14 **Abstract.** Compared to the severe winter haze episodes in the North China Plain (NCP), haze pollution during summertime has
15 drawn little public attention. In this study, we present the highly time-resolved chemical composition of submicron particles (PM₁)
16 measured in Beijing and Xinxiang in the NCP region during summertime to evaluate the driving factors of aerosol pollution.
17 During the campaign periods (30 June to 27 July, 2015, for Beijing and 8 to 25 June, 2017, for Xinxiang), the average PM₁
18 concentrations were 35.0 $\mu\text{g m}^{-3}$ and 64.2 $\mu\text{g m}^{-3}$ in Beijing and Xinxiang, respectively. Pollution episodes characterized with
19 largely enhanced nitrate concentrations were observed at both sites. In contrast to the slightly decreased mass fractions of sulfate,
20 semi-volatile oxygenated organic aerosol (SV-OOA), and low-volatile oxygenated organic aerosol (LV-OOA) in PM₁, nitrate
21 displayed a significantly enhanced contribution with the aggravation of aerosol pollution, highlighting the importance of nitrate
22 formation as the driving force of haze evolution in summer. Rapid nitrate production mainly occurred after midnight, with a higher
23 formation rate than that of sulfate, SV-OOA, or LV-OOA. Based on observation measurements and thermodynamic modeling,
24 high ammonia emissions in the NCP region favored the high nitrate production in summer. Nighttime nitrate formation through
25 heterogeneous hydrolysis of dinitrogen pentoxide (N₂O₅) enhanced with the development of haze pollution. In addition, air masses
26 from surrounding polluted areas during haze episodes also led to more nitrate production. Finally, atmospheric particulate nitrate
27 data acquired by mass spectrometric techniques from various field campaigns in Asia, Europe, and North America uncovered a
28 higher concentration and higher fraction of nitrate present in China. Although measurements in Beijing during different years
29 demonstrate a decline in the nitrate concentration in recent years, the nitrate contribution in PM₁ still remains high. To effectively
30 alleviate particulate matter pollution in summer, our results call for the urgent need to initiate ammonia emission control measures
31 and further reduce nitrogen oxide emissions over the NCP region.

32 1 Introduction

33 Atmospheric aerosol particles are known to significantly impact visibility (Watson, 2002) and human health (Pope et al., 2009;
34 Cohen et al., 2017), as well as affect climate change by directly and indirectly altering the radiative balance of Earth's atmosphere
35 (IPCC, 2007). The effects of aerosols are intrinsically linked to the chemical composition of particles, which are usually dominated
36 by organics and secondary inorganic aerosols (i.e., sulfate, nitrate, and ammonium) (Jimenez et al., 2009).

37 In recent years, severe haze pollution has repeatedly struck the North China Plain (NCP), and its effects on human health have
38 drawn increasing public attention. Correspondingly, the chemical composition, sources, and evolution processes of particulate

39 matter (PM) have been thoroughly investigated (Huang et al., 2014; Guo et al., 2014; Cheng et al., 2016; Li et al., 2017a), mostly
40 during extreme pollution episodes in winter. Unfavorable meteorological conditions, intense primary emissions from coal
41 combustion and biomass burning, and fast production of sulfate through heterogeneous reactions were found to be the driving
42 factors of heavy PM accumulation in the NCP region (Zheng et al., 2015; Li et al., 2017b; Zou et al., 2017). Although summer is
43 characterized by relatively better air quality compared to the serious haze pollution in winter, fine particle (PM_{2.5}) concentration
44 in the NCP region still remains high during summertime. Through one-year real-time measurements of non-refractory submicron
45 particles (NR-PM₁), Sun et al. (2015) showed that the aerosol pollution during summer was comparable to that during other seasons
46 in Beijing, and the hourly maximum concentration of NR-PM₁ during the summer reached over 300 $\mu\text{g m}^{-3}$. Previous studies
47 focusing on the seasonal variations of aerosol characteristics have noted quite different behaviors of aerosol species in winter and
48 summer (Hu et al., 2017). Therefore, figuring out the specific driving factors of haze evolution in summer would help establish
49 effective air pollution control measures.

50 Compared to more than 70% reduction of sulfur dioxide (SO₂) emissions since 2006 due to the wide application of flue-gas
51 desulfurization devices in power plants and the phase-out of small, high emitting power generation units (Li et al., 2017c), nitrogen
52 oxide (NO_x) emissions in China remain high and decreased by less than 20% from 2012 to 2015 (Liu et al., 2016). Therefore, the
53 role of nitrate formation in aerosol pollution is predicted to generally increase as a consequence of high ammonia (NH₃) emissions
54 in the NCP region. However, due to the significantly enhanced production of sulfate in extreme winter haze resulting from the
55 high relative humidity (RH) and large SO₂ emissions from coal combustion, little attention has been paid to nitrate behaviors. In
56 PM_{2.5}, aerosol nitrate mostly exists in the form of ammonium nitrate, via the neutralization of nitric acid (HNO₃) with NH₃. HNO₃
57 is overwhelmingly produced through secondary oxidation processes, NO₂ oxidized by OH during the day and hydrolysis of N₂O₅
58 at night, with the former being the dominant pathway (Alexander et al., 2009). The neutralization of HNO₃ is limited by the
59 availability of NH₃, as NH₃ prefers to react first with sulfuric acid (H₂SO₄) to form ammonium sulfate with lower volatility
60 (Seinfeld and Pandis, 2006). Because ammonium nitrate is semi-volatile, its formation also depends on the gas-to-particle
61 equilibrium, which is closely related to variations in temperature and RH. A recent review on PM chemical characterization
62 summarized that aerosol nitrate accounts for 16~35% of submicron particles (PM₁) in China (Li et al., 2017a). Some studies also
63 pointed out the importance of aerosol nitrate in haze formation in the NCP region (Sun et al., 2012; Ge et al., 2017; Yang et al.,
64 2017). However, detailed investigations and the possible mechanisms governing nitrate behaviors during pollution evolution are
65 still very limited.

66 In this study, we present in-depth analysis of the chemical characteristics of PM₁ at urban sites in Beijing and Xinxiang, China
67 during summertime. Based on the varying aerosol composition with the increase of PM₁ concentration, the driving factors of haze
68 development were evaluated, and the significance of nitrate contribution was uncovered. In particular, we investigated the chemical
69 behavior of nitrate in detail and revealed the factors favoring rapid nitrate formation during summer in the NCP region.

70 **2 Experiments**

71 **2.1 Sampling site and instrumentation**

72 The data presented in this study were collected in Beijing from 30 June to 27 July, 2015, and in Xinxiang from 8 to 25 June, 2017.
73 Beijing is the capital city of China, adjacent to Tianjin municipality and Hebei province, both bearing high emissions of air
74 pollutants. The Beijing-Tianjin-Hebei region is regularly listed as one of the most polluted areas in China by the China National
75 Environmental Monitoring Centre. The field measurements in Beijing were performed on the roof of a three-floor building on the
76 campus of Tsinghua University (40.0 °N, 116.3 °E). The sampling site is surrounded by school and residential areas, and no major

77 industrial sources are located nearby. Xinxiang is a prefecture-level city in northern Henan province, characterized by considerable
78 industrial manufacturing. In February 2017, the Chinese Ministry of Environmental Protection issued the “Beijing-Tianjin-Hebei
79 and the surrounding areas air pollution prevention and control work program 2017” to combat air pollution in Northern China. The
80 action plan covers the municipalities of Beijing and Tianjin and 26 cities in Hebei, Shanxi, Shandong and Henan provinces, referred
81 to as “2+26” cities. The 26 cities were identified according to their impacts on Beijing’s air quality through regional air pollution
82 transport. Xinxiang is listed as one of the “2+26” cities. The average $PM_{2.5}$ concentrations in Xinxiang in 2015 and 2016 were 94
83 $\mu g m^{-3}$ and 84 $\mu g m^{-3}$, respectively. Our sampling in Xinxiang was performed in the mobile laboratory of Nanjing University,
84 deployed in the urban district near an air quality monitoring site (35.3 °N, 113.9 °E). The observations in both Beijing and Xinxiang
85 would help to figure out the generality and individuality of air pollution in the NCP region.

86 An Aerodyne Aerosol Chemical Speciation Monitor (ACSM) was deployed for the chemical characterization of NR- PM_1 , with a
87 time resolution of 15 minutes. Briefly, ambient aerosols were sampled into the ACSM system at a flow rate of 3 L min⁻¹ through
88 a $PM_{2.5}$ cyclone to remove coarse particles and then a silica gel diffusion dryer to keep particles dry (RH < 30%). After passing
89 through a 100 μm critical orifice mounted at the entrance of an aerodynamic lens, aerosol particles with a vacuum aerodynamic
90 diameter of ~30-1000 nm were directly transmitted into the detection chamber, where non-refractory particles were flash vaporized
91 at the oven temperature (~600 °C) and chemically characterized by 70 eV electron impact quadrupole mass spectrometry. Detailed
92 descriptions of the ACSM technique can be found in Ng et al. (2011). The mass concentration of refractory BC in PM_1 was recorded
93 by a multi-angle absorption photometer (MAAP Model 5012, Thermo Electron Corporation) on a 10-min resolution basis (Petzold
94 and Schönlinner, 2004; Petzold et al., 2005). The MAAP was equipped with a PM_1 cyclone, and a drying system was incorporated
95 in front of the sampling line. A suite of commercial gas analyzers (Thermo Scientific) were also deployed to monitor variations in
96 the gaseous species (i.e., CO, O₃, NO, NO_x, and SO₂).

97 For observations in Beijing, the total PM_1 mass was simultaneously measured using a PM-714 Monitor (Kimoto Electric Co., Ltd.,
98 Japan) based on the β -ray absorption method (Li et al., 2016). Meteorological conditions, including temperature, RH, wind speed,
99 and wind direction, were reported by an automatic meteorological observation instrument (Milos520, VAISALA Inc., Finland).
100 For measurements in Xinxiang, the online $PM_{2.5}$ mass concentration was measured using a heated Tapered Elemental Oscillating
101 Microbalance (TEOM series 1400a, Thermo Scientific). The temperature and RH were obtained using a Kestrel 4500 Pocket
102 Weather Tracker.

103 **2.2 ACSM data analysis**

104 The mass concentrations of aerosol species, including organics, sulfate, nitrate, ammonium, and chloride, can be determined from
105 the ion signals detected by the quadrupole mass spectrometer (Ng et al., 2011) using the standard ACSM data analysis software
106 (v.1.5.3.0) within Igor Pro (WaveMetrics, Inc., Oregon USA). Default relative ionization efficiency (RIE) values were assumed
107 for organics (1.4), nitrate (1.1), and chloride (1.3). The RIEs of ammonium and sulfate were determined to be 7.16 and 1.08,
108 respectively, through calibration with pure ammonium nitrate and ammonium sulfate. To account for the incomplete detection of
109 aerosol particles (Ng et al., 2011), a constant collection efficiency (CE) of 0.5 was applied to the entire dataset. After all the
110 corrections, the mass concentration of ACSM NR- PM_1 plus BC was closely correlated with that of total PM_1 obtained by PM-714
111 in Beijing ($r^2 = 0.59$; Fig. S1). The slope was slightly higher than 1, which was probably caused by different measuring methods
112 of the different instruments and the uncertainties. For measurements in Xinxiang, the mass concentration of ACSM NR- PM_1 plus
113 BC also displayed a good correlation with $PM_{2.5}$ concentration measured by TEOM, with a slope of 0.83 ($r^2 = 0.85$; Fig. S1).
114 Positive matrix factorization (PMF) with the PMF2.exe algorithm (Paatero and Tapper, 1994) was performed on ACSM organics
115 mass spectra to explore various sources of organic aerosol (OA). Only m/z ’s up to 120 were considered due to the higher

116 uncertainties of larger m/z 's and the interference of the naphthalene internal standard at m/z 127-129. In general, signals with m/z >
117 120 only account for a minor fraction of total signals. Therefore, this kind of treatment has little effect on the OA source
118 apportionment. PMF analysis was performed with an Igor Pro-based PMF Evaluation Tool (PET) (Ulbrich et al., 2009), and the
119 results were evaluated following the procedures detailed in Ulbrich et al. (2009) and Zhang et al. (2011). According to the
120 interpretation of the mass spectra, the temporal and diurnal variations of each factor, and the correlation of OA factors with external
121 tracer compounds, a four-factor solution with FPEAK = 0 and a three-factor solution with FPEAK = 0 were chosen as the optimum
122 solutions in Beijing and Xinxiang, respectively. The total OA in Beijing was resolved into a hydrocarbon-like OA (HOA) factor,
123 a cooking OA (COA) factor, a semi-volatile oxygenated OA (SV-OOA) factor, and a less-volatile oxygenated OA (LV-OOA)
124 factor, where the former two represented primary sources, and the latter two came from secondary formation processes. In Xinxiang,
125 the identified OA factors included HOA, SV-OOA, and LV-OOA. Procedures for OA source apportionment are detailed in the
126 supplementary materials (Text S1; Tables S1-2; Figs. S2-7).

127 **2.3 ISORROPIA-II equilibrium calculation**

128 To investigate factors influencing the particulate nitrate formation, the ISORROPIA-II thermodynamic model was used to
129 determine the equilibrium composition of an NH_4^+ - SO_4^{2-} - NO_3^- - Cl^- - Na^+ - Ca^{2+} - K^+ - Mg^{2+} - water inorganic aerosol (Fountoukis
130 and Nenes, 2007). When applying ISORROPIA-II, we assumed that the aerosol was internally mixed and composed of a single
131 aqueous phase, and the bulk PM_1 or $\text{PM}_{2.5}$ properties had no compositional dependence on particle size. The validity of the model
132 performance for predicting particle pH, water, and semi-volatile species has been examined by a number of studies in various
133 locations (Guo et al., 2015, 2016, 2017a; Hennigan et al., 2015; Bougiatioti et al., 2016; Weber et al., 2016; Liu et al., 2017). In
134 this study, the sensitivity analysis of PM_1 nitrate formation to gas-phase NH_3 and PM_1 sulfate concentrations was performed using
135 the ISORROPIA-II model, running in the “forward mode” for a metastable aerosol state. Input to ISORROPIA-II includes the
136 average RH, T, and total NO_3^- ($\text{HNO}_3 + \text{NO}_3^-$) for typical summer conditions (RH = 56%, T = 300.21K) in Beijing and Xinxiang,
137 along with a selected sulfate concentration. Total NH_4^+ ($\text{NH}_3 + \text{NH}_4^+$) was left as the free variable. The variations in nitrate
138 partitioning ratio ($\epsilon(\text{NO}_3^-) = \text{NO}_3^- / (\text{HNO}_3 + \text{NO}_3^-)$) were examined with varying sulfate concentrations from 0.1 to 45 $\mu\text{g m}^{-3}$ and
139 equilibrated NH_3 between 0.1 and 50 $\mu\text{g m}^{-3}$.

140 **2.4 Air mass trajectory analysis**

141 Back trajectory analysis using the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPPLIT) model (Draxler and Hess,
142 1998) was conducted to explore the influence of regional transport on aerosol characteristics in Beijing. The meteorological input
143 was adopted from the NOAA Air Resource Laboratory Archived Global Data Assimilation System (GDAS)
144 (<ftp://arlftp.arlhq.noaa.gov/pub/archives/>). The back trajectories initialized at 100 m above ground level were calculated every hour
145 throughout the campaign and then clustered into several groups according to their similarity in spatial distribution. In this study, a
146 four-cluster solution was adopted, as shown in Fig. S8.

147 **3 Results and discussion**

148 **3.1 Overview of aerosol characteristics**

149 Summer is usually the least polluted season of the year in the NCP region due to favorable weather conditions and lower emissions
150 from anthropogenic sources (Hu et al., 2017). Figures 1 and 2 show the time series of meteorological parameters, gaseous species
151 concentrations, and aerosol species concentrations in Beijing and Xinxiang. The weather during the two campaigns was relatively

152 hot (average $T = 27.1 \pm 4.1$ °C for Beijing and 26.9 ± 4.0 °C for Xinxiang) and humid (average $RH = 55.9 \pm 18.5\%$ for Beijing
153 and $63.5 \pm 17.2\%$ for Xinxiang), with regular variations between day and night. The average PM_1 (= NR- PM_1 + BC) concentration
154 was $35.0 \mu\text{g m}^{-3}$ in Beijing and $64.2 \mu\text{g m}^{-3}$ in Xinxiang, with the hourly maximum reaching $114.9 \mu\text{g m}^{-3}$ and $208.1 \mu\text{g m}^{-3}$,
155 respectively. Several pollution episodes were clearly observed at the two sites, along with largely increased nitrate concentrations.
156 Secondary inorganic aerosol, including sulfate, nitrate, and ammonium, dominated the PM_1 mass with an average contribution
157 above 50%. The higher nitrate fraction (24% in Beijing and 26% in Xinxiang) is similar to previous observations during summer
158 (Sun et al., 2015; Hu et al., 2016), likely due to photochemical processes being more active than in winter. The mass fraction of
159 OA is lower than that measured during winter in the NCP region (Hu et al., 2016; Li et al., 2017b), in accordance with the large
160 reduction of primary emissions in summer. According to the source apportionment results, OA at both sites is largely composed
161 of secondary factors, in which 44-52% is LV-OOA and 22-23% is SV-OOA (Figs. S4-5). Primary organic aerosol accounts for
162 only 34% and 24% of the total OA in Beijing and Xinxiang, respectively. As there is no need for residential home-heating in
163 summer, which results in lower air pollutant emissions from coal combustion, chloride accounts for a smaller fraction of
164 approximately 1% in total PM_1 .

165 The diurnal variations of aerosol species are similar in the measurements from Beijing and Xinxiang (Fig. S9). Organics
166 demonstrated two pronounced peaks at noon and in the evening. Source characterization of OA suggested that the noon peak was
167 primarily driven by cooking emissions, while the evening peak was a combination of various primary sources, i.e., traffic and
168 cooking. Relatively flat diurnal cycles were observed for sulfate, suggesting that the daytime photochemical production of sulfate
169 may be masked by the elevated boundary layer height after sunrise. Nitrate displayed lower concentrations in the afternoon and
170 higher values at night.

171 **3.2 Enhancement of nitrate formation during pollution episode**

172 To effectively mitigate aerosol pollution through policy-making, the driving factors of the PM increase need to be determined.
173 Figure 3 illustrates the mass contributions of various species in PM_1 as a function of PM_1 concentration in Beijing and Xinxiang.
174 OA dominated PM_1 at lower mass loadings ($> 40\%$ when $PM_1 < 20 \mu\text{g m}^{-3}$), but its contribution significantly decreased with
175 increased PM_1 concentration. The source apportionment of OA demonstrated that the large reduction in OA fraction was primarily
176 driven by POA, especially in Beijing. The contribution of SV-OOA and LV-OOA decreased slightly as a result of the
177 photochemical production. The results here are largely different from our winter study in Handan, a seriously polluted city in
178 Northern China, where primary OA emissions from coal combustion and biomass burning facilitated haze formation (Li et al.,
179 2017b). While in Beijing the contribution of sulfate increased slightly at lower PM_1 concentrations, the sulfate fraction generally
180 presented a mild decrease with elevated PM_1 mass at the two sites. By contrast, nitrate displayed an almost linearly enhanced
181 contribution with increased PM_1 . Accordingly, the nitrate/sulfate mass ratio steadily increased as PM_1 went up.

182 Notably, the large enhancement of nitrate production mainly occurred after midnight. Figure 4 displays the scatter plots of nitrate
183 versus PM_1 as well as sulfate versus PM_1 for comparison, both color-coded by the time of day. Though the ratios of sulfate versus
184 PM_1 mostly increased in the afternoon, nitrate versus PM_1 showed steeper slopes from midnight to early morning. The correlation
185 of nitrate with SV-OOA and LV-OOA also indicated that the formation rate of nitrate is considerably higher than that of SV-OOA
186 and LV-OOA after midnight (Fig. S10). Therefore, we further checked the variations in the mass fractions of aerosol species as a
187 function of PM_1 concentration for two periods, 0:00 to 11:00 and 12:00 to 23:00. Taking Beijing as an example, both the nitrate
188 contribution in PM_1 and the nitrate/sulfate ratio were significantly enhanced for the period of 0:00 to 11:00 (Fig. S11). These results
189 suggest that rapid nitrate formation is mainly associated with nighttime productions, when the heterogeneous hydrolysis of N_2O_5
190 dominates the formation pathways (Pathak et al., 2011). The observed high N_2O_5 concentrations in urban Beijing further support

191 our hypothesis (Wang et al., 2017). In addition, a recent study by Sun et al (2018) revealed that more ammonium nitrate content
192 can reduce mutual deliquescence relative humidity (MDRH). With the enhanced formation of nitrate and higher RH during night,
193 the heterogeneous reactions in the liquid surface of aerosols would result in more nitrate formation. Because the materiality of
194 nitrate formation to haze evolution was observed in both Beijing and Xinxian, we regard this as the regional generality in summer.
195 Considering the efficient reduction in SO_2 emissions in China (Zhang et al., 2012), the results here highlight the necessity of further
196 NO_x emission control for effective air pollution reduction in Northern China.

197 **3.3 Factors influencing the rapid nitrate formation**

198 Submicron nitrate mainly exists in the form of semi-volatile ammonium nitrate and is produced by the reaction of NH_3 with HNO_3
199 in the atmosphere. The formation pathways of HNO_3 include the oxidation of NO_2 by OH during the day and the hydrolysis of
200 N_2O_5 at night. Thus, to investigate factors influencing the rapid nitrate formation in summer, the following conditions need to be
201 considered: (1) the abundance of ammonia in the atmosphere, (2) the influence of temperature and RH, and (3) different daytime
202 and nighttime formation mechanisms. Here, we explore nitrate formation processes based on Beijing measurements.

203 Under real atmospheric conditions, NH_3 tends to first react with H_2SO_4 to form $(\text{NH}_4)_2\text{SO}_4$ due to its stability (Seinfeld and Pandis,
204 2006). Thus, if possible, each mole of sulfate will remove 2 moles of NH_3 from the gas phase. NH_4NO_3 is formed when excess
205 NH_3 is available. During the sampling period, the observed molar ratios of ammonium to sulfate were mostly larger than 2 (Fig.
206 5), corresponding to an excess of NH_3 . The scatter plot of the molar concentration of excess ammonium versus the molar
207 concentration of nitrate showed that, nitrate was completely neutralized by excess ammonium at most times. When ammonium is
208 in deficit, nitrate may associate with other alkaline species or be part of an acidic aerosol (Kouimtzis and Samara, 1995).

209 Based on the ISORROPIA-II thermodynamic model, we performed a comprehensive sensitivity analysis of nitrate formation to
210 the gas-phase NH_3 and PM_{10} sulfate concentrations. Under typical Beijing summer conditions ($T = 300.21\text{K}$, $\text{RH} = 56\%$), we
211 assumed that total inorganic nitrate ($\text{HNO}_3 + \text{NO}_3^-$) in the atmosphere was $10 \mu\text{g m}^{-3}$. Total ammonia (gas + particle) and PM_{10}
212 sulfate concentrations were independently varied and input in the ISORROPIA-II model. The predicted equilibrium of the nitrate
213 partitioning ratio ($\epsilon(\text{NO}_3^-) = \text{NO}_3^- / (\text{HNO}_3 + \text{NO}_3^-)$) is shown in Fig. 6. At a sulfate concentration from 0.1 to $45 \mu\text{g m}^{-3}$, a $10 \mu\text{g m}^{-3}$
214 increase of gaseous NH_3 generally results in an enhancement of $\epsilon(\text{NO}_3^-)$ by around 0.1 units or even higher, thus increasing the
215 particulate nitrate concentration. The variations of gaseous NH_3 and $\epsilon(\text{NO}_3^-)$ are not linearly related. Interestingly, for ammonia-
216 rich systems, the existence of more particulate sulfate favors the partitioning of nitrate towards the particle phase. The formation
217 of particulate ammonium nitrate is a reversible process with dissociation constant K_p :

219 K_p equals the product of the partial pressures of gaseous NH_3 and HNO_3 . For an ammonium sulfate-nitrate solution, K_p not only
220 depends on temperature and RH but also on sulfate concentrations, which is usually expressed by the parameter Y (Seinfeld and
221 Pandis, 2006):

222
$$Y = \frac{[\text{NH}_4\text{NO}_3]}{[\text{NH}_4\text{NO}_3] + 3[(\text{NH}_4)_2\text{SO}_4]} \quad (2)$$

223 When the concentration of ammonium sulfate increases compared to that of ammonium nitrate, the parameter Y decreases and the
224 equilibrium product of NH_3 and HNO_3 decreases. The additional ammonium and sulfate ions make the system favorable for the
225 heterogeneous formation of ammonium nitrate, by increasing particle liquid water content but not perturbing particle pH
226 significantly. Particle pH is not highly sensitive to sulfate and associated ammonium (Weber et al., 2016; Guo et al., 2017b).
227 Therefore, more ammonium sulfate in the aqueous solution will tend to increase the concentration of ammonium nitrate in the
228 particle phase. As shown in Fig. 6, at a certain concentration of gaseous NH_3 , the increase of sulfate concentration results in a

229 higher $\epsilon(\text{NO}_3^-)$ and more particulate nitrate. Generally, these results suggest that the decreases in SO_2 emissions and NH_3 emissions
230 are effective on nitrate reduction, indicating the importance of multi-pollutant control strategy in Northern China.
231 The influence of temperature and RH on nitrate formation was also evaluated based on ISORROPIA-II simulations by varying
232 temperature and RH separately. As shown in Fig. S12, under typical Beijing summer conditions ($T = 30^\circ\text{C}$), $\epsilon(\text{NO}_3^-)$ remains
233 lower than 0.1, even until RH reaches 80%. When $\text{RH} > 90\%$, $\epsilon(\text{NO}_3^-)$ increases sharply as a function of RH. For $T = 0^\circ\text{C}$,
234 representative of Beijing winter conditions, $\epsilon(\text{NO}_3^-)$ is as high as 0.7, even at low RH. Figure 7 demonstrates the variations in the
235 nitrate/sulfate ratio as a function of temperature and RH in Beijing. The nitrate/sulfate ratio increased with decreasing temperature
236 and increasing RH, which drives the nitrate partitioning towards the particle phase. This is further supported by the variations in
237 the equilibrium constant K_{AN} of Eq. (1), which can be calculated as:

238
$$K_{\text{AN}} = K_{\text{AN}}(298 \text{ K}) \exp \left\{ a \left(\frac{298}{T} - 1 \right) + b \left[1 + \ln \left(\frac{298}{T} \right) - \frac{298}{T} \right] \right\} \quad (3)$$

239 where T is the ambient temperature in Kelvin, $K_{\text{AN}}(298) = 3.36 \times 10^{16} (\text{atm}^{-2})$, $a = 75.11$, and $b = -13.5$ (Seinfeld and Pandis, 2006).
240 Similar to the nitrate/sulfate ratio, the diurnal profile of K_{AN} peaks at night due to the lower temperature and higher RH.
241 As described in Sect. 3.2, the rapid nitrate formation in this study appeared to be mainly associated with its nighttime enhancement.
242 In addition to the effects of temperature and RH, the nighttime nitrate formation pathways may also play a role. Overnight,
243 particulate nitrate primarily forms via the heterogeneous hydrolysis of N_2O_5 on the wet surface of aerosol (Ravishankara, 1997).
244 N_2O_5 is produced by the reversible reaction between NO_2 and the NO_3 radical, where NO_2 reacts with O_3 to form the NO_3 radical.
245 Assuming N_2O_5 and the NO_3 radical are both in steady state considering their short lifetimes (Brown et al., 2006), the nighttime
246 production of N_2O_5 and HNO_3 is proportional to the concentration of NO_2 and O_3 ($[\text{NO}_2][\text{O}_3]$) (Young et al., 2016; Kim et al.,
247 2017). For the different PM_1 concentration bins, we examined the NO_2 and O_3 data at 0:00 to assess the nighttime HNO_3 production
248 rate. It can be seen that $[\text{NO}_2][\text{O}_3]$ was obviously enhanced with an increase in the PM_1 mass loading (Fig. S13), implying that
249 nitrate formation by the N_2O_5 pathway favors the driving role of nitrate in haze evolution.

250 According to the Multi-resolution Emission Inventory for China (MEIC, <http://www.meicmodel.org>), NO_x emissions localized in
251 Beijing are much smaller than emissions in adjacent Hebei, Shandong, and Henan provinces. In Fig. 1, episodes in Beijing,
252 characterized by largely enhanced nitrate concentrations, usually occurred with the change in the wind direction from north and
253 west to south and east, where the highly polluted Hebei, Shandong, and Henan provinces are located. When the relatively clean air
254 masses from north and west returned, aerosol pollution was instantly swept away. Therefore, the importance of regional transport
255 on haze formation in Beijing should also be considered. We examined the association of aerosol concentration and composition
256 with air mass origins determined through cluster analysis of HYSPLIT back trajectories. As illustrated in Fig. 8, the aerosol
257 characteristics are quite different for air masses from different regions. Cluster 1 mainly passed through Shanxi and Hebei provinces,
258 and Cluster 2 originated from Hebei, Shandong, and Henan provinces. Consistent with the high air pollutant emissions in these
259 areas, Cluster 1 and Cluster 2 were characterized with high PM_1 concentrations and high contributions of secondary aerosols. The
260 nitrate fraction in PM_1 was 24% for Cluster 1 and 26% for Cluster 2. In comparison, Cluster 3 and Cluster 4 resulted from long-
261 range transport from the cleaner northern areas and were correspondingly characterized by lower PM_1 concentrations. Organics
262 dominated PM_1 for Cluster 3 and Cluster 4, with a nitrate contribution of 14% and 16%, respectively. Figure S14 shows the cluster
263 distribution as a function of PM_1 concentration. With an increase in the PM_1 mass, the contribution of cleaner Cluster 3 and Cluster
264 4 significantly decreased. When PM_1 concentrations were above $20 \mu\text{g m}^{-3}$, the air masses arriving in Beijing were mostly
265 contributed by Cluster 1 and Cluster 2, which led to rapid nitrate accumulation.

266 **3.4 Comparison with other regions and policy implications**

267 Figure 9 summarizes the chemical composition of PM_{1} or NR- PM_{1} (BC excluded) measured during summer in Asia, Europe, and
268 North America. Three types of sampling locations were included: urban areas, urban downwind areas, and rural/remote areas.
269 Aerosol particles were dominated by organics (25.5-80.4%; avg = 48.1%) and secondary inorganic aerosols (18.0-73.7%; avg =
270 47.3%), and the nitrate contribution largely varied among different locations. Data for the pie charts are given in Table S3.

271 For further comparison, we classified the datasets into three groups according to the location type and examined their difference
272 in nitrate mass concentrations and mass contributions. Overall, the nitrate concentrations varied from $0.04 \mu\text{g m}^{-3}$ to $17.6 \mu\text{g m}^{-3}$ in
273 summer, with contributions of 0.9% to 25.2%. Patterns in Fig. 10 demonstrate that the nitrate concentrations in mainland China
274 are usually much higher than those in other areas, consistent with the severe haze pollution in China. In particular, the percentage
275 of nitrate in aerosol particles is generally several times higher in mainland China than in other regions, except for measurements
276 in Riverside, CA, which were conducted near the local highway (Docherty et al., 2011). Compared to rural/remote areas, nitrate
277 shows higher mass concentrations and mass fractions in urban and urban downwind areas, revealing the influence of anthropogenic
278 emissions, i.e., traffic and power plant, on nitrate formation. In Beijing, the capital of China, field measurements among different
279 years show an obvious reduction in the nitrate mass concentration, especially after 2011. The large decrease in nitrate concentration
280 in the summer of 2008 was primarily caused by the strict emission control measures implemented during the 2008 Olympic Games
281 (Wang et al., 2010). However, nitrate contributions in China still remain high over the years, especially in urban and urban
282 downwind areas, revealing the importance of nitrate formation in haze episodes.

283 Due to the installation of flue-gas desulphurization (FGD) systems, the construction of larger units and the decommissioning of
284 small units in power plants, SO_2 emissions in China decreased by 45% from 2005 to 2015 (Li et al., 2017d). However, NO_x
285 emissions in China increased during the last decade. During the 11th Five-Year Plan (FYP), NO_x emissions showed a sustained and
286 rapid growth with the economic development and the lack of relevant emissions controls. Since 2011, the government carried out
287 end-of-pipe abatement strategies by installing selective catalytic reduction (SCR) in power plants and releasing strict emission
288 regulations for vehicles. Based on the bottom-up emission inventory, NO_x emissions showed a decline of 21% from 2011 to 2015
289 (Liu et al., 2017). The changes are consistent with satellite-observed NO_2 levels in China (Miyazaki et al., 2017). Given the high
290 concentration and, in particular, the high contribution of nitrate in aerosols, further NO_x reduction and initiation of NH_3 emission
291 controls are in urgent need in China.

292 **4 Conclusions**

293 Summertime field measurements were conducted in both Beijing (30 June to 27 July, 2015) and Xinxiang (8 to 25 June, 2017) in
294 the NCP region, using state-of-the-art online instruments to investigate the factors driving aerosol pollution. The average PM_{1}
295 concentration reached $35.0 \mu\text{g m}^{-3}$ in Beijing and $64.2 \mu\text{g m}^{-3}$ in Xinxiang, with significantly enhanced nitrate concentrations during
296 pollution episodes. Secondary inorganic aerosol dominated PM_{1} , with high nitrate contributions of 24% in Beijing and 26% in
297 Xinxiang. With the development of aerosol pollution, OA showed a decreasing contribution to total PM_{1} , despite its obvious
298 domination at lower PM_{1} mass loadings. The reduction in the OA mass fraction was primarily driven by primary sources (i.e.,
299 traffic and cooking emissions), especially in Beijing. Generally, the mass fraction of sulfate decreased slightly as a function of PM_{1}
300 concentration. In contrast, nitrate contribution enhanced rapidly and continuously with the elevation of PM_{1} mass, suggesting the
301 important role of nitrate formation in causing high aerosol pollution during summer. Rapid nitrate production mainly occurred
302 after midnight, and the formation rate was higher for nitrate than for sulfate, SV-OOA, or LV-OOA.

303 Comprehensive analysis of nitrate behaviors revealed that abundant ammonia emissions in the NCP region favored the large nitrate
304 formation in summer. According to the ISORROPIA-II thermodynamic predictions, $\varepsilon(\text{NO}_3^-)$ is significantly increased when there
305 is more gas-phase ammonia in the atmosphere. Decreased SO_2 emissions have co-beneficial impacts on nitrate reduction. Lower
306 temperature and higher RH drive the equilibrium partitioning of nitrate towards the particle phase, thus increasing the particulate
307 nitrate concentration. As an indicator to evaluate the contribution of nighttime N_2O_5 hydrolysis to nitrate formation, $[\text{NO}_2]/[\text{O}_3]$
308 obviously enhanced at night with the anabatic pollution levels, suggesting the increased role of nighttime nitrate production in haze
309 evolution. Based on cluster analysis via the HYSPLIT model, regional transport from surrounding polluted areas was found to play
310 a role in increasing nitrate production during haze periods.

311 Finally, nitrate data acquired from this study were integrated with the literature results, including various field measurements
312 conducted in Asia, Europe, and North America. Nitrate is present in higher mass concentrations and mass fractions in China than
313 in other regions. Due to large anthropogenic emissions in urban and urban downwind areas, the mass concentrations and mass
314 contributions of nitrate are much higher in these regions than in remote/rural areas. Although the nitrate mass concentrations in
315 Beijing have steadily decreased over the years, its contribution still remains high, emphasizing the significance of further reducing
316 NO_x emissions and NH_3 emissions in China.

317 Most of the previous studies conducted during wintertime reveal that secondary formation of sulfate together with primary
318 emissions from coal combustion and biomass burning are important driving factors of haze evolution in the NCP region. According
319 to this study, in Beijing and Xinxiang, rapid nitrate formation is regarded as the propulsion of aerosol pollution during summertime.
320 Therefore, to better balance economic development and air pollution control, different emission control measures could be
321 established corresponding to the specific driving forces of air pollution in different seasons. Further studies on seasonal variations
322 are needed to test the conclusions presented here and provide more information on haze evolution in spring and fall.

477

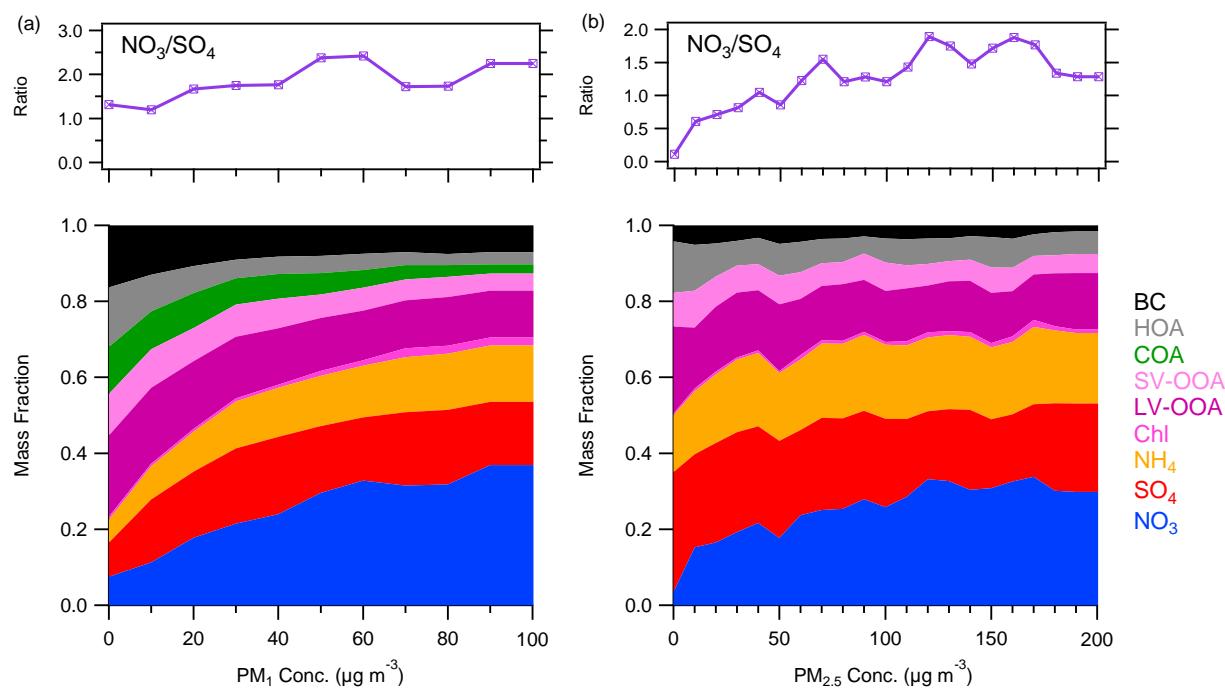

478 **Figure 1.** Time series of meteorological parameters, gaseous species, and submicron aerosol species in Beijing.

479

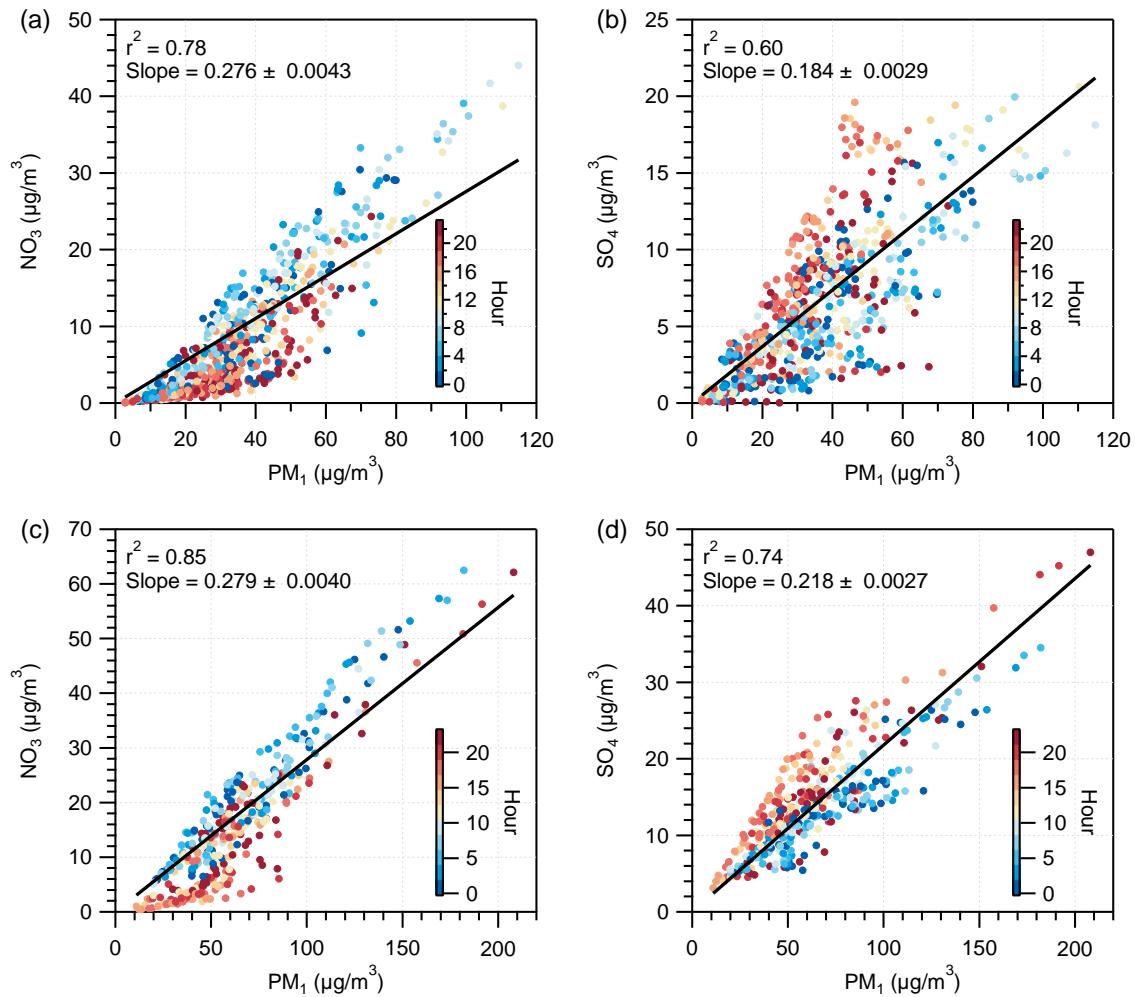

480

481 **Figure 2.** Time series of meteorological parameters, gaseous species, and submicron aerosol species in Xinxiang.

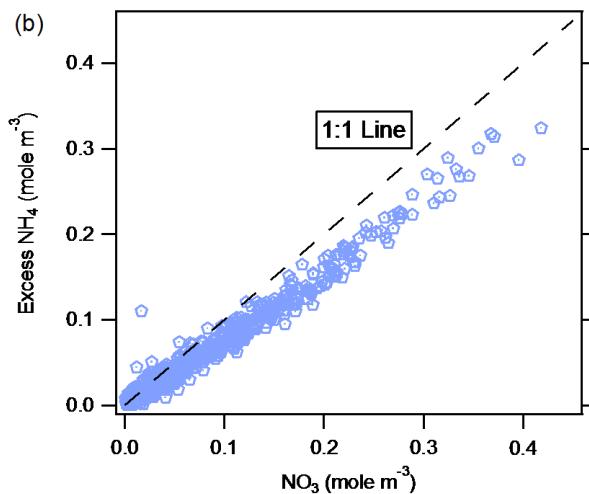

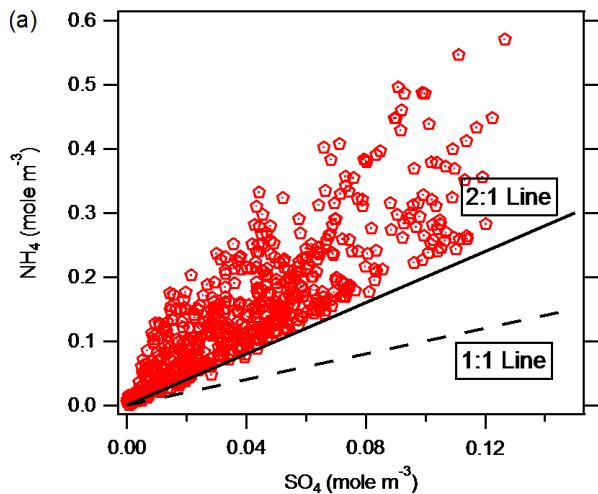

484 **Figure 3. Variations in the mass fraction of aerosol species and nitrate/sulfate mass ratio as a function of total PM₁ mass loadings in (a)**
 485 **Beijing and (b) Xinxiang.**

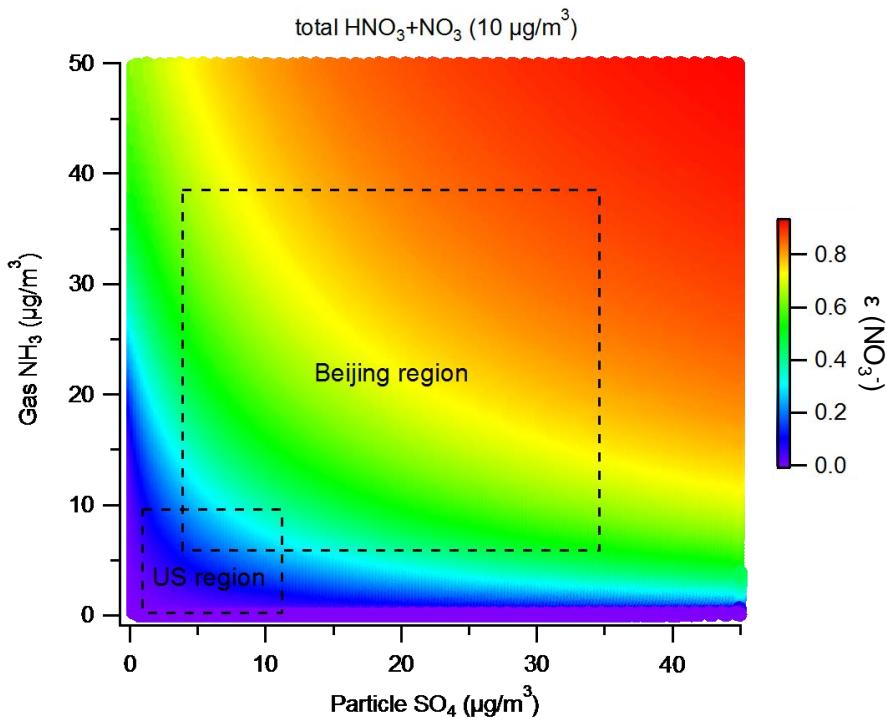

488 **Figure 4. Scatterplots of nitrate vs. PM₁ concentration and sulfate vs. PM₁ concentration, colored by the hour of the day, in (a-b) Beijing**

489 and (c-d) Xinxiang.

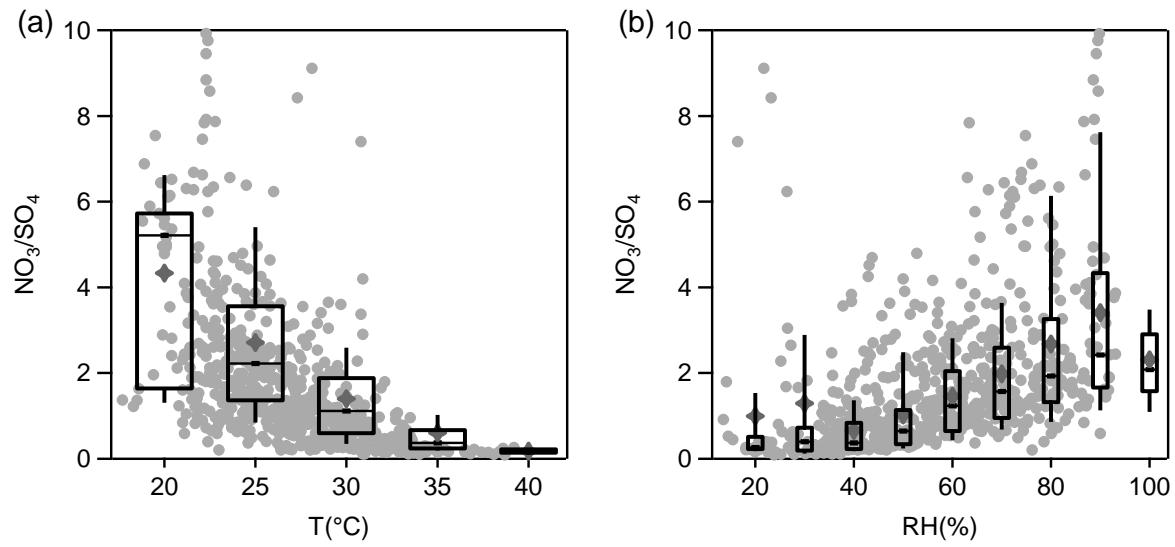

494 **Figure 5. Comparison of the molar concentrations of (a) ammonium and sulfate (the 2:1 reference line represents complete H_2SO_4 neutralization) and (b) excess ammonium and nitrate (the 1:1 reference line represents complete HNO_3 neutralization).**

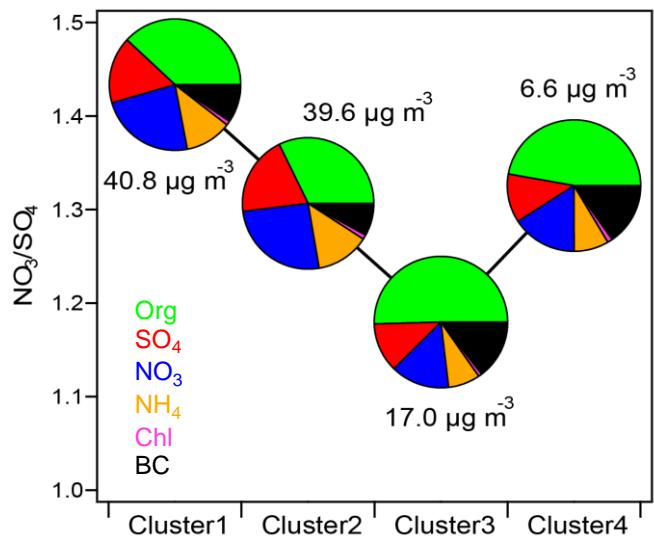

495

496 **Figure 6.** Sensitivity of the nitrate partitioning ratio ($\varepsilon(\text{NO}_3^-) = \text{NO}_3^-/(\text{HNO}_3 + \text{NO}_3^-)$) to gas-phase ammonia and PM_1 sulfate
 497 concentrations based on thermodynamic predictions under typical Beijing and Xinxiang summertime conditions. The total nitrate
 498 concentration is assumed to be $10 \mu\text{g m}^{-3}$, according to the observed PM_1 nitrate concentration.

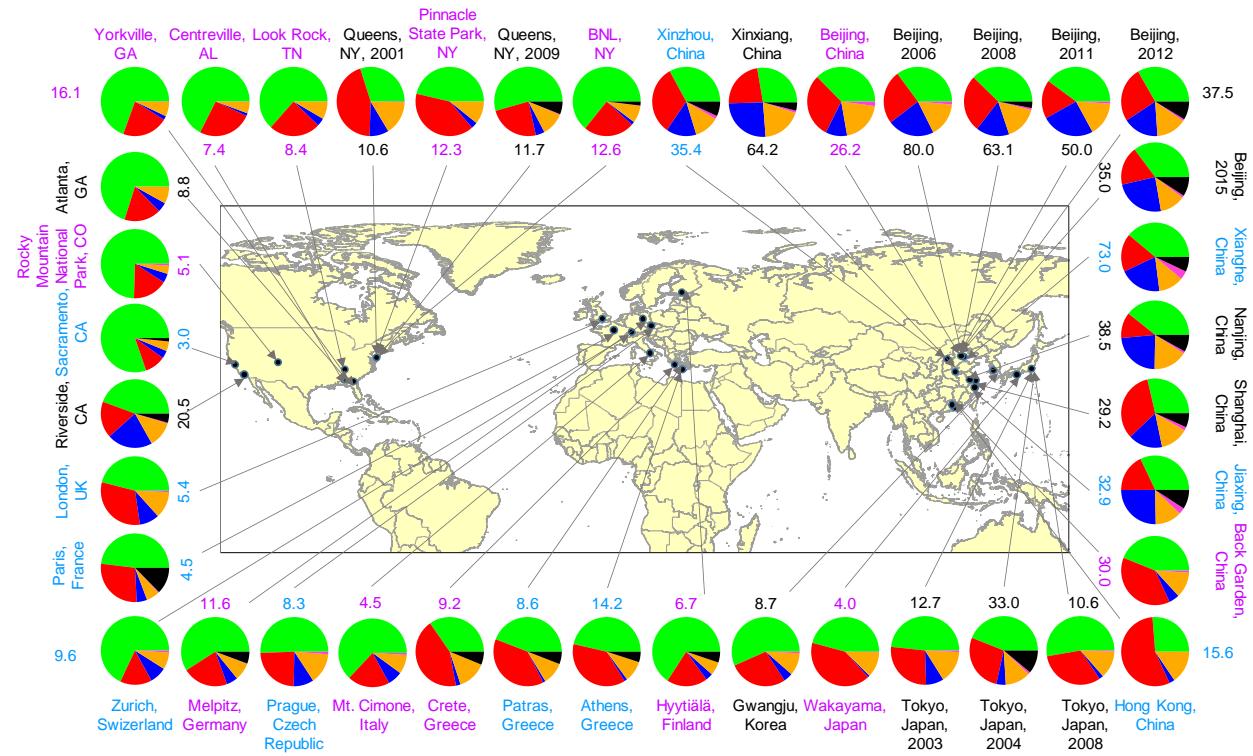

499

501 **Figure 7. Variations in the nitrate/sulfate mass ratio as a function of (a) temperature (T) and (b) relative humidity (RH). The data were**
 502 **binned according to T and RH, and the mean (cross), median (horizontal line), 25th and 75th percentiles (lower and upper box), and 10th**
 503 **and 90th percentiles (lower and upper whiskers) are shown for each bin.**

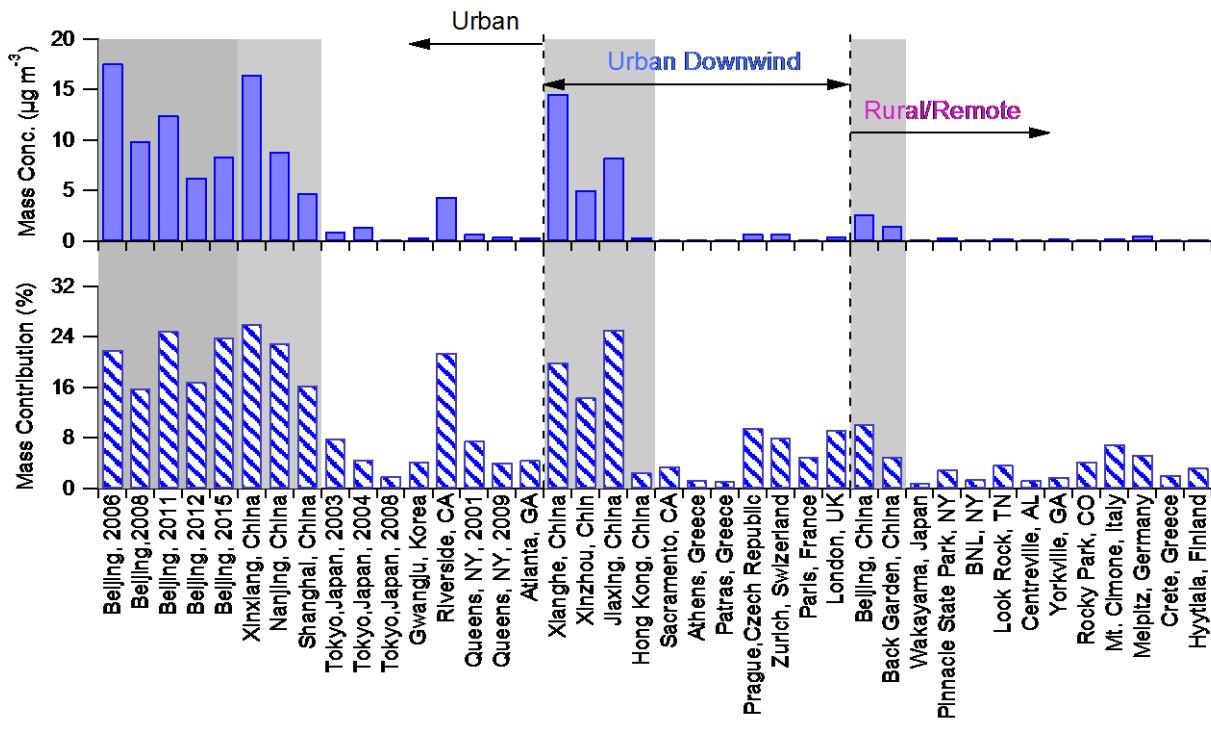

506 **Figure 8. Nitrate/sulfate mass ratios for each cluster. The pie charts represent the average PM₁ chemical composition of the different**
 507 **clusters. In addition, the total PM₁ concentrations for each cluster are also shown.**

508

509 **Figure 9. Summary of the submicron particle measurements using ACSM or Aerosol Mass Spectrometer in Asia, Europe, and North**
 510 **America (data given in Table S1 in the supplementary materials). Colors for the study labels indicate the type of sampling location:**
 511 **urban areas (black), urban downwind areas (blue), and rural/remote areas (pink). The pie charts show the average mass concentration**
 512 **and chemical composition of PM₁ or NR-PM₁: organics (green), sulfate (red), nitrate (blue), ammonium (orange), chloride (purple), and**
 513 **BC (black).**

514

515 **Figure 10.** Average mass concentrations and mass fractions of nitrate at various sampling sites for three types of locations: urban, urban
 516 downwind, and rural/remote areas. Within each category, the sites are ordered from left to right as Asia, North America, and Europe.
 517 The shaded area indicates the results from China.
