde and glyoxal VCDs from inversion experiments**

499 The qualitative analyses in Section 3 showed that the GOME-2A and OMI retrievals of formaldehyde
500 and glyoxal VCDs provide disparate information on seasonal Chinese NMVOC emissions. Thus, our

501 four inversion experiments on monthly Chinese NMVOC emissions using different satellite
502 observations as constraints (Table 2) represent a range of probable top-down estimates given current
503 satellite observations. Figure 2 shows the monthly top-down Chinese NMVOC emission estimates
504 from the four inversion experiments for January, April, June, and October and compares them against
505 the *a priori* emission estimates. The top-down emission estimates for the full twelve months are shown
506 in Figure S3. Figure S4 shows the changes in the normalized cost functions over China in the four
507 inversion experiments. Relative to their respective initial cost function values, the optimized cost
508 function values were reduced by 10%-60% for all four experiments.

509

510 Figure 4 (i-l) and Figure 5 (i-l) show the *a posteriori* monthly mean VCDs of formaldehyde and
511 glyoxal, respectively, from the GOME-2A formaldehyde-glyoxal inversion experiment IE-1. Overall,
512 IE-1 greatly improved the agreement between the *a posteriori* VCDs and the GOME-2A observations
513 for both formaldehyde and glyoxal. The *a posteriori* VCDs of formaldehyde and glyoxal over eastern
514 China both decreased in January and increased in June. During the transition months of April and
515 October, IE-1 decreased the *a posteriori* formaldehyde VCDs while increasing the *a posteriori* glyoxal
516 VCDs. Figure 2 illustrates how these changes in VCDs were driven by the top-down NMVOC
517 emission estimates. For IE-1, the estimated emissions of all NMVOC species were reduced in January
518 but enhanced in June. In April and October, however, IE-1 decreased the total NMVOC emissions
519 while preferentially increasing the emissions of anthropogenic glyoxal precursors.

520

521 Figure 6 (i-l) and Figure 7 (i-l) show the *a posteriori* monthly mean VCDs of formaldehyde and
522 glyoxal, respectively, from the OMI formaldehyde-glyoxal inversion experiment IE-2. IE-2 was
523 effective in reducing the *a posteriori* formaldehyde VCDs over eastern China year-round to better
524 agree with the OMI formaldehyde observations. However, the inversion increased the *a posteriori*
525 glyoxal VCDs only slightly and was less effective in bringing agreement with the OMI glyoxal
526 observations. Figure 2 shows that the *a posteriori* NMVOC emission estimates from IE-2 were lower
527 than the *a priori* estimates for all months. This was due to a combination of factors at work in the
528 inversion. The low formaldehyde observations from OMI in all months drove a large reduction in the
529 emissions of NMVOCs that produced only formaldehyde ($\geq C_4$ alkanes and $\geq C_3$ alkenes from

530 anthropogenic activities, as well as primary formaldehyde from biomass burning). At the same time,
531 the relatively high glyoxal observations from OMI drove an increase in the emissions of NMVOCs that
532 produced mainly glyoxal (ethene, ethyne, and aromatics from anthropogenic activities, as well as
533 primary glyoxal from biomass burning). For precursors that produced large amounts of both
534 formaldehyde and glyoxal (most importantly biogenic isoprene), the inversion reduced the top-down
535 emissions. This was because the formaldehyde observations had more leverage on the inversion due to
536 their lower observational errors. This manifested the importance of well-characterized retrievals with
537 reliable error estimates.

538

539 Figure 4 (q-t) shows the *a posteriori* formaldehyde VCDs from the inversion experiment IE-3, which
540 was constrained by the GOME-2A-observed formaldehyde VCDs scaled by a factor of 1.7. The *a*
541 *posteriori* formaldehyde VCDs in IE-3 were further increased during the warmer months relative to
542 IE-1, especially over the NCP and central China in June. In January, the scaled-up GOME-2A
543 observations were still lower than the simulated formaldehyde VCDs using the *a priori* emissions,
544 leading to a small reduction in the *a posteriori* formaldehyde VCDs. Figure 2 shows that the top-down
545 emission estimates of all NMVOC species were lower than the *a priori* in January and higher than the
546 *a priori* in June. Consequently, although no observations of glyoxal were used as constraints in IE-3,
547 the *a posteriori* glyoxal VCDs also decreased in January and increased in June (Figure 5(m) and (o)).
548 This is in agreement with our findings in Section 3, whereby the constraints exerted by the GOME-2A
549 formaldehyde and glyoxal observations were consistent in January and in June, when the NMVOC
550 emissions were dominated by anthropogenic and biogenic sources, respectively. However, IE-3 had
551 almost no effects on the simulated glyoxal VCDs and the top-down emission estimates of
552 anthropogenic glyoxal precursors in April and October (Figure 5 (n) and (p)). This demonstrated the
553 necessity of glyoxal observations on constraining the emissions of NMVOC species that preferentially
554 produced glyoxal, including most importantly aromatics.

555

556 The impacts of satellite glyoxal observations on constraining Chinese NMVOC emission estimates was
557 further demonstrated in IE-4. Figure 7 (m-p) shows the *a posteriori* glyoxal VCDs from IE-4, which
558 used only the OMI glyoxal observations as constraints. The *a posteriori* glyoxal VCDs for all months
559 increased, to an extent greater than those in IE-2. Figure 2 shows that this increase in the *a posteriori*

560 glyoxal VCDs in IE-4 was achieved mainly by increasing the emission estimates of anthropogenic
561 glyoxal precursors for all months. In June, the emissions of biogenic isoprene (precursor to both
562 glyoxal and formaldehyde) also increased. As a result, the *a posteriori* formaldehyde VCDs in IE-4
563 increased in June but remained similar to the *a priori* simulation for the other months (Figure 6 (m-p)).
564

565 **4.2 Top-down estimates of Chinese NMVOC emissions from inversion experiments**

566 Table 2 and Figure 8 shows the top-down estimates for Chinese annual total NMVOC emissions from
567 the four inversion experiments and compare them against the *a priori*. Our top-down annual total
568 estimates for Chinese NMVOCs ranged from 23.4 to 35.4 Tg C y⁻¹, compared to the 27.4 Tg C y⁻¹ of
569 the *a priori*. The highest top-down estimate was from IE-3, constrained by 1.7 times the GOME-2A
570 formaldehyde VCD observations. The lowest top-down estimate was from IE-2, due to the relatively
571 low formaldehyde observations from OMI.

572
573 Anthropogenic sources constituted 53%-57% of the total top-down NMVOC emissions. The highest
574 top-down anthropogenic emissions estimate was from IE-4 (19.7 Tg C y⁻¹), which reflected the strong
575 traction of the OMI glyoxal observations on constraining anthropogenic NMVOC emissions. The
576 lowest top-down anthropogenic emission estimate was from IE-2 (13.5 Tg C y⁻¹). All four inversion
577 experiments consistently showed larger emissions of anthropogenic glyoxal precursors than the *a priori*.
578 In particular, our top-down estimates for anthropogenic aromatics ranged from 5.0 to 7.3 Tg C y⁻¹,
579 consistently larger than the *a priori* of 4.9 Tg C y⁻¹ (Li et al., 2014).

580
581 The top-down estimates for biogenic NMVOCs emission ranged between 8.9 and 14.8 Tg C y⁻¹. The
582 top-down estimates for biogenic isoprene were 4.9 to 10.5 Tg C y⁻¹. The top-down estimate for biomass
583 burning NMVOC emissions were between 1.06 to 1.47 Tg C y⁻¹, with the largest top-down estimate
584 driven by the scaled-up GOME-2A formaldehyde VCDs (IE-3).

585
586 Figure 9 shows the spatial distribution of the scale factors for Chinese annual NMVOC emissions from
587 each of the four inversion experiments relative to the *a priori* emission estimates. The use of
588 GOME-2A formaldehyde and glyoxal observations as constraints in IE-1 led to a domain-wide increase

589 in biogenic NMVOC emissions, except in the northeast. IE-1 also found an increase in biomass burning
590 emissions over the NCP in June. A similar spatial distribution was found for the emission scale factors
591 of IE-3. Again, this indicated a consistency between the constraints exerted by the formaldehyde and
592 glyoxal observations from GOME-2A. The optimized emission scale factors from IE-2 and IE-4 were
593 of opposite signs. Using only OMI glyoxal observations as constraints in IE-4 led to a domain-wide
594 increase in NMVOC emissions from all sectors. However, when further constraints of the relatively
595 low OMI formaldehyde observations were added in IE-2, the top-down emission estimates decreased
596 across the domain.

597

598 As discussed previously, our four inversion experiments using different satellite retrievals as
599 constraints represent the range of probable top-down estimates given currently available satellite
600 observations. To represent the difference between these top-down estimates relative to the *a priori*, we
601 averaged the top-down estimates from the four inversion experiments. Our averaged top-down estimate
602 for Chinese total annual NMVOC emissions was 30.8 Tg C y⁻¹, including 17.0 Tg C y⁻¹, 12.6 Tg C y⁻¹,
603 and 1.2 Tg C y⁻¹ from anthropogenic, biogenic, and biomass burning sources, respectively. Our average
604 estimate for anthropogenic aromatic flux was 6.1 Tg C y⁻¹, which was 24% larger than the *a priori*
605 estimate of Li et al. (2014).

606

607 Figure 1 (e-l) shows the spatial distribution of annual Chinese NMVOC emission of our averaged
608 top-down estimate and the scale factors relative to the *a priori* estimates. Our averaged top-down
609 estimate of Chinese NMVOC emissions were spatially consistent with the *a priori*, but the total fluxes
610 increased by 10% to 40% throughout eastern China relative to the *a priori*. In particular, we found a 40%
611 increase in the biomass burning emissions over the NCP. We also found a 20%-40% increase in the
612 anthropogenic NMVOC emissions in coastal eastern China. Largest scale factors for biogenic NMVOC
613 were found near the northwestern border of China and along the northeast-to-southwest division line of
614 vegetation density. This potentially indicated an underestimation of biogenic NMVOC emission from
615 semi-arid ecosystems in the MEGAN inventory.

616

617 5 Comparison with previous estimates of Chinese NMVOC emissions

618 Table 1 compares our top-down estimates of Chinese annual NMVOC emissions for the year 2007
619 against estimates in the literature for the years between 2005 and 2012. It should be noted that
620 bottom-up inventories often estimated the total NMVOCs emitted from a source sector using emission
621 factors for total NMVOCs, then distributed the emissions using different species profile data. As a
622 result, bottom-up estimates often included additional NMVOC species not represented here in our
623 study.

624

625 Our top-down estimate for biogenic NMVOC emissions range from 8.9 to 14.8 Tg C y⁻¹, on average 17%
626 larger than the flux calculated from the MEGAN inventory (Guenther et al., 2006). Our top-down
627 estimate for isoprene emission (the single most emitted NMVOC species) ranged from 4.9 to 10.5 Tg C
628 y⁻¹, bracketing the *a priori* of 6.6 Tg C y⁻¹. Stavrakou et al. (2015) previously used GOME-2A and OMI
629 formaldehyde observations to derive top-down estimates of isoprene emissions over China of 5.0 Tg C
630 y⁻¹ (GOME-2A) and 5.5 Tg C y⁻¹ (OMI), respectively. In comparison, our top-down isoprene emission
631 estimates constrained by GOME-2A and OMI (both formaldehyde and glyoxal) observations, were 8.2
632 Tg C y⁻¹ (from IE-1) and 4.9 Tg C y⁻¹ (from IE-2), respectively. Our top-down estimates constrained by
633 GOME-2A observations was larger than that of Stavrakou et al. (2015) due to the additional glyoxal
634 constraints. Our estimate constrained by OMI observations was lower than that of Stavrakou et al.
635 (2015) because the OMI formaldehyde VCDs over China retrieved by González Abad et al. (2015)
636 were systematically lower than the OMI formaldehyde VCDs retrieved by De Smedt et al. (2015).

637

638 Our top-down estimates for Chinese annual biomass burning NMVOC emissions ranged from 1.06 to
639 1.47 Tg C y⁻¹. These numbers are in good agreement with the estimate of Huang et al. (2012). Previous
640 bottom-up biomass burning NMVOC emission estimates by Bo et al. (2008) and Wu et al. (2016)
641 ranged from 1.9 to 2.4 Tg C y⁻¹, but only 25% to 30% of these emissions were from open burning of
642 crop residues; the rest were emitted from biofuel burning. The GFED3 inventory (van der Werf et al.,
643 2010), based on satellite burnt area observations, severely underestimated biomass burning emissions
644 over China, particularly those associated with crop residue burning. Top-down estimate of Chinese
645 biomass burning NMVOC emissions by Stavrakou et al. (2015) was between 1.1-1.5 Tg C y⁻¹, very

646 close to our top-down estimate range (1.06-1.47 Tg C y⁻¹). Similar to Fu et al. (2007) and Stavrou et
647 al. (2016), our study also highlighted the large emissions from crop residue over the NCP in June
648 (Figure 2).

649

650 Previous bottom-up estimates of Chinese anthropogenic NMVOC emissions ranged widely from 10.7
651 to 29.8 Tg C y⁻¹ (Bo et al., 2008; Cao et al., 2011; Kurokawa et al., 2013; Li et al., 2014; Wu et al.,
652 2016) due to the use of different emission factors, activity data, and statistical models. Previous
653 top-down estimates of Chinese anthropogenic NMVOC emissions ranged from 17.3-28.7 Tg C y⁻¹ (Liu
654 et al., 2012; Stavrou et al., 2015). Our top-down estimates had a smaller range between 13.5 to 19.7
655 Tg C y⁻¹. Our top-down estimates for anthropogenic aromatics (5.0 to 7.3 Tg C y⁻¹) were approximately
656 middle-of-the-range relative to previous estimates of 2.1-11.3 Tg C y⁻¹. The large difference between
657 previous top-down estimates and our top-down estimates of anthropogenic NMVOCs were
658 predominantly due to the choices of satellite observation constraints, and to a lesser extent due to the
659 choices of chemical transport model, the NMVOC species modeled, and the *a priori* emission
660 estimates. Specifically, the much higher estimate of anthropogenic aromatic emission by Liu et al.
661 (2012) (11.3 Tg C y⁻¹) compared to our top-down estimates (5.0-7.3 Tg C y⁻¹) was due to (1) the high
662 glyoxal VCDs observed by the SCIAMACHY instrument compared to those observed the GOME-2A
663 and OMI instruments over China; (2) the assumption made by Liu et al. (2012) that all anomalous
664 glyoxal was produced by aromatics oxidation; (3) the lower yields of glyoxal from aromatics oxidation
665 used in Liu et al. (2012) than those used in our model.

666

667 Our four inversion experiments all indicated stronger anthropogenic NMVOC emissions in summer
668 than in winter. In contrast, the *a priori* estimates showed a slightly stronger NMVOC emission in
669 winter than in summer, which was driven by stronger activity levels in winter in the bottom-up
670 inventories along with seasonally-invariant emission factors (Li et al., 2017). However, studies showed
671 that the NMVOC emission factors, in particular those for transport and industrial sectors, were strongly
672 and positively correlated with temperature (Rubin et al., 2006; Wei et al., 2016).

673

674 **6 Impacts on simulated surface ozone levels over China**

675 We evaluated the impacts on surface ozone concentrations due to our average top-down emission
676 estimates of NMVOCs. Figure 10 compares the monthly mean afternoon (13:00-17:00 LT) surface
677 ozone concentrations simulated using our averaged top-down emission estimates against those
678 simulated using the *a priori* emissions for June and December 2007. Also shown in Figure 10 are
679 surface observations at representative regional sites (Li et al., 2007; Xu et al., 2008; J. M. Zhang et al.,
680 2009; Zheng et al., 2010; Wang et al., 2012; Wang et al., 2015; Li and Bian, 2015; Sun et al., 2016; Xu
681 et al., 2016). Using the *a priori* emissions, the highest simulated afternoon surface ozone concentrations
682 were between 100-110 ppb over the NCP in June. This was lower than the observations at two sites in
683 the NCP, including a rural site outside Beijing (>100 ppb) and Mt. Tai (108 ppb). In comparison, by
684 using our averaged top-down NMVOC emission estimate, the simulated afternoon surface ozone
685 increased by 5-10 ppb over the NCP in June and were in better agreement with the observations. In
686 December, the simulated afternoon surface ozone using *a priori* emission consistently overestimated
687 the observed concentrations in eastern China. In comparison, by using our averaged top-down
688 NMVOC emission estimates, the simulated afternoon surface ozone over eastern China decreased by 5
689 to 13 ppb, again in better agreement with the observations. It thus appears that our top-down emission
690 estimates for Chinese NMVOCs improved simulation of regional ozone.

691

692 **7 Conclusions**

693 We used the GEOS-Chem model and its adjoint, as well as satellite observations of tropospheric
694 column concentrations of formaldehyde and glyoxal, to constrain monthly Chinese NMVOC emissions
695 from anthropogenic, biogenic, and biomass burning sources for the year 2007. We updated the
696 gas-phase chemistry in the GEOS-Chem model and constructed its adjoint. The *a priori* emission
697 estimates were taken from widely-used bottom-up emission inventories. We conducted four inversion
698 experiments, which were constrained by formaldehyde and glyoxal observations from the GOME-2A
699 instrument (IE-1), formaldehyde and glyoxal observations from the OMI instrument (IE-2), 1.7 times
700 the formaldehyde observations from the GOME-2A instrument (IE-3), and glyoxal observations from
701 the OMI instrument (IE-4), respectively. The results from these experiments represented the range of
702 probable top-down NMVOC emission estimates for China given current satellite observational

703 constraints.

704

705 Our top-down estimates of total annual Chinese NMVOC emission from the four inversion
706 experiments ranged from 23.4 to 35.4 Tg C y⁻¹. Our top-down estimates of Chinese anthropogenic
707 NMVOC emission was 13.5 to 19.7 Tg C y⁻¹. In particular, we top-down estimate of Chinese
708 anthropogenic aromatic emissions range from 5.0 to 7.3 Tg C y⁻¹, much smaller than the top-down
709 estimate of 11.3 Tg C y⁻¹ by Liu et al. (2012). Our top-down estimate of Chinese biogenic NMVOC
710 emission ranged from 8.9 to 14.8 Tg C y⁻¹, with 4.9 to 10.5 Tg C y⁻¹ attributed to isoprene. Our
711 top-down estimate for Chinese biomass burning NMVOC emission range from 1.1 to 1.5 Tg C y⁻¹ and
712 was mostly associated with seasonal open burning of crop residue after local harvests, such as over the
713 NCP in June.

714

715 We evaluated the impacts on regional surface ozone concentrations from our average top-down
716 Chinese NMVOC emission estimates. We found that the simulated monthly mean afternoon surface
717 ozone concentrations increased by 5-12 ppb over the NCP in June, compared to the *a priori* simulation.
718 In December, the simulated monthly mean afternoon surface ozone concentrations decreased by 5-13
719 ppb over northern and central China, compared to the *a priori* simulation. For both seasons, the
720 simulation using our averaged top-down emission estimates were in better general agreement with
721 regional surface observations.

722

723 We concluded that formaldehyde and glyoxal observations from GOME-2A and OMI provide
724 quantitative constraints on the monthly emissions of Chinese NMVOCs. In particular, the simultaneous
725 use of the observations of both species helps distinguish NMVOC precursors and thus provides better
726 quantification of individual sources. However, better validation of these satellite data over China are
727 urgently needed, particularly in terms of discrepancies between different retrievals for the same species.

Table 1. Comparison of recent estimates for Chinese annual NMVOC emissions

Literature ^a	Target year	NMVOC [Tg C y ⁻¹]				
		Anthropogenic		Biogenic		Biomass burning
		Total	Aromatics	Total	Isoprene	
Bottom-up						
Bo et al. (2008) ^b	2005	10.7				2.2 ^e
Zhang et al. (2009) ^b	2006	19.7 (±68%)	2.1			
Cao et al. (2011) ^b	2007	29.8				
Kurokawa et al. (2013) ^b	2008	22.8 (±46%)				
Li et al. (2014) ^b	2010	19.8	4.9			
Wu et al. (2016) ^b	2008	15.6				2.2 ^e
	2009	18.3				1.9 ^e
	2010	20.0				2.1 ^e
	2011	20.8				2.1 ^e
	2012	21.5				2.4 ^e
Huang et al. (2012) ^b	2006					1.3 (0.62-2.0)
van der Werf et al. (2010)	2007					0.24
Guenther et al. (2006)	2007			10.8 ^f	6.6 ^f	
Top-down						
Liu et al. (2012) ^c	2007	28.7	11.3			
Stavrakou et al. (2015) ^d	2010	(17.3-20.7)			(5.0-5.5)	(1.1-1.5)
This work	2007	17.0 ^g (13.5-19.7)	6.1 ^g (5.0-7.3)	12.6 ^g (8.9-14.8)	8.4 ^g (4.9-10.5)	1.22 ^g (1.06 – 1.47)

1099

1100 ^a Emission estimates from literature were originally in units of Tg y⁻¹. We converted the units to Tg C y⁻¹ using to
 1101 carbon to organic compound mass ratios (0.84 for anthropogenic VOCs, 0.57 for biomass burning VOCs, and 0.85
 1102 for biogenic VOCs based on the *a priori* emission estimates).

1103 ^b These emission estimates included NMVOC species that were not included in this work. See color keys in Figure
 1104 2 for NMVOC species whose emissions were included in this work.

1105 ^c Used SCIAMACHY-observed glyoxal VCDs as constraints.

1106 ^d Used GOME-2A-observed and OMI-observed formaldehyde VCDs as constraints.

1107 ^e Consisted of emissions from open burning of crop residues and from biofuel burning.

1108 ^f Calculated by the GEOS-Chem model using GEOS-5 meteorological data.

1109 ^g Average of top-down estimates from four inversion experiments.

1118 **Table 2. Inversion experiments to constrain Chinese NMVOC emissions**

Inversion experiments	Observational constraints from satellites [±uncertainties]	Annual Chinese NMVOC emission estimates [Tg C y ⁻¹]			
		Anthropogenic	Biogenic	Biomass burning	Total
		<i>A priori</i> emission estimates [±uncertainties]			
		15.5 (4.9 for aromatics) ^a [±200%]	10.8 (6.6 for isoprene) ^b [±55%]	1.10 [±300%] ^c	27.4
		<i>A posteriori</i> emission estimates [range]			
IE-1	GOME-2A formaldehyde [±90%] and glyoxal [±150%]	15.7 (5.9 for aromatics)	12.5 (8.2 for isoprene)	1.13	29.3
IE-2	OMI formaldehyde [±90%] and glyoxal [±150%]	13.5 (5.0 for aromatics)	8.9 (4.9 for isoprene)	1.06	23.4
IE-3	GOME-2A formaldehyde × 170% [±90%]	19.2 (6.0 for aromatics)	14.8 (10.5 for isoprene)	1.47	35.4
IE-4	OMI glyoxal [±150%]	19.7 (7.3 for aromatics)	14.1 (9.9 for isoprene)	1.24	35.1
Our top-down estimates		17.0 ^d [13.5 - 19.7] (6.1 ^d [5.0 - 7.3] for aromatics)	12.6 ^d [8.9 - 14.8] (8.4 ^d [4.9 - 10.5] for isoprene)	1.2 ^d [1.1 - 1.5]	30.8 ^d [23.4 - 35.4]

1119 ^a From Li et al. (2014)1120 ^b From Guenther et al. (2006).1121 ^c Compiled from the emission estimated by van der Werf et al. (2010) plus a scaling of the emission estimated by
1122 Huang et al. (2012). See text (section 2.2) for details.1123 ^d Average of top-down estimates from the four inversion experiments.

Table 3. Technical details for GOME-2A and OMI formaldehyde and glyoxal retrievals used in this study

Technical details		GOME-2A		OMI	
		Formaldehyde ^a	Glyoxal ^b	Formaldehyde ^c	Glyoxal ^d
Onboard satellite		European Metop-A		NASA Aura	
Operation time		October 2006-present		July 2004-present	
Overpass time		9:30 LT		13:30 LT	
Global coverage		1.5 days ^e		1 day	
Spatial resolution		80 km × 40 km		13 km × 24 km	
Spectral window		240-790 nm		270-500 nm	
Spectral resolution		0.26-0.5 nm		0.42 nm and 0.63 nm	
Selected absorption band		328.5 - 346 nm	435 - 460 nm	328.5 - 356.5 nm	435 - 461 nm
Retrieval algorithm		DOAS fitting		Direct fitting	
Cloud parameters		FRESCO+ (Wang et al., 2008)		OMCLDO2 (Acarreta et al., 2004)	
Surface albedo		Kleipool et al. (2008)		Kleipool et al. (2008)	
Air mass factor calculation	Radiative transfer model	LIDORT (Spurr, 2008)		VLIDORT (Spurr, 2006)	
	Tracer gas profiles	IMAGE v2 (Stavrakou et al., 2009b)		GEOS-Chem (González Abad et al., 2015)	
Extinction by aerosols		Considered implicitly via cloud correction		Considered implicitly in the cloud retrieval	
Discarded pixels		Cloud fraction > 40% or zenith angles >60°		Cloud fraction > 40%	Impacted by random telegraph signals (RTS) ^f

1139 ^a From De Smedt et al. (2012)

1140 ^b From Lerot et al. (2010)

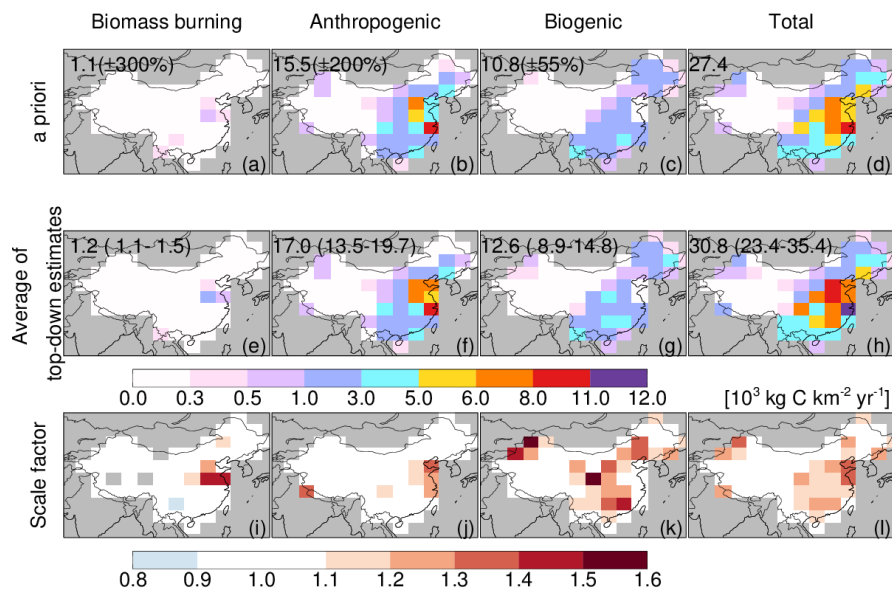

1141 ^c From González Abad et al. (2015)

1142 ^d From Chan Miller et al. (2014)

1143 ^e Before the swath was narrowed in June 2013. After that, the global coverage is achieved every 3 days.

1144 ^f Pixels that have been flagged as RTS in the level 1-B product (Kleipool, 2005).

Figure 1. Spatial distributions of annual NMVOC emissions from China. (a)-(d): the *a priori* annual NMVOC emission estimates from (a) biomass burning, (b) anthropogenic, (c) biogenic, and (d) total sources. (e)-(h): averaged top-down estimates of annual NMVOC emissions. Annual Chinese total emission estimates are shown inset in units of $[\text{Tg C yr}^{-1}]$. The uncertainties of the *a priori* emission estimates and the range of top-down emission estimates are shown in parentheses. (i)-(l): scale factors for our averaged top-down estimates relative to the *a priori* estimates.

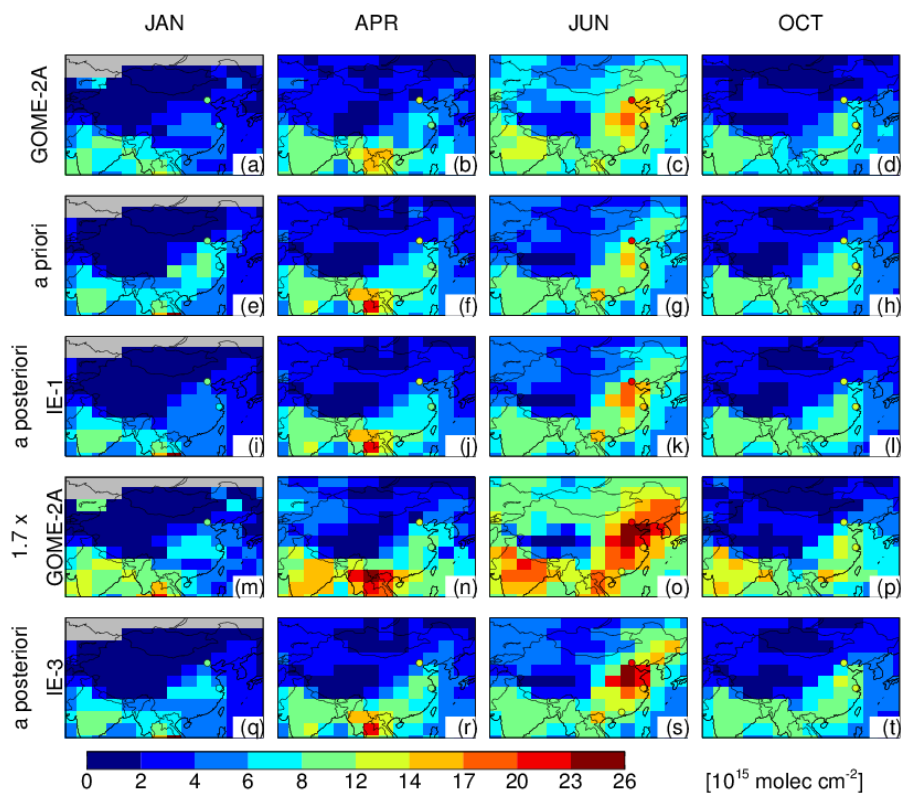

1154

1155 **Figure 2.** Estimates of monthly Chinese NMVOC emissions for January, April, June, and October 2007. For each
 1156 month, the bars from left to right represent: the *a priori* emission estimates and the *a posteriori* emission estimates
 1157 from IE-1, IE-2, IE-3, and IE-4. The red dashed boxes and red numbers indicate monthly emissions of
 1158 anthropogenic glyoxal precursors. Color keys for NMVOC species are shown inset, with the suffixes of ‘bb’, ‘an’
 1159 and ‘bg’ indicating emissions from biomass burning, anthropogenic, and biogenic activities, respectively.

1176

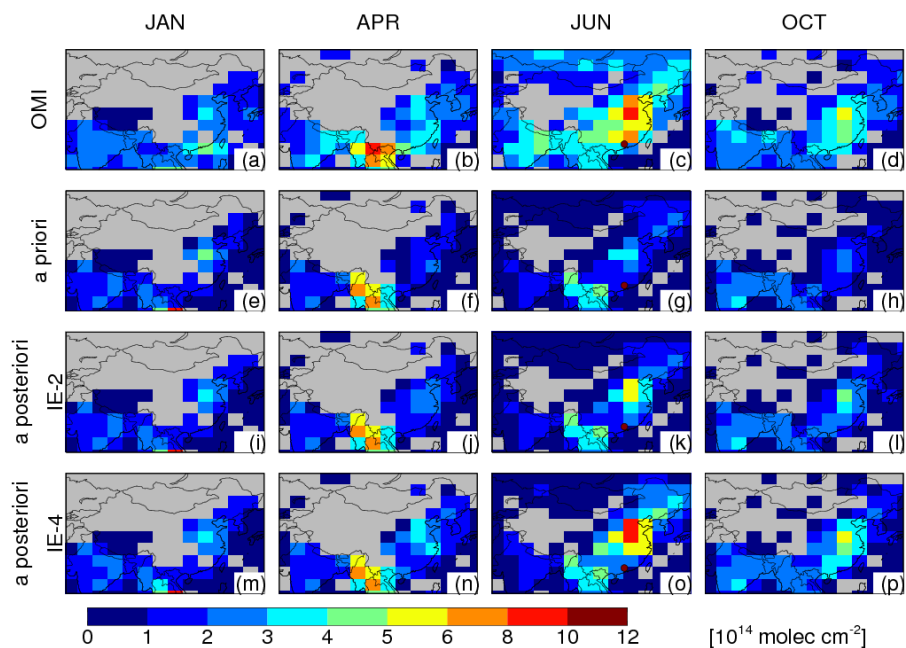

Figure 5. Monthly mean glyoxal VCDs over China (a-d) observed by the GOME-2A instrument, (e-h) simulated by the model using the *a priori* emission estimates, (i-l) obtain from inversion IE-1, and (m-p) obtain from inversion IE-3. Also shown are ground-based MAX-DOAS measurements at Back Garden in July 2006 (Li et al, 2013).

1177

1178 **Figure 6.** Monthly mean formaldehyde VCDs over China. (a-d): formaldehyde VCDs observed by the OMI
1179 instrument. (e-h): formaldehyde VCDs simulated by the model using the *a priori* emission estimates. (i-l): the *a*
1180 *posteriori* formaldehyde VCDs from inversion IE-2. (m-p): the *a posteriori* formaldehyde VCDs from inversion
1181 IE-4. Also shown are ground-based MAX-DOAS measurements at 13:30 LT (circles) at Beijing (De Smedt et al.,
1182 2015), Wuxi (Wang et al, 2017), and Back Garden (Li et al, 2013).

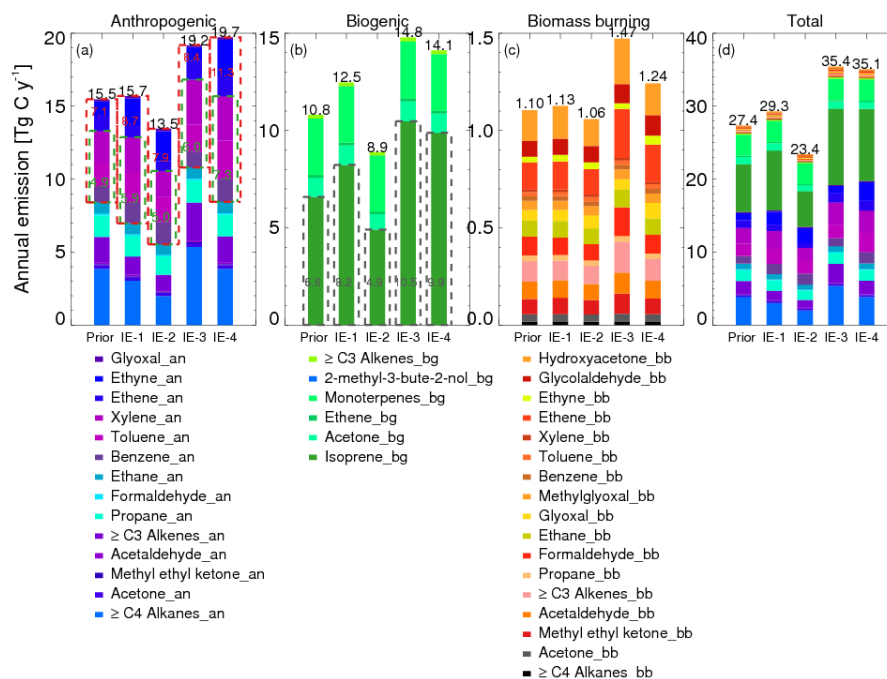

1183

1184

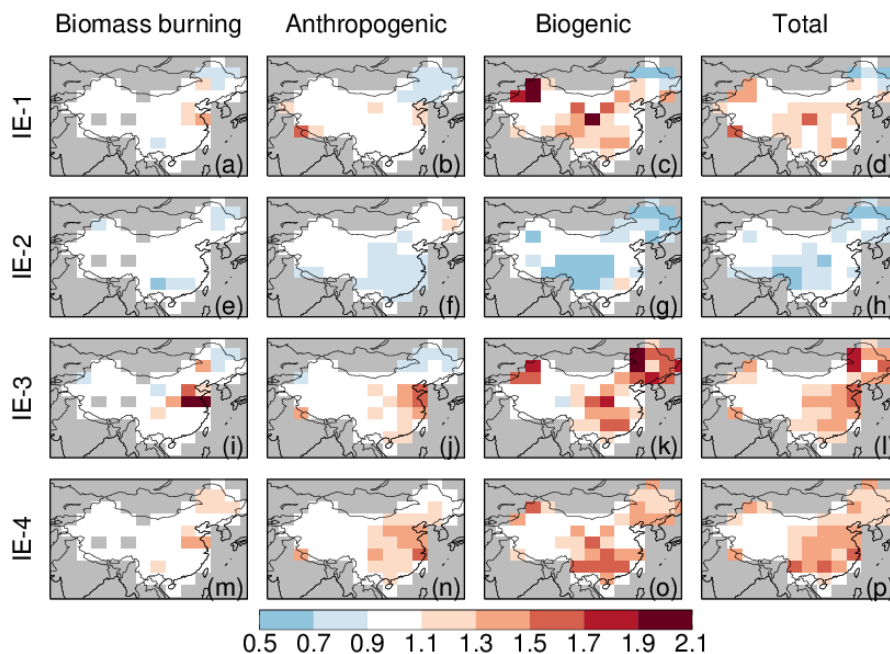

1185 **Figure 7.** Monthly mean glyoxal VCDs over China (a-d) observed by the OMI instrument, (e-h) simulated by the
 1186 model using the *a priori* emission estimates, (i-l) obtained from inversion IE-2, and (m-p) obtained from the
 1187 inversion IE-4. Also shown are ground-based MAX-DOAS measurements at 13:30 LT (circles) at Back Garden in
 1188 July 2006 (Li et al, 2013).

1189

1190

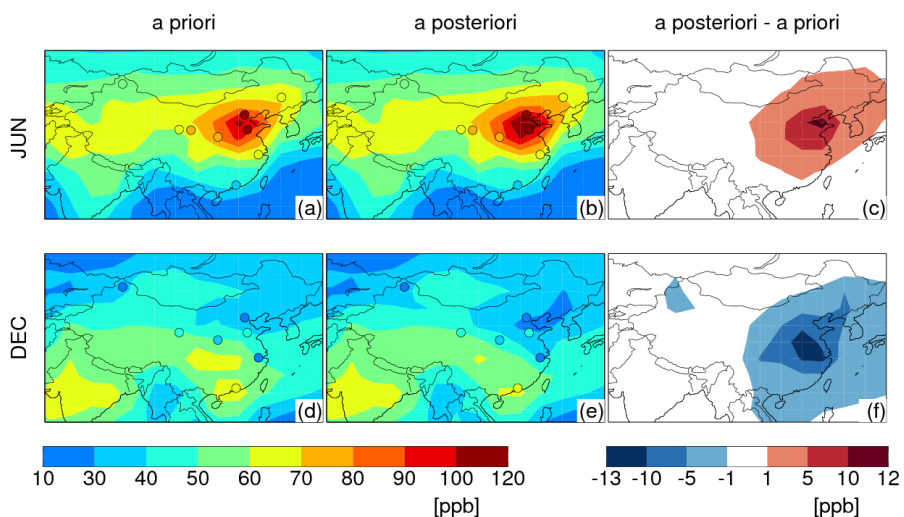

1191 **Figure 8.** Comparison of estimates of annual Chinese NMVOC emissions from (a) anthropogenic, (b) biogenic, (c)
 1192 biomass burning, and (d) total sources. For each subfigure, shown from left to right are the *a priori* estimates and
 1193 our *a posteriori* estimates from IE-1, IE-2, IE-3, and IE-4. Annual total NMVOC emission estimates are shown in
 1194 black numbers on top of each bar. The red dashed boxes and red numbers in (a) indicate annual emissions of
 1195 anthropogenic glyoxal precursors. The green dashed boxes and green numbers in (a) indicate annual emissions of
 1196 anthropogenic aromatics. The grey dashed boxes and grey numbers in (b) indicate annual biogenic isoprene
 1197 emissions. Color keys to NMVOC species are shown at the bottom, with suffixes of ‘an’, ‘bg’, ‘bb’ indicating
 1198 anthropogenic source, biogenic source, and biomass burning source, respectively.
 1199
