1     **Abstract:**

2     Particulate matter (PM) pollution on the peripheries of rapidly expanding megacities in China can  
3     be as serious as in the cities due to direct emission and transport of primary PM from cities and  
4     effective formation of secondary PM. To investigate the emission and formation of PM on the  
5     periphery of Guangzhou (a megacity in southern China), a suite of real-time instruments were  
6     deployed at Panyu, downwind of Guangzhou, for PM measurements from November to December  
7     2014. Dominated by organics, PM<sub>1</sub> (particles with diameter less than 1 μm) concentrations in  
8     Panyu were higher (average ~55.4 μg/m<sup>3</sup>) than those in nearby cities such as Hong Kong and  
9     Shenzhen. Five sources for organic aerosols (OA) were resolved by positive matrix factorization  
10    (PMF) analysis with the multilinear engine (ME-2). These sources are hydrocarbon-like organic  
11    aerosol (HOA), cooking organic aerosol (COA), biomass burning related organic aerosol (BBOA),  
12    as well as semi-volatile oxygenated organic aerosol (SVOOA) and low-volatile oxygenated  
13    organic aerosol (LVOOA). The use of the COA mass spectrum obtained in our earlier study at a  
14    urban site in Hong Kong as a constraining factor in ME-2 produced the most interpretable results  
15    for the Panyu dataset. Freshly emitted HOA contributed 40% to the high concentrations of organics  
16    at night. The mass concentration of SOA (SVOOA+LVOOA) continuously increased as odd  
17    oxygen (O<sub>x</sub> = O<sub>3</sub> + NO<sub>2</sub>) increased during daytime, attributable to the secondary production of PM  
18    facilitated by photochemistry. The SOA-to-O<sub>x</sub> ratio was higher than those reported in previous  
19    studies in North America (covering the period from spring to summer), indicating efficient  
20    photochemical production of SOA even in late autumn and early winter at this subtropical  
21    downwind site. The efficient SOA formation during daytime was likely fueled by the sufficient  
22    SOA precursors in the atmosphere. The large input of NO<sub>x</sub>, which tracked well with HOA from  
23    automobile emissions, resulted in the significant formation of nitrate in both daytime and nighttime.  
24    Strong correlations between particulate nitrate and excess ammonium ( $[\text{NH}_4^+]/[\text{SO}_4^{2-}] - 1.5) \times$   
25     $[\text{SO}_4^{2-}]$ ) were observed. Higher partitioning of nitrate into the gas phase was found in November  
26    than in December, likely due to the lower temperatures in December. Results from this study  
27    suggest that there is much room to mitigate the PM pollution in urbanized areas such as Guangzhou,  
28    as well as their peripheries, by reductions in traffic-related pollutants.

29  
30

31 **1. Introduction:**

32 The Pearl River Delta (PRD) economic zone is one of the most urbanized and industrialized  
33 regions in China, producing about 19% of China's gross domestic product each year (Zhong et al.,  
34 2013). The fast economic development in the PRD has led to rapid deterioration in air quality  
35 (Chan and Yao, 2008; Ho et al., 2003). The PRD is situated in a subtropical region where  
36 photochemistry may differ from those in other urbanized city clusters in China. For instance, the  
37 relatively high photochemical activity, high temperature, and high relative humidity (RH) in this  
38 subtropical region facilitate effective secondary formation of particulate matter (PM) in PRD (Lee  
39 et al., 2013; Li et al., 2013; Qin et al., 2016a). With densely populated cities including two  
40 megacities Guangzhou and Shenzhen and other smaller but also highly urbanized ones, the PRD  
41 region is emerging into a giant city cluster. There are, nevertheless, some less populated areas  
42 between those cities and presumably can serve as a "buffer" zone in regional air quality. Given the  
43 complex and non-linear processes in secondary production of PM, the impacts of the adjacent  
44 cities to the air quality of these "buffer" areas can be crucial but they have not been thoroughly  
45 investigated.

46 Over the last decade, many studies in PRD have revealed that organic aerosols (OA) and sulfate  
47 are the most abundant components of fine particles (e.g., Hagler et al., 2006; Huang et al., 2006;  
48 Louie et al., 2005). The main precursor of sulfate, SO<sub>2</sub>, began to decrease since 2006, because of  
49 the widespread application of flue-gas desulfurization devices in power plants in response to a new  
50 policy implemented by the Chinese government (Lu et al., 2010; Zhang et al., 2012b). Over the  
51 same period, however, emissions from vehicles, e.g. NO<sub>x</sub>, volatile organic compounds (VOCs),  
52 black carbon (BC) and traffic-related organics, however, have increased (Wang et al., 2013; Zhang  
53 et al., 2012a). A recent study showed that 4.16 million tons (Mt) of hydrocarbon, 7.72 Mt of NO<sub>x</sub>,  
54 and 0.37 Mt of PM<sub>2.5</sub> (particles with diameter less than 2.5 micron) were produced by vehicular  
55 emissions in China in 2013 (Wu et al., 2016). Although the high-polluting vehicles (such as heavy-  
56 duty diesel trucks) are not allowed to enter the inner areas of many megacities during the day in  
57 China, they are nevertheless active at night until early morning, especially on the peripheries of  
58 these cities. This regulatory policy results in nighttime peaks in vehicular pollutants commonly  
59 observed in many cities in China (Zhang and Cao, 2015). The oxidation of traffic-related gaseous  
60 pollutants (e.g., NO<sub>x</sub> and VOCs) leads to generally less volatile products, which have the tendency  
61 to either nucleate or condense onto pre-existing particles (Hallquist et al., 2009), result in the

62 formation of secondary PM. Particles from vehicle exhaust, such as hydrocarbon-like organic  
63 aerosol (HOA), can also undergo chemical transformation in the atmosphere (Zhang et al., 2015)  
64 and lead to photochemical smog on the following day.

65 To better understand the impact of traffic emissions in Guangzhou to its peripheral areas, we  
66 deployed an Aerodyne HR-ToF-AMS at a site downwind Guangzhou in late autumn to early  
67 winter 2014, during a period of prevailing northerly winds, to measure non-refractory PM<sub>1</sub> (NR-  
68 PM<sub>1</sub>). Factor analysis of OA for source apportionment was performed with a new positive matrix  
69 factorization (PMF) procedure using the multilinear engine (ME-2) with the source finder (SoFi)  
70 (Canonaco et al., 2013). The procedure allows an effective exploration of the solution space, a  
71 more objective selection of the best solution, and an estimation of the rotational uncertainties  
72 (Canonaco et al., 2013; Crippa et al., 2014; Elser et al., 2016; Fröhlich et al., 2015; Paatero and  
73 Hopke, 2009). The source and formation of nitrate and SOA at this downwind site of Guangzhou  
74 will be discussed in detail.

## 75 2. Method

### 76 2.1. Sampling site description

77 The sampling site is located at Panyu District, a downwind site from downtown Guangzhou. This  
78 suburban site is about 15 km south of the city center (Tan et al., 2013; Zou et al., 2015; Cheung et  
79 al., 2016). It is located at the summit of Dazhengang (23°00 N, 113°21 E) at an altitude of about  
80 150 m (Fig. S1 in the Supplement) and surrounded by residential neighborhoods with no  
81 significant industrial sources nearby. Ambient sampling was conducted from November 07<sup>th</sup>, 2014  
82 to January 3<sup>rd</sup>, 2015.

### 83 2.2. Measurements

84 In the HR-ToF-AMS measurements (DeCarlo et al., 2006), ambient air was sampled through a  
85 PM<sub>2.5</sub> cyclone on the rooftop, with a flow rate of approximately 0.084 L/min drawn by the AMS  
86 and the remainder drawn by an auxiliary pump. A diffusion drier was used to dry the sampled air  
87 stream, which reduced the RH of air to below 30 % before going into the HR-ToF-AMS. Other  
88 data presented in this work were obtained from collocated instruments, which included a Grimm  
89 180 for PM<sub>2.5</sub>, a thermo-optical ECOC analyzer (Sunset Laboratory Inc.), a Magee AE33, a dual  
90 spot filter based instrument for black carbon (Drinovec et al., 2015), a gas analyzer system  
91 (Teledyne Instruments), and a monitor for aerosols and gases in ambient air (MARGA). The PM<sub>2.5</sub>

92 mass concentration by Grimm 180 was corrected by the daily  $PM_{2.5}$  mass concentration with quartz  
93 filter measurement. Meteorological data (e.g. wind, temperature and RH) were obtained from a  
94 weather station located near the sampling site. Solar irradiance data were measured from a station  
95 in Nansha District, around 27.5 km from the sampling site. Particle liquid water content (LWC)  
96 was estimated by Aerosol Inorganic Model (E-AIM II) (Clegg et al., 1998). The AMS collected  
97 5-minute average particle mass spectra spanning from  $m/z$  12 to 300 for the V + particle time-of-  
98 flight (pToF) mode (high sensitivity) and the W mode (high resolution). And the dataset were only  
99 analyzed with  $m/z$  below 200 for the high resolution analysis. AMS calibrations, including  
100 ionization efficiency (IE) calibration, flow rate calibration, and size calibration, as well as data  
101 quality assurance protocols were used (DeCarlo et al., 2006; Lee et al., 2013; Schurman et al.,  
102 2015). IE calibrations with DMA size-selected (mobility diameter,  $D_m = 400$  nm) pure ammonium  
103 nitrate particles were carried out weekly. Filtered ambient air with a HEPA filter was sampled on  
104 a daily basis for 30 minutes to obtain background signals. Flow rate calibrations with a Gilian  
105 Gilibrator and PToF size calibrations were made with Nanosphere TM PSL particles (Duke  
106 Scientific, Palo Alto, CA, USA) and ammonium nitrate particles with selected size by scanning  
107 mobility particle sizer (SMPS) in the range of 178 to 800 nm were performed both before and after  
108 the sampling campaign. Gaseous  $CO_2$  contributions to  $m/z$  44 were quantified using a  
109  $CO_2$  monitor (PICARRO 2301).

### 110 **2.3. Data analysis**

111 AMS data analysis was performed using the SQUIRREL (v1.56D) and PIKA (v1.15D) toolkits  
112 written in Igor Pro 6.37A (WaveMetrics Inc., Lake Oswego, OR)  
113 (<http://cires1.colorado.edu/jimenez-group/ToFAMSResources/ToFSoftware/index.html>). Default  
114 relative ionization efficiency (RIE) values of 1.2 for sulfate, 1.1 for nitrate, 1.3 for chloride, and  
115 1.4 for organics were used. The ammonium RIE of 4.7 was chosen as the average from IE  
116 calibrations. To account for particle losses within the instrument, a particle collection efficiency  
117 factor (CE) was used. The influence of RH in this study is considered minor, as a diffusion drier  
118 kept the sampling line RH consistently below 30%. Under these conditions, the Middlebrook  
119 parameterization would suggest a CE of ~45–50% based on the measured inorganic constituents.  
120 However, organic compounds, less bouncy than inorganics, dominated at the measurement site.  
121 They may also hinder the complete efflorescence of particles in the drier and further reduce the  
122 particle bounce effect and increase the particle collection efficiency. The mass concentrations of

123 PM<sub>1</sub> (sum of NR-PM<sub>1</sub> and BC) were comparable to those of PM<sub>2.5</sub> with a slope of 1.1 and Pearson  
124 correlation coefficient (R<sub>p</sub>) of 0.95 (Fig. S2a) when using a CE of 0.7. Furthermore, total AMS  
125 organics were also correlated with organic matter (OM) concentrations derived from the OC  
126 measurements (Fig. S2b) with a slope of 1.1 and R<sub>p</sub> of 0.82. The OC to OM conversion was  
127 calculated by organic matter to organic carbon ratio (OM:OC) data from the HR-ToF-AMS  
128 elemental analysis. AMS-measured sulfate, nitrate, and ammonium were comparable to those  
129 measured by MARGA with slopes of 1.0, 0.9, and 0.7, respectively. These comparisons supported  
130 a choice of CE = 0.7 is appropriate for the OA-dominating NR-PM<sub>1</sub> in this study.

131 Source apportionment for OA was performed by the newly developed ME-2 and controlled via  
132 the interface SoFi coded in Igor Pro (Canonaco et al., 2013). Fully unconstrained runs (PMF) were  
133 first explored. However, the three-factor solution suffers from mixing of factors of the HOA factor  
134 with the cooking organic aerosol (COA) factor (Fig. S3), as well as SVOOA with biomass burning  
135 related organic aerosol (BBOA) factor. The four-factor solution splits highly oxidized low-volatile  
136 OOA (LVOOA) into two sub-factors (Fig. S4). The inclusion of additional factors still cannot  
137 resolve pure primary OA factors (HOA, COA and BBOA), as they may have similar time series  
138 or profiles. Zhang et al. (2013) also reported that the PCA-resolved HOA might be affected by  
139 cooking emission with a distinct noontime peak in Beijing in spring and summer. The ME-2,  
140 however, by introducing *a priori* information of source profiles for HOA, COA and BBOA,  
141 provides additional control over the rotational ambiguity (Canonaco et al., 2013; Paatero and  
142 Hopke, 2009). The *a* value, ranging from zero to unity, stands for the percentage by which each  
143 m/z signal of the final solution spectra may differ from the anchor. A value of 0 means no deviation  
144 is allowed, while a value of 1 means 100% deviation is allowed. Several source profiles from  
145 previously reported HR-ToF-AMS data with different *a* values were explored. However, some  
146 ions were missing from the reference source profile when compared with our dataset. For these  
147 ions, the signal intensities were estimated based on the unit-mass-resolution (UMR) source profile  
148 from the average of multiple ambient data sets (Ng et al., 2011) as follows:

149 
$$I_{m/z} = k * I_{UMR(m/z)} - I_{HRrest(m/z)} \quad (1);$$

150 
$$k = I_{UMR(total)} / I_{HR(total)} \quad (2).$$

151 where  $I_{m/z}$  is the signal intensity of the missing ions in the reference profile;  $k$  is a correction factor,

152 derived from the ratio of total signal intensities in the UMR and HR profiles, which accounts for  
153 the difference in total signal intensity between the profiles;  $I_{\text{UMR}(m/z)}$  is the total signal intensity at  
154 UMR level for the missing ions in the UMR profile; and  $I_{\text{HRrest}(m/z)}$  is the sum of the signal  
155 intensities of the rest of the ions from HR reference profile that shares the same integer  $m/z$  as the  
156 missing ions. For these ions, whose intensities are derived from the above equation, an  $a$  value of  
157 1 (100% deviation) was used.

158 To tackle the problem of mixing of traffic and cooking source in our PMF runs, we used the ME-  
159 2 solver with reference HOA and COA mass spectra adopted from the Paris campaign (Crippa et  
160 al., 2013). The  $a$  values, ranging from 0 to 0.5 in increments of 0.1, were tested. However, the  
161 resolved-HOA factor contributed no more than 5% of total OA, and only exhibited a small morning  
162 rush peak in the diurnal pattern (Fig. S5). Furthermore, another factor was observed to share similar  
163 features with the HOA mass spectrum (Fig. S5). This factor exhibited clear rush-hour peaks during  
164 the morning and late afternoon, as with traffic-related pollutants (e.g.  $\text{NO}_x$  and BC). Also, the mass  
165 fraction of this factor is 3-4 times higher than the resolved-HOA factor (Fig. S5). The factor was  
166 observed, even with additional input for BBOA source profile and solutions with additional factors  
167 (Fig. S5) and continued to persist even after several HOA source profiles were tested. Alternatively,  
168 we directly extracted a local HOA source profile ( $\text{HOA}_{\text{loc}}$ ) from the data set using a separate PMF  
169 run in selected time series with peaks in organic mass concentration. Similar approach has also  
170 been reported in by Fröhlich et al. (2015). We performed PMF on a short-term peak in the organic  
171 time series (Fig. S6) as well as on all of the short peaks with organic concentration above  $30 \mu\text{g}/\text{m}^3$   
172 (Fig. S6). These two methods resolved similar mass spectra for local primary OA factors with  
173  $R_{\text{uc}}=0.99$  (Fig. S7a, S7b). The results remain the same with even more factors (Fig. S7c). We then  
174 used the HOA source profile obtained from all of the short peaks with organic concentration above  
175  $30 \mu\text{g}/\text{m}^3$  ( $\text{HOA}_{\text{local}_2}$ ) as the input HOA source profile. However, constrained HOA alone cannot  
176 resolved an environmentally reasonable solution either (Fig. S8). We then tried to added a COA  
177 constrain. For COA source profile, we compared the COA reference from the Paris campaign  
178 (Crippa et al., 2013) and the Mong Kok campaign in Hong Kong (Lee et al., 2015). When the two  
179 different COA source profiles were used in the ME-2 runs, similar COA (both in mass spectra and  
180 time series) were obtained for the current dataset (Fig. S9). The time series of the mass  
181 concentration of the COA factors tracked well with that of the COA tracer ion ( $\text{C}_3\text{H}_3\text{O}^+$ ) and had  
182 clear mealtime peaks (Fig. S9). The ME-2 runs using these two COA source profiles differed

183 slightly in terms of the proportion of COA and LVOOA, with results using the COA profile from  
184 the Paris campaign yielding a lower concentration of COA and a higher concentration of LVOOA.  
185 The discrepancy was within  $2 \mu\text{g}/\text{m}^3$  (Fig. S9). As cooking styles and ingredients in Guangzhou  
186 are more similar to those in Hong Kong than in Paris, we chose the COA source profile from the  
187 Hong Kong campaign (HK) to constrain our ME-2 runs. For the BBOA factor, we used the  
188 reference BBOA profile from MILAGRO (Aiken et al., 2009). The resolved BBOA factor tracked  
189 well with its tracer ion ( $\text{C}_2\text{H}_4\text{O}_2^+$ ) and potassium ( $\text{K}^+$ ) in time series.

190 A four-factor (HOA, COA, BBOA and a free factor) solution had a higher  $Q/Q_{\text{exp}}$ , while a six-  
191 factor (HOA, COA, BBOA and three free factors) solution seemed to split OOA factors without  
192 obvious physical meaning. We first tried to explore the a value with the range of a values from 0  
193 to 0.5. An five-factor solution with  $a$  values of 0.1, 0.2, 0.3 for  $\text{HOA}_{\text{local}}$ ,  $\text{COA}_{\text{HK}}$ , and  
194  $\text{BBOA}_{\text{MILAGRO}}$ , respectively, was finally adopted. The  $a$  values for these POA factors were also in  
195 line with previous ME-2 studies (Canonaco et al., 2013; Crippa et al., 2014; Fröhlich et al., 2015).  
196 We further run the ME-2 with the optimal conditions with 10 runs to explore the stability of  
197 solution. The time series and mass spectra for each runs were quite steady (Fig. S10). The final  
198 solution came from results obtained with averaging these ten runs. Two oxygenated organic  
199 aerosol factors, SVOOA and LVOOA, were assigned based on their degree of oxygenation. The  
200 mass spectra of all OA factors and their mass concentrations will be discussed in Section 2.2. The  
201 correlations of OA factors with external tracers are shown in Table S1.

### 202 3. Results and Discussion:

#### 203 3.1. Overall composition

204 Fig. 1 shows the time series of NR- $\text{PM}_{10}$  species (sulfate, nitrate, ammonium, chloride, and  
205 organics), BC, and meteorological factors (precipitation, RH, temperature, wind direction, and  
206 wind speed) for the whole campaign. Northerly winds (hourly integrated) prevailed through the  
207 whole campaign, bringing pollutants from downtown area of Guangzhou.  $\text{NO}_x$  ranged from 9 to  
208 333 ppb, averaging at 40.8 ppb. The high  $\text{NO}_x$  levels reflect heavy influences from traffic  
209 emissions. Ozone ranged from 0.2 to 119.9 ppb with an average of 22.7 ppb. An episodic high  $\text{O}_3$   
210 period occurred from the November 14<sup>th</sup> to 27<sup>th</sup>, 2014, and peaked in every afternoon. The average  
211 temperature was  $5^\circ\text{C}$  lower in December than in November. A detailed discussion of the diurnal  
212 patterns of meteorological conditions together with gaseous and particulate pollutants is presented

213 in the supplementary information (Section 1). Mass concentrations of PM<sub>1</sub> ranged from 1.7 to  
214 208.4 µg/m<sup>3</sup>, with an average of 55.4 µg/m<sup>3</sup>. The concentration was significantly higher than those  
215 in Hong Kong (Lee et al., 2013, 2015; Li et al., 2015; Qin et al., 2016a) and Shenzhen (He et al.,  
216 2011), similar with those in Lanzhou and Sichuan basin (Hu et al., 2016; Xu et al., 2016), and  
217 lower than those in Beijing (Hu et al., 2016) and Sichuan Basin. In our study, organics accounted  
218 for 24.5 µg/m<sup>3</sup> (or 46.3 %) of the PM<sub>1</sub> mass on average. Sulfate, nitrate, ammonium, BC, and  
219 chloride accounted for 23.1%, 11.2%, 9.1%, 8.3%, and 1.9% of the PM<sub>1</sub> mass, respectively (Fig.  
220 2 a). Fig. 2b shows the variations in species mass fractions in PM<sub>1</sub> species as a function of total  
221 PM<sub>1</sub> (with BC inclusive) mass loading, as well as the probability density of PM<sub>1</sub> mass loading.  
222 Organic mass fraction was the highest across different PM<sub>1</sub> levels with little variation. On the  
223 contrary, the mass fraction of sulfate dropped from 0.25 to 0.15 as PM<sub>1</sub> concentration increased  
224 from 10 to 160 µg/m<sup>3</sup>. The decrease in sulfate mass fraction was compensated by the increased  
225 mass fraction of nitrate, and to a lesser extent, chloride. The increase in the relative contribution  
226 of nitrate on highly polluted days was also observed in AMS studies in other locations in China,  
227 such as Shenzhen (He et al., 2011), Beijing (Huang et al., 2010), and Changdao (Hu et al., 2013).

### 228 3.2. Organics

229 Since OA accounted for over 45% of PM<sub>1</sub> in this study, it is worth investigating the detailed  
230 characteristics of this portion of PM. Elemental analysis of OA (ratios of H:C, O:C and OM:OC)  
231 provides useful information for assessing OA characteristics and their evolution. Ions in the high  
232 resolution mass spectra were used to calculate the elemental ratios using the Improved-Ambient  
233 method (Canagaratna et al., 2015). Results obtained from the Aiken-Ambient (Aiken et al., 2007)  
234 protocol were also listed in Table 1 for comparison with elemental ratios reported in the literature.  
235 We further used empirical constants (11% for H:C, 27% for O:C, and 9% for OM:OC) from  
236 Canagaratna et al. (2015) to estimate the ratios accounting for possible underestimation of the O:C  
237 ratio in earlier studies. As there are significant differences in O<sub>x</sub>, RH and temperature between  
238 November and December, we conducted the following analysis in November and December  
239 separately. However, the average O:C, H:C, and OM:OC ratios showed little variation between  
240 the two months, with average values of 0.53 for O:C, 1.63 for H:C, 1.87 for OM:OC in November,  
241 and 0.53 for O:C, 1.65 for H:C and 1.87 for OM:OC in December. The observed elemental ratios  
242 generally agreed with other AMS-based reported values in PRD (Table 1). The H:C ratio was  
243 similar to those at rural sites in Kaiping (1.64) and Heshan (1.65) and slightly higher than that at

244 suburban HKUST (1.54 and 1.55) but lower than those at urban sites in Shenzhen (1.81) and  
245 Mong Kok (1.84). O:C and OM:OC ratios, on the contrary, are higher than those at the urban sites  
246 and lower than that in Kaiping, but similar to those in Heshan and at HKUST. Overall, the  
247 relatively low H:C ratio and high O:C ratio suggest that OA at this site has degree of oxygenation  
248 higher than those at urban sites (e.g. Shenzhen), but lower than those at rural sites (e.g. Kaiping).  
249 The degree of oxygenation reflects the characteristics of OA at the peripheries of urbanized areas  
250 as a mixture of background air with urban recently formed secondary OA.

251 As shown in Fig. 3, the diurnal variations in H:C, O:C, OM:OC and carbon oxidation state ( $\overline{OS}_c \approx$   
252  $2 \times O:C - H:C$ ) showed similar patterns during both November and December. The average H:C ratio  
253 ranged from 1.6 to 1.7, with a pronounced increase in the late afternoon from 16:00 to 20:00, and  
254 remaining at a maximum value until mid-night. This observation suggests important fresh organic  
255 source at evening and nighttime. The O:C, OM:OC ratios and  $\overline{OS}_c$  increased during daytime with  
256 afternoon peaks at around 15:00, likely due to high photochemical activity and production of SOA  
257 during daylight hours.

258

259 The mass spectra of all OA factors and their mass concentrations from PMF analysis with ME-2,  
260 together with the time series of external tracers, are shown in Fig. 4. HOA correlated well with  
261  $NO_x$  since both are traffic-related species. While COA shares spectral similarities with HOA, it is  
262 distinguished from HOA by a higher contribution of  $C_3H_3O^+$  at  $m/z$  55, and a much lower  
263 contribution of ions at  $m/z$  57 compared to HOA (He et al., 2010; Mohr et al., 2012). The time  
264 series of the COA was highly correlated with one of its tracer ions,  $C_3H_3O^+$ . The other primary  
265 factor, BBOA, is characterized by the presence of signals at  $m/z$  60 ( $C_2H_4O_2^+$ ) and  $m/z$  73  
266 ( $C_3H_5O_2^+$ ), which are typically associated with levoglucosan (Alfarra et al., 2007; Schneider et al.,  
267 2006). The time series of BBOA also tracked well with the one of its marker ions. The two  
268 oxygenated organic aerosol factors (SVOOA and LVOOA) are characterized by oxygenated ions  
269  $C_2H_3O^+$  at  $m/z$  43 and  $CO_2^+$  at  $m/z$  44, respectively. The ratio of most oxidized ions  $CO_2^+$  ( $m/z$  44)  
270 to moderately oxygenated ions  $C_2H_3O^+$  ( $m/z$  43) is higher in LVOOA than that in SVOOA  
271 (Jimenez et al., 2009). Overall, a good correlation between the concentrations of SVOOA and  
272 nitrate, a semi-volatile secondary inorganic species, was observed. From 21<sup>st</sup> November to 1<sup>st</sup>  
273 December, SVOOA showed distinct peaks that are beyond the comparable trend with nitrate. The  
274 sharp peaks of SVOOA coincide with those of  $O_3$  as shown in the inserted panel. Moreover, higher

275 temperatures were also observed during this period (Fig. 1). LVOOA also correlated well with  
276 sulfate in time series, as both species are regional pollutants. On average, HOA, SVOOA and  
277 LVOOA were the main sources of OA, made up 26%, 31% and 30% of the total OA respectively  
278 (Fig. 5).

279

280 The diurnal patterns of mass concentrations and fractions for the five OA factors are depicted in  
281 Fig. 6. HOA exhibited two typical peaks during both November and December, first during the  
282 morning rush hours at 09:00, before starting to increase again at 16:00 prior to peaking between  
283 20:00 and mid-night. The high HOA level in the evening and at night was likely due to the heavily  
284 polluting trucks passing by en route to the downtown area at night (22:00 to 07:00). The diurnal  
285 variations in HOA corresponded to those in H:C ratio and NO<sub>x</sub>, and BC (Fig. S11), suggesting that  
286 vehicle-related pollutants are the main contributor to this OA factor. On the other hand, COA had  
287 clear peaks at lunch and dinner times. Even though COA only contributed to 8% of total OA on  
288 average, its contribution could be as high as 15% of OA during mealtime in both months.  
289 Contribution of COA to OA at this peripheral site of the megacity Guangzhou, however, is still far  
290 lower than those directly measured at urban areas, which often had COA contribution of 15 – 20%  
291 of OA (Crippa et al., 2013; Lee et al., 2015; Sun et al., 2016, 2013). BBOA did not exhibit a clear  
292 diurnal variation in November, but it had a daytime valley in December, possibly due to intensive  
293 biomass burning activities at night. SVOOA had a clear noon-to-afternoon peak in November,  
294 consistent with peaks in ozone (Fig. S11), but this peak was less pronounced in December. The  
295 noon-to-afternoon peak for SVOOA has been commonly observed worldwide under the  
296 photochemically oxidation process (Hayes et al., 2013; Qin et al., 2016). Zotter et al. (2014) further  
297 found that the noon-to-afternoon SVOOA peak can be caused by the large increase in fossil carbon.  
298 LVOOA, in our study, showed a relatively flat diurnal pattern as in Shenzhen (He et al., 2011),  
299 but significant noon-to-afternoon peaks for LVOOA were observed at rural sites in Kaiping  
300 (Huang et al., 2011) and Hesan (Gong et al., 2012).

301

### 302 3.3. Formation of SOA

303 The evolution of AMS OA factors has been used to infer SOA formation via photochemical  
304 oxidation in the PRD (Lee et al., 2013; Li et al., 2013; Qin et al., 2016a). Odd-oxygen (O<sub>x</sub>)  
305 concentrations are closely linked to the extent of photochemical oxidation in an air mass because

306 O<sub>3</sub> production results from OH reactions with VOCs and CO. The ratio of SOA to O<sub>x</sub>, therefore,  
307 provides a useful metric for quantifying the dependence of SOA concentration on photochemical  
308 oxidation. Following the work of Hayes et al. (2013), we examine the correlations of SOA with  
309 O<sub>x</sub>, instead of O<sub>3</sub>, to account for the titration of O<sub>3</sub> by freshly emitted NO, which produces NO<sub>2</sub>.  
310 Fig. 7a shows that SOA (SVOOA+LVOOA) continuously increased as O<sub>x</sub> increased during  
311 daytime (7:00 to 18:00) in both November and December. The regression slope for SOA versus  
312 O<sub>x</sub> are 0.23 ±0.014 (R<sub>pr</sub>=0.85) and 0.25 ±0.025 (R<sub>pr</sub>=0.55) μg / (sm<sup>3</sup> ppb) in November and  
313 December, respectively. The volume unit “sm” stands for volume under standard-temperature-  
314 pressure conditions. The slopes are higher than those reported in earlier studies during spring to  
315 summer in North America (Table 2), indicating efficient SOA photochemical production even in  
316 late autumn and early winter at this subtropical site. Such a significant production of SOA might  
317 have been fueled by photo-oxidation of large amounts of accumulated VOCs between the city and  
318 this peripheral site of Guangzhou. Meteorological parameters can also influence the formation of  
319 SOA in several ways. Such influences can be effective by changing SOA partitioning at high  
320 temperature conditions, or promoting aqueous-phase chemistry at high liquid water content  
321 conditions. The temperature effect on gas-particle partitioning did not appear to be important in  
322 this study. Higher temperatures should favor the partitioning of SOA to the vapor phase, but higher  
323 SOA mass loading was associated with higher temperature in our case (Fig. 7b). In November,  
324 LWC stayed in a relatively narrow range (Fig. 7c) when SOA experienced the drastic changes. In  
325 December, LWC was lower than that in November, yet, SOA increased as LWC increased. The  
326 enhanced LWC may facilitate the SOA formation in December yet influence was not clear in  
327 November. Furthermore, there is no correlation between SOA/OA and LWC in either month.  
328

### 329 3.4. Formation of nitrate

330 With the growth of NO<sub>x</sub> emissions in recent years, the concentration and proportions of nitrate in  
331 PM have increased significantly in most Chinese megacities (Pan et al., 2016; Wen et al., 2015;  
332 Xue et al., 2014). As shown in Fig. 2, an obvious increased proportion of nitrate was also observed  
333 in high-PM episodes in our study. The increased contribution of nitrate to PM calls for a more  
334 detailed investigation of this species.

335 We used molar concentration of total nitrate [HNO<sub>3</sub>(g) + NO<sub>3</sub><sup>-</sup>(p)] to examine the increase of  
336 nitrate species, where HNO<sub>3</sub>(g) was measured with MARGA and NO<sub>3</sub><sup>-</sup>(p) was measured with HR-

337 ToF-AMS. Organic nitrates may show similar fragments ( $\text{NO}^+$  and  $\text{NO}_2^+$ ) with inorganic nitrate  
338 in HR-ToF-AMS and contribute to the nitrate concentration measured by AMS. Farmer et al. (2010)  
339 have successfully used  $\text{NO}^+$  to  $\text{NO}_2^+$  ratio to estimate organic nitrates from HR-ToF-AMS  
340 measurement. The rationale behind such an estimation was that the response of  $\text{NO}^+/\text{NO}_2^+$  of  
341 inorganic nitrate differed greatly those from organic nitrates. Xu et al.(2015) used the  $\text{NO}^+/\text{NO}_2^+$   
342 values of 5 and 10, which likely correspond to the upper and lower bounds of the ratios from  
343 organic nitrates. This method using  $\text{NO}^+/\text{NO}_2^+$  (Method 1) was adopted in this study to estimate  
344 the contributions of inorganic and organic nitrates. However, it should be noted that the vast array  
345 of possible organic nitrate parent compounds in ambient particles and the variations of the  
346  $\text{NO}^+/\text{NO}_2^+$  ratios between instruments may led to some bias in the calculation. A lower bound of  
347 organic nitrate concentration can also be estimated using the organic concentration and elemental  
348 ratios (OM:OC and N:C) from HR-ToF-AMS measurement (Method 2) (Schurman et al., 2015b).  
349 A detailed calculation of the two methods is presented in the supplemental information (Text S2).  
350 Using these two methods, the estimated inorganic nitrate concentrations were derived by  
351 subtracting the contributions of organic nitrates from the total nitrate as measured by the HR-ToF-  
352 AMS. Overall, the contribution from organic nitrate ranged from around 10% to 25%, while  
353 inorganic nitrate contributed to the majority signals of AMS-measured nitrate. The scatter plot of  
354 estimated inorganic nitrate versus nitrate from HR-ToF-AMS measurement is shown in Fig. 8. The  
355 estimated inorganic nitrate tracked well ( $R_p^2 \geq 0.95$ ) with the total HR-ToF-AMS nitrate  
356 concentration and followed with the 1 to 1 line. Even though organic nitrates also contributed to  
357 the total nitrate we measured, both the variation and the concentration of the nitrate did not change  
358 significantly after subtracting the organic nitrates. Furthermore, as shown in Fig. S2,  
359 concentrations of nitrate from AMS were comparable to those from MAGRA, which uses  
360 chromatographic speciation, with a correlation slope of 0.9 and a  $R_p$  of 0.95. The influence from  
361 organic nitrates in our calculation of total nitrate should be minor. Given the uncertainties  
362 associated with each estimation, we prefer to use the raw HR-ToF-AMS nitrate concentration in  
363 the following discussion. In Fig. 9, the total nitrate is closely correlated with  $\text{NO}_x$  during both  
364 daytime and nighttime. At the same  $\text{NO}_x$ , total nitrate increased as  $\text{O}_x$  increased during daytime,  
365 suggesting that  $\text{NO}_x$  was photochemically oxidized to nitrate species. At night (Fig. 9b),  $\text{O}_x$   
366 concentration was relatively low when  $\text{NO}_x$  concentrations were high. The slope of total nitrate  
367 against  $\text{NO}_x$  during daytime is steeper than that at nighttime. Nighttime formation of nitric acid

368 involves the consumption of  $\text{NO}_x$  and  $\text{O}_3$  (Seinfeld and Pandis, 2006). While  $\text{NO}_x$  can be  
369 replenished by primary emissions,  $\text{O}_3$  is mainly produced during daytime and is consumed at night.  
370 Thus, it is reasonable to observe that high total nitrate concentration was correlated with high  $\text{NO}_x$   
371 and low  $\text{O}_3$  at night.

372 The formation of particulate nitrate is limited by the availability of ammonia. Gas-to-particle  
373 partitioning of nitrate species to form particulate nitrate can be affected by the concentrations of  
374 ammonium and sulfate. An increase in ammonium or a decrease in sulfate could enhance the  
375 formation of particulate nitrate (Seinfeld and Pandis, 2006). Many studies indicated that the molar  
376 ratio of ammonium to sulfate of 1.5 demarcates the observation of particulate nitrate (Pathak et al.,  
377 2004, Griffith et al., 2015; Liu et al., 2015). Under ammonium rich (AR,  $[\text{NH}_4^+]/[\text{SO}_4^{2-}] > 1.5$ )  
378 conditions, additional ammonia is available to transfer  $\text{HNO}_3$  to the particle phase. In contrast,  
379 under (AP,  $[\text{NH}_4^+]/[\text{SO}_4^{2-}] < 1.5$ ) conditions, all of the ammonia is used to neutralize  $\text{H}_2\text{SO}_4$  until  
380  $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$  (letovicite) is formed. AR conditions prevailed during the whole campaign. Excess  
381 ammonium, defined as  $([\text{NH}_4^+]/[\text{SO}_4^{2-}] - 1.5) \times [\text{SO}_4^{2-}]$ , tracked well with particulate nitrate  
382 concentration with a slope of 0.93 (Fig. 10). In Fig. 11, we also examined the relationship between  
383 nitrate in  $\text{PM}_{2.5}$  and excess ammonium, and alkali cations ( $\text{Na}^+$  and  $\text{Ca}^{2+}$ , mainly from soil dust  
384 and sea salt particles, respectively). Results showed that nitrate tracked better with excess  
385 ammonium than the alkali cations did. The slope of nitrate to excess ammonium was smaller than  
386 1, indicating that ammonium was sufficient to neutralize the particulate nitrate. The molar  
387 concentration of alkali cations was around 7-10 times lower than that of nitrate and their role in  
388 stabilizing nitrate was negligible in our study.

389 The partitioning of nitrate between the gas and particle phases shows significant differences  
390 between November and December (data points in Fig. 12). The average ratio of nitrate to  $\text{HNO}_3$   
391 (the slope of scatter plot) was 3.2 in November, compared to 7.8 in December. The  $\text{NH}_3$   
392 concentration in the gas phase was not a limiting factor as the concentration of  $\text{NH}_3$  was even  
393 higher in November (Fig. 11a). Lower temperatures in December shifted the equilibrium toward  
394 the particle phase, increasing the nitrate concentration in the particle phase (Fig. 12b). Higher RH  
395 or particle liquid water content favored the thermodynamic equilibrium to form particulate nitrate.  
396 However, this effect fails to explain the gap between the different months (Fig. 12 c,d) as the  
397 higher nitrate to  $\text{HNO}_3$  ratio (December data) was associated with the lower RH and LWC. Overall,  
398 the differences in the ambient temperature may be the key factor causing the large difference in

399 gas-particle partitioning of nitrate in different time of a year. The implication for this finding is  
400 that meteorological parameters might couple with chemistry in the formation of PM species such  
401 as the semi-volatile nitrate. As such, the complex effects in PM formation deserve further  
402 investigations, especially in city peripheries where precursors are abundant and photochemistry is  
403 active.

404

#### 405 **4. Conclusions**

406 This study presents the emission sources and formation routes of PM at Panyu District in peripheral  
407 Guangzhou, from November to December 2014. The measured PM<sub>1</sub> (sum of NR-PM<sub>1</sub> and BC)  
408 mass concentration ranged from 1.7 to 208.4 μg/m<sup>3</sup>, with an average of 55.4 μg/m<sup>3</sup>. The PM<sub>1</sub>  
409 concentration is high compared to other cities in PRD, but slightly lower than those in the northern  
410 and north-western parts of China. OA was the overwhelmingly dominate species (> 45%) at all  
411 PM<sub>1</sub> levels. The mass fraction of sulfate decreased from 0.25 to 0.15 as PM<sub>1</sub> concentration  
412 increased from 10 to 160 μg/m<sup>3</sup>. The decrease in sulfate mass fraction was compensated by the  
413 increased mass fraction of nitrate. For organics, the average H:C ratio showed a pronounced  
414 increase starting in late afternoon and lasting until mid-night, suggesting the presence of an  
415 important fresh OA source at nighttime in peripheral Guangzhou, most likely heavy-duty diesel  
416 trucks. The O:C and OM:OC ratios, as well as  $\overline{OS}_c$  increased during daytime with clear afternoon  
417 peaks, likely due to efficient photochemical production of SOA during daytime. OA components  
418 were resolved by PMF analysis with ME-2. Fully unconstrained runs (PMF) suffers from the  
419 mixing of factors of the HOA factor with the COA factor, as well as the SVOOA) with the BBOA  
420 factor. A systematic approach to minimize the mixing of factors is explored. The final resolved  
421 components are HOA, COA, BBOA, SVOOA, and LVOOA. Results show that HOA was an  
422 important contributor (40%) to the high organic concentrations at night. SOA (SVOOA+LVOOA)  
423 plays a more important role during daytime. SOA concentration changed with the photochemical  
424 oxidation marker (O<sub>x</sub>). More interestingly, the ratios of SOA to O<sub>x</sub> during the late autumn and  
425 early wintertime were higher than those reported for several urban sites in North American during  
426 the summer (e.g. Pasadena and Mexico City), indicating the efficient SOA production. This  
427 efficient SOA formation was probably a result of active photochemistry at this subtropical site and  
428 was fueled by the large source of SOA precursors (e.g. HOA and VOCs) in the periphery of  
429 Guangzhou. The formation of total nitrate was closely correlated with NO<sub>x</sub> during both nighttime

430 and daytime, again demonstrating a close tie to traffic emissions at this site peripheral to the  
431 megacity. However, the slope of total nitrate against  $\text{NO}_x$  at daytime is steeper than that at  
432 nighttime. During daytime, at the same  $\text{NO}_x$  level, total nitrate increased as  $\text{O}_x$  increased,  
433 suggesting that  $\text{NO}_x$  photochemically oxidizes to nitrate. At night, high total nitrate concentration  
434 was associated with high  $\text{NO}_x$  but low  $\text{O}_x$ . Ammonium-rich conditions prevailed throughout the  
435 whole campaign and particulate nitrate was highly associated with the excess ammonium. The  
436 fraction of nitrate in the particulate phase out of total nitrate is higher in December, primarily due  
437 to difference in temperature. Nevertheless, in addition to its close tie to traffic emissions ( $\text{NO}_x$  as  
438 the precursors), formation of particulate nitrate may be affected by meteorological parameters as  
439 well. This study underlines the effects of traffic emissions to peripheral Guangzhou. The  
440 contributions to PM can be direct contribution of primary OA (HOA), secondary formation of  
441 semi-volatile OA (SVOOA), as well as secondary formation and subsequent partitioning of nitrate  
442 during late autumn and early winter.

Table 1 Elemental ratios of organic PM<sub>1</sub> in PRD

Site/ characteristics	Month	Aiken-Ambient (A-A) method			Improved-Ambient (I-A) method			Reference
		O:C	H:C	OM:OC	O:C	H:C	OM:OC	
Panyu/suburban	November	0.42	1.49	1.71	0.53	1.63	1.87	This study
	December	0.41	1.5	1.70	0.53	1.65	1.87	
Kaiping/rural	November	0.47	1.48	1.77	0.60*	1.64*	1.94*	Huang et al., 2011
Shenzhen/Urban	November	0.3	1.63	1.57	0.38*	1.81*	1.66*	He et al., 2011
Heshan/Rural	November	0.4	1.49	1.72	0.51*	1.65*	1.83*	Gong et al., 2012
HKUST/Suburban	February	0.42	1.39	1.71	0.53*	1.54*	1.86*	Li et al., 2015
	December	0.43	1.4	1.71	0.55*	1.55*	1.87*	
Mong Kok/Urban	March-mid	0.25	1.68	1.49	0.32	1.84	1.59	Lee et al., 2015
	May							

\* Improved-Ambient elemental ratios were estimated from the A-A method with the empirical constants from M. R. Canagaratna et al. 2015

Table 2 SOA-Ox average ratio comparison

Site	Month	Season	SOA-Ox average ratio	Reference
<b>Panyu, Guangzhou</b>	November	Late autumn	0.23 $\mu\text{g}/(\text{sm}^3 \text{ppb})^*$	This study
	December	Winter	0.25 $\mu\text{g}/(\text{sm}^3 \text{ppb})^*$	
<b>Pasadena, CA</b>	May-June (morning)	Late spring-summer	0.183 $\mu\text{g}/(\text{sm}^3 \text{ppb})^*$	Hayes et al., 2013
	May-June (afternoon)	Late spring-summer	0.163 $\mu\text{g}/(\text{sm}^3 \text{ppb})^*$	
<b>Riverside, CA</b>	July-August	summer	0.142 $\mu\text{g}/(\text{sm}^3 \text{ppb})^*$	Docherty et al., 2011
<b>Mexico City</b>	March	spring	0.156 $\mu\text{g}/(\text{sm}^3 \text{ppb})^*$	Aiken et al., 2009
<b>New York City</b>	July	summer	0.12 $\mu\text{g}/(\text{sm}^3 \text{ppb})^*$	Sun et al., 2011

\*The volume unit "sm" stands for volume under standard-temperature-pressure conditions

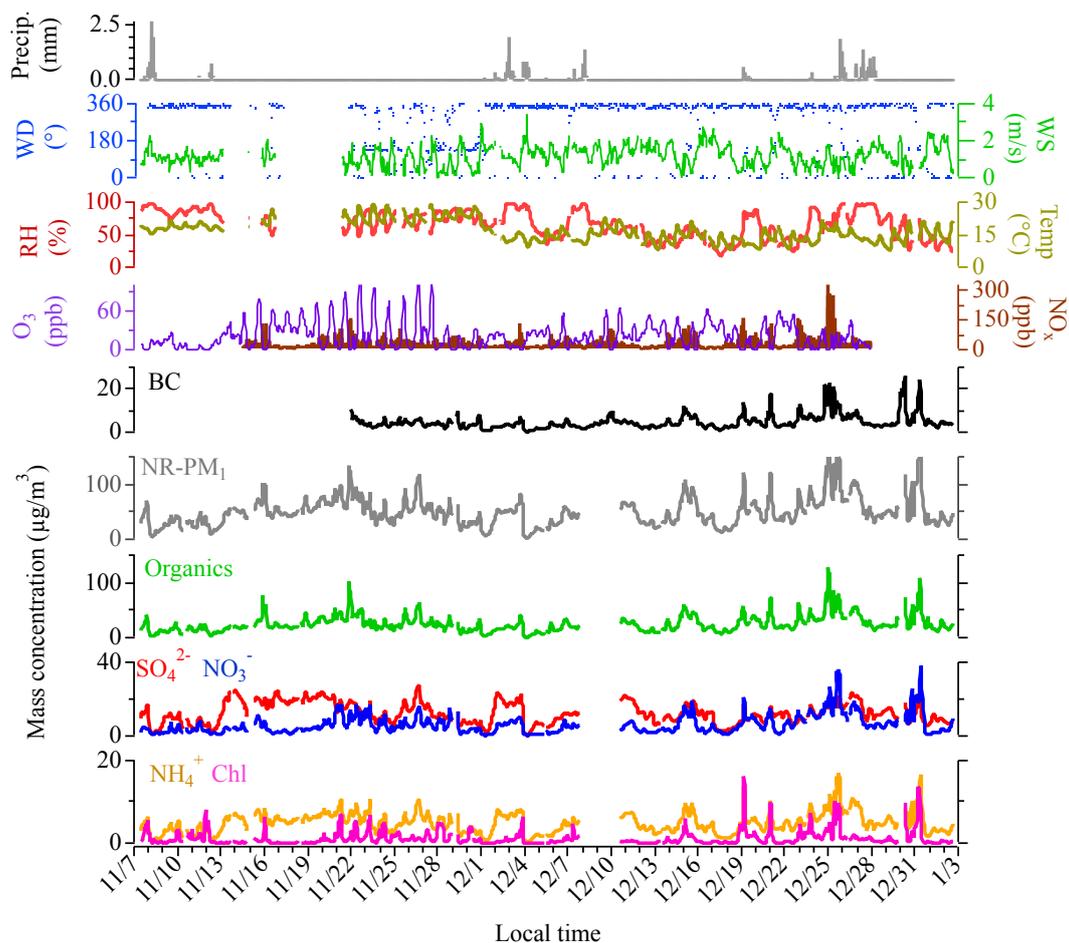

Figure 1 Time series of NR-PM<sub>1</sub> species (sulfate, nitrate, ammonium, chloride, and organics), BC, and meteorological factors (precipitation, relative humidity, temperature, wind direction and wind speed) for the campaign. Hourly averages are shown.

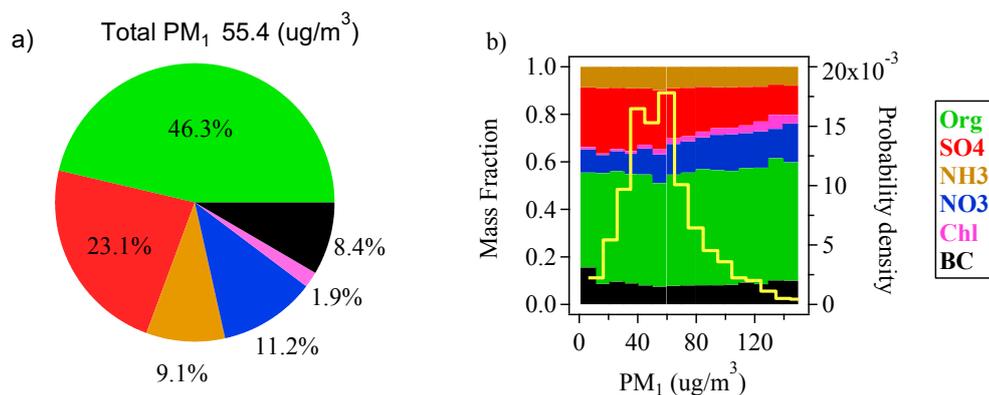

Figure 2a) Average mass fraction of PM<sub>1</sub> (with BC inclusive) during the whole campaign; b) Mass fraction variation of PM<sub>1</sub> species as well as the probability density of PM<sub>1</sub> as a function of total PM<sub>1</sub> mass loading. The probability density distribution describes the relative likelihood for the PM<sub>1</sub> mass loading in a certain range of concentrations.

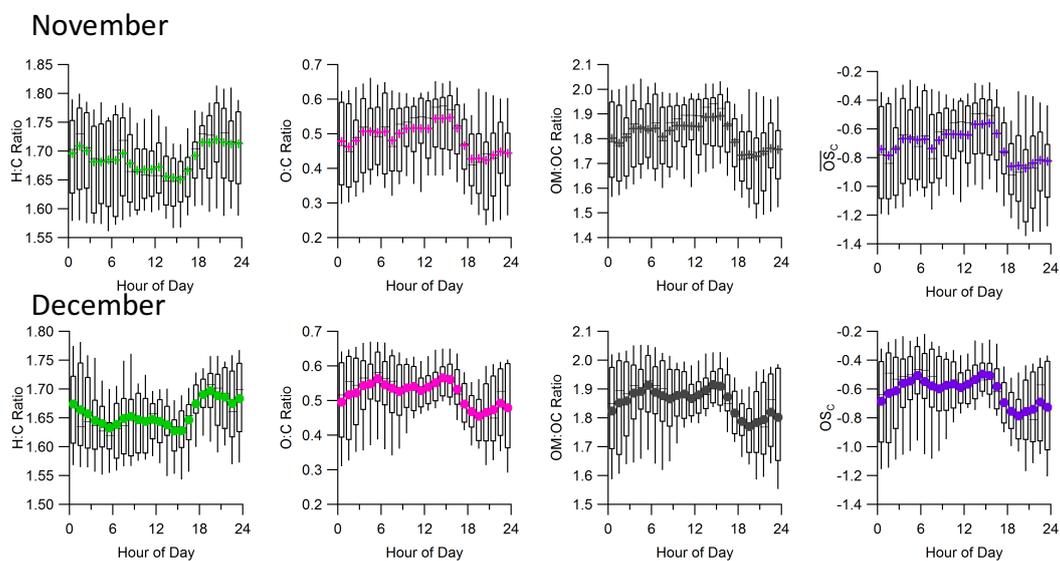

Figure 3 Diurnal variation of H:C and O:C OM:OC ratio and carbon oxidation state ( $\overline{OS}_c \approx 2 \times O:C-H:C$ ) during Nov. and Dec. (25th and 75th percentile boxes, 5th and 95th percentile whiskers, median as line in box, and mean as solid colored line).

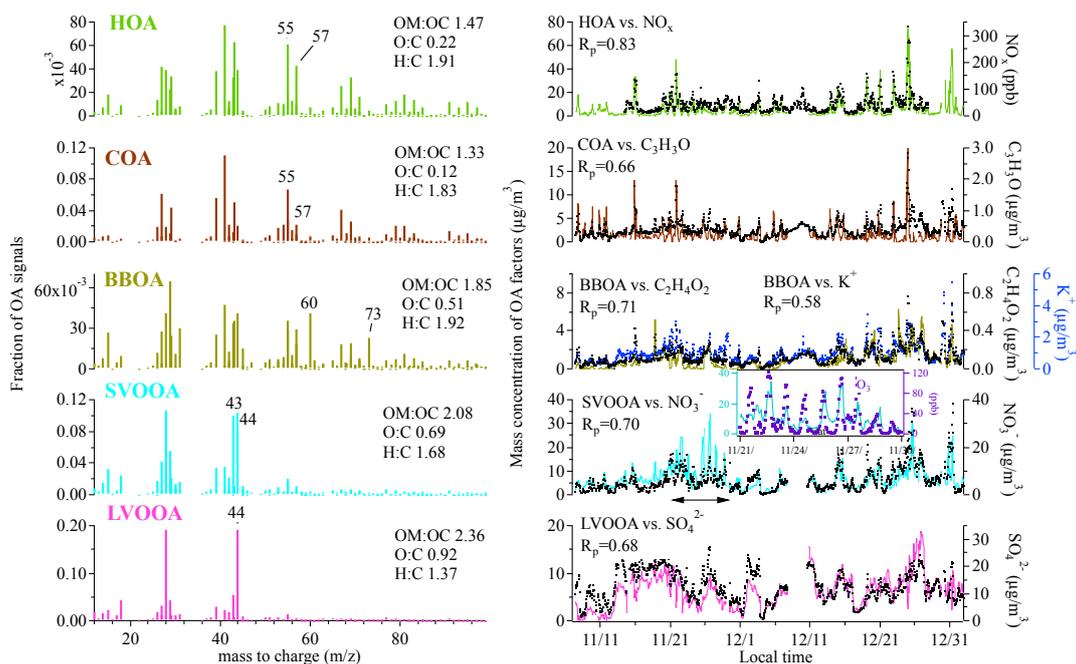

Figure 4. The mass spectra of all OA factors and the time series of their mass concentrations together with external tracers.

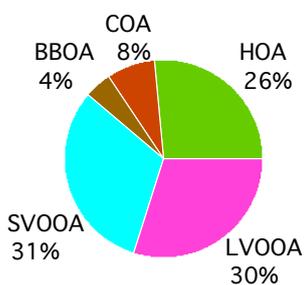

Figure 5. Campaign average mass fraction of each factor.

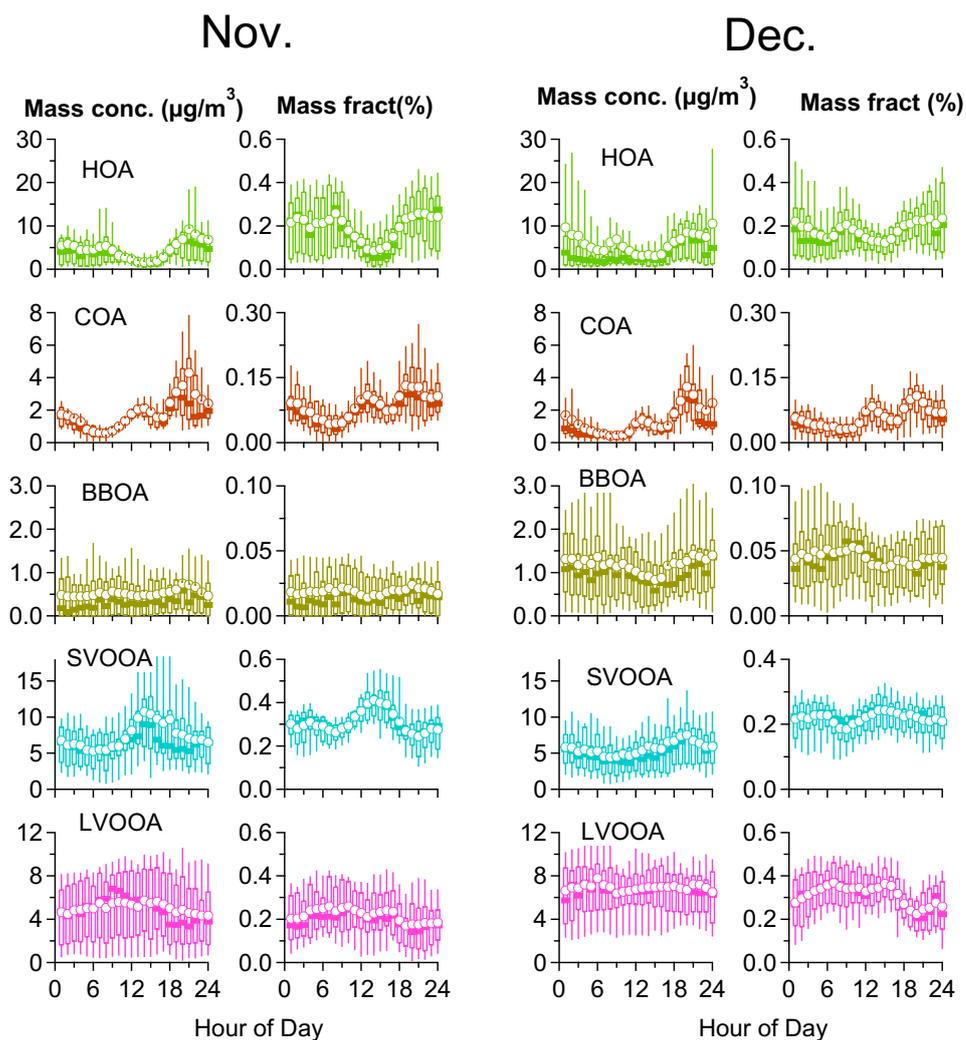

Figure 6 Diurnal variations of ME-2 resolved OA factors. Mass concentration of each OA factor (left). Mass fraction of each OA factor (right). 25th and 75th percentile boxes, 5th and 95th percentile whiskers, median as line in box, and mean as solid colored line.

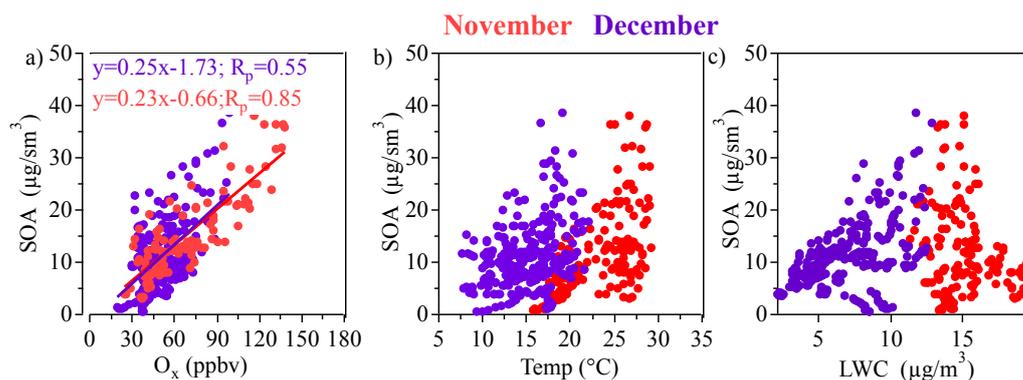

Figure 7 (a)SOA against  $\text{O}_x$ ; (b)SOA against temperature; (c) SOA against LWC during daytime.. The concentration of SOA has been converted to standard-temperature-pressure conditions in order to compare the slope of SOA/ $\text{O}_x$  with literature values.

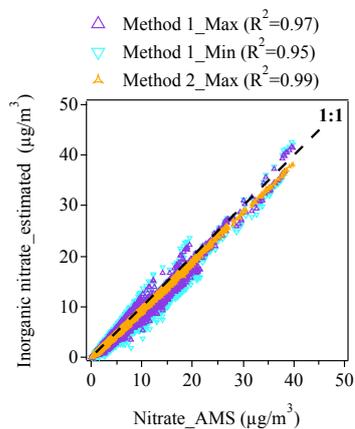

Figure 8 Scatter plot of estimated inorganic nitrate versus nitrate from HR-ToF-AMS measurement.

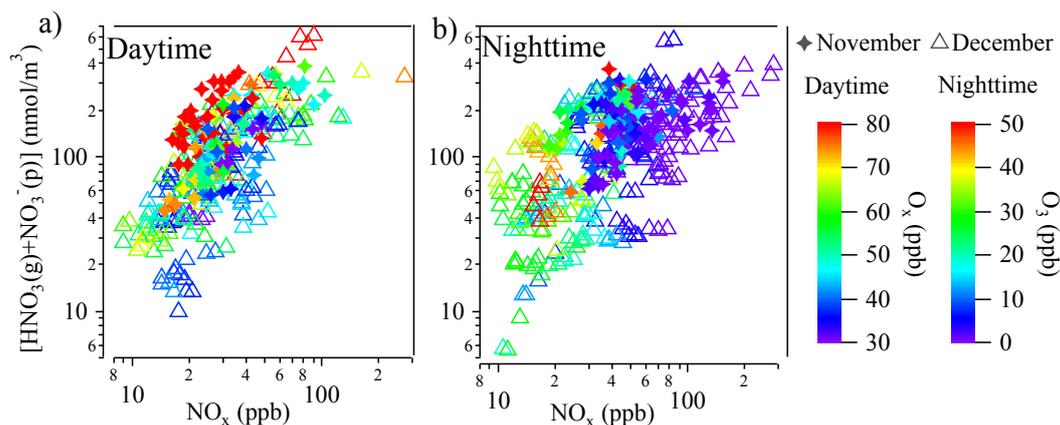

Figure 9 Correlations between total nitrate ( $\text{HNO}_3(\text{g})+\text{NO}_3(\text{p})$ ) and  $\text{NO}_x$  ( $\text{NO}+\text{NO}_2$ ). Triangles and circles represent data for November and December respectively. Data are color-coded by  $\text{O}_3$  during daytime and  $\text{O}_3$  during nighttime.

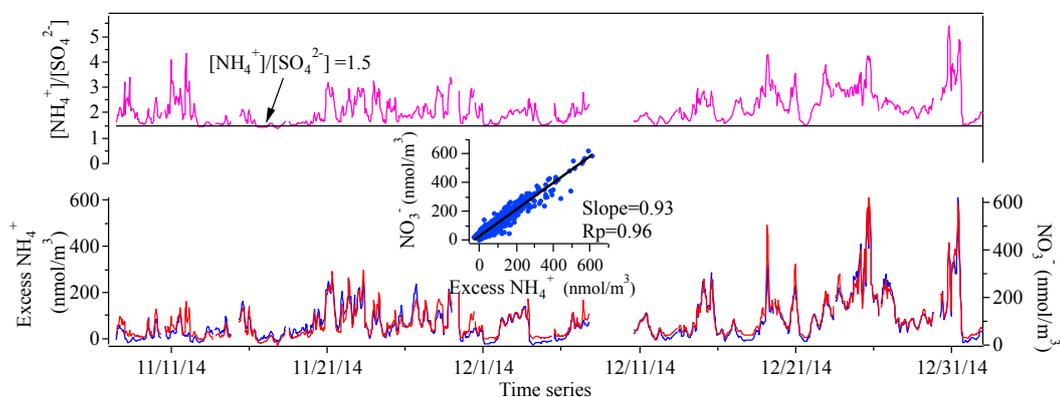

Figure 10 Time series of nitrate, excess  $\text{NH}_4$  and  $\text{NH}_4$ -to- $\text{SO}_4$  molar ratio.

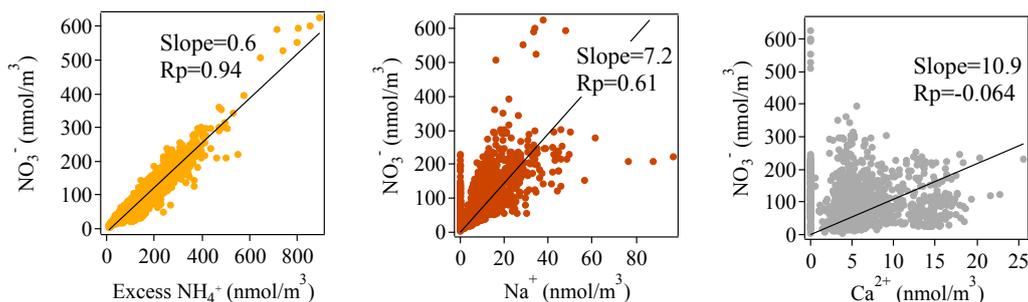

Figure 11 Scatter plots of  $\text{NO}_3^-$  molar concentration from MARGA ( $\text{PM}_{2.5}$ ) against those of Excess  $\text{NH}_4^+$ ,  $\text{Na}^+$  and  $\text{Ca}^{2+}$ .

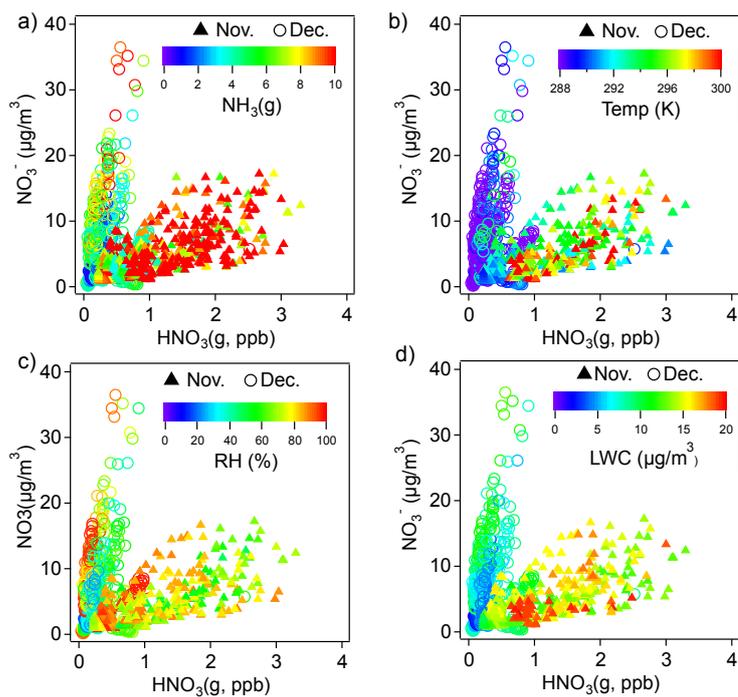

Figure 12. Distribution of nitrate species between  $\text{HNO}_3(\text{g})$  and  $\text{NO}_3^-(\text{p})$ . Colored by (a)  $\text{NH}_3$  concentration (b) temperature, (c) R (d) LWC.
