Abstract:

The seasonal evolution of O₃ and its photochemical production regime in a polluted region of eastern China between 2014 and 2017 has been investigated using different observations and modelling. We used tropospheric ozone (O₃), carbon monoxide (CO) and formaldehyde (HCHO, a marker of VOCs (volatile organic compounds)) partial columns derived from high resolution Fourier transform spectrometry (FTS), tropospheric nitrogen dioxide (NO₂, a marker of NO_x (nitrogen oxides)) partial column deduced from Ozone Monitoring Instrument (OMI), surface meteorological data, and a back trajectory cluster analysis technique. A broad O₃ maximum during both spring and summer (MAM/JJA) is observed; the day-to-day variations in MAM/JJA are generally larger than those in autumn and winter

(SON/DJF). Tropospheric O₃ columns in June are, on average, 0.50×10^{18} molecules*cm⁻² (47.6%) higher than those in December which has a mean value of 1.05×10^{18} molecules*cm⁻². Compared with SON/DJF season, the observed tropospheric O₃ levels in MAM/JJA are mainly influenced by transport of air masses from densely populated and industrialized areas while the broad and high O₃ level and variability in MAM/JJA is determined by the photochemical O₃ production. The tropospheric column HCHO/NO₂ ratio is used as a proxy to investigate the photochemical O₃ production rate (PO₃). The results show that the PO₃ is mainly nitrogen oxides (NO_x) limited in MAM/JJA, while it is mainly VOC or mix VOC-NO_x limited in SON/DJF. Statistics show that NO_x limited, mix VOC-NO_x limited, and VOC limited PO₃ accounts for 60.1%, 28.7%, and 11%, respectively. Considering most of PO₃ are NO_x limited or mix VOC-NO_x limited, reductions in NO_x would reduce most of the O₃ pollution in eastern China.

1 Introduction

Human health, terrestrial ecosystems, and materials degradation are impacted by poor air quality resulting from high photochemical ozone (O₃) levels (Wennberg and Dabdub, 2008; Edwards et al., 2013; Schroeder et al., 2017). In polluted areas, tropospheric O₃ generates from a series of complex reactions in the presence of sunlight involving carbon monoxide (CO), nitrogen oxides (NO_x ≡ NO (nitric oxide) + NO₂ (nitrogen dioxide)), and volatile organic compounds (VOCs) (Oltmans et al., 2006; Schroeder et al., 2017). Briefly, VOCs first react with the hydroxyl radical (OH) to form a peroxy radical (HO₂ + RO₂) which increases the rate of catalytic cycling of NO to NO₂. O₃ is then produced by subsequent reactions between HO₂ or RO₂ and NO that lead to radical propagation (via subsequent reformation of OH). Radical termination proceeds via reaction of OH with NO_x to form nitric acid (HNO₃) (reaction (1), referred to as LNO_x) or by radical-radical reactions resulting in stable peroxide formation (reactions (2) – (4), referred to as LRO_x, where RO_x ≡ RO₂ + HO₂) (Schroeder et al., 2017):

Typically, the relationship between these two competing radical termination processes (referred to as the ratio $\text{LRO}_x/\text{LNO}_x$) can be used to evaluate the photochemical regime. In high-radical, low- NO_x environments, reactions (2) – (4) remove radicals at a faster rate than reaction (1) (i.e., $\text{LRO}_x \gg \text{LNO}_x$), and the photochemical regime is regarded as “ NO_x limited”. In low-radical, high- NO_x environments the opposite is true (i.e., $\text{LRO}_x \ll \text{LNO}_x$) and the regime is regarded as “VOC limited”. When the rates of the two loss processes are comparable ($\text{LNO}_x \approx \text{LRO}_x$), the regime is said to be at the photochemical transition/ambiguous point, i.e., mix VOC- NO_x limited (Kleinman et al., 2005; Sillman et al., 1995a; Schroeder et al., 2017).

Understanding the photochemical regime at local scales is a crucial piece of information for enacting effective policies to mitigate O_3 pollution (Jin et al., 2017; Schroeder et al., 2017). In order to determine the regime, the total reactivity with OH of the myriad of VOCs in the polluted area has to be estimated (Sillman, 1995a; Xing et al., 2017). In the absence of such information, the formaldehyde (HCHO) concentration can be used as a proxy for VOC reactivity because it is a short-lived oxidation product of many VOCs and is positively correlated with peroxy radicals (Schroeder et al., 2017). Sillman (1995a) and Tonnesen and Dennis (2000) found that in situ measurements of the ratio of HCHO (a marker of VOCs) to NO_2 (a marker of NO_x) could be used to diagnose local photochemical regimes. Over polluted areas, both HCHO and tropospheric NO_2 have vertical distributions that are heavily weighted toward the lower troposphere, indicating that tropospheric column measurements of these gases are fairly representative of near surface conditions. Many studies have taken advantage of these favorable vertical distributions to investigate surface emissions of NO_x and VOCs from space (Boersma et al., 2009; Martin et al., 2004a; Millet et al., 2008; Streets et al., 2013). Martin et al. (2004a) and Duncan et al. (2010) used satellite measurements of column HCHO/ NO_2 ratio to explore near-surface O_3 sensitivities from space and disclosed that this diagnosis of O_3 production rate (PO_3) is consistent with previous finding of surface photochemistry.

Witte et al. (2011) used the similar technique to estimate changes in PO_3 to the strict emission control measures (ECMs) during Beijing Summer Olympic Games period in 2008. Recent papers have applied the findings of Duncan et al. (2010) to observe O_3 sensitivity in other parts of the world (Choi et al., 2012; Witte et al., 2011; Jin and Holloway, 2015; Mahajan et al., 2015; Jin et al., 2017).

With in situ measurements, Tonnesen and Dennis (2000) observed a radical-limited environment with HCHO/NO_2 ratios < 0.8 , a NO_x -limited environment with HCHO/NO_2 ratios > 1.8 , and a transition environment with HCHO/NO_2 ratios between 0.8 and 1.8. With 3-d chemical model simulations, Sillman (1995a) and Martin et al. (2004b) estimated that the transition between the VOC- and NO_x -limited regimes occurs when the HCHO/NO_2 ratio is ~ 1.0 . With a combination of regional chemical model simulations and the Ozone Monitoring Instrument (OMI) measurements, Duncan et al. (2010) concluded that O_3 production decreases with reductions in VOCs at column HCHO/NO_2 ratio < 1.0 and NO_x at column HCHO/NO_2 ratio > 2.0 ; both NO_x and VOCs reductions decrease O_3 production when column HCHO/NO_2 ratio lies in between 1.0 and 2.0. With a 0-D photochemical box model and airborne measurements, Schroeder et al. (2017) presented a thorough analysis of the utility of column HCHO/NO_2 ratios to indicate surface O_3 sensitivity and found that the transition/ambiguous range estimated via column data is much larger than that indicated by in situ data alone. Furthermore, Schroeder et al. (2017) concluded that many additional sources of uncertainty (regional variability, seasonal variability, variable free tropospheric contributions, retrieval uncertainty, air pollution levels and meteorological conditions) may cause transition threshold vary both geographically and temporally, and thus the results from one region are not likely to be applicable globally.

With the rapid increase in fossil fuel consumption in China over the past three decades, the emission of chemical precursors of O_3 (NO_x and VOCs) has increased dramatically, surpassing that of North America and Europe and raising concerns about worsening O_3 pollution in China (Tang et al., 2011; Wang et al., 2017; Xing et al., 2017). Tropospheric O_3 was already included in the new air quality standard as a

routine monitoring component (<http://www.mep.gov.cn>, last access on 23 May 2018), where the limit for the maximum daily 8 h average (MDA8) O₃ in urban and industrial areas is 160 µg/m³ (~ 75 ppbv at 273 K, 101.3 kPa). According to air quality data released by the Chinese Ministry of Environmental Protection, tropospheric O₃ has displaced PM_{2.5} as the primary pollutant in many cities during summer (<http://www.mep.gov.cn/>, last access on 23 May 2018). A precise knowledge of O₃ evolution and photochemical production regime in polluted troposphere in China has important policy implications for O₃ pollution controls (Tang et al., 2011; Xing et al., 2017; Wang et al., 2017).

In this study, we investigate O₃ seasonal evolution and photochemical production regime in the polluted troposphere in eastern China with tropospheric O₃, CO and HCHO derived from ground-based high resolution Fourier transform spectrometry (FTS) in Hefei, China, tropospheric NO₂ deduced from the OMI satellite (<https://aura.gsfc.nasa.gov/omi.html>, last access on 23 May 2018), surface meteorological data, and a back trajectory cluster analysis technique. Considering the fact that most NDACC (Network for Detection of Atmospheric Composition Change) FTS sites are located in Europe and Northern America, whereas the number of sites in Asia, Africa, and South America is very sparse, and there is still no official NDACC FTS station that covers China (<http://www.ndacc.org/>, last access on 23 May 2018), this study can not only improve our understanding of regional photochemical O₃ production regime, but also contributes to the evaluation of O₃ pollution controls.

This study is organized as below: in section 2 the location and the instrument is described, section 3 describes the retrieval of the gases. In section 4, the tropospheric evolution of O₃ in Hefei is investigated. In section 5, the production regimes are evaluated. The work concludes with a summary in section 6.

2 Site description and instrumentation

The FTS observation site (117°10'E, 31°54'N, 30 m a.s.l. (above sea level)) is located in the western suburbs of Hefei city (the capital of Anhui Province, 8 million population) in central-eastern China (Figure S1). Detailed description of this site and

its typical observation scenario can be found in Tian et al. (2018). Similar to other Chinese megacities, serious air pollution is common in Hefei throughout the whole year (<http://mep.gov.cn/>, last access on 23 May 2018).

Our observation system consists of a high resolution FTS spectrometer (IFS125HR, Bruker GmbH, Germany), a solar tracker (Tracker-A Solar 547, Bruker GmbH, Germany), and a weather station (ZENO-3200, Coastal Environmental Systems, Inc., USA). The near infrared (NIR) and middle infrared (MIR) solar spectra were alternately acquired in routine observations (Wang et al., 2017). The MIR spectra used in this study are recorded over a wide spectral range (about 600 – 4500 cm^{-1}) with a spectral resolution of 0.005 cm^{-1} . The instrument is equipped with a KBr beam splitter & MCT detector for O_3 measurements and a KBr beam splitter & InSb detector for other gases. The weather station includes sensors for air pressure ($\pm 0.1\text{hpa}$), air temperature ($\pm 0.3\text{ }^\circ\text{C}$), relative humidity ($\pm 3\%$), solar radiation ($\pm 5\%$), wind speed ($\pm 0.2\text{ m/s}$), wind direction ($\pm 5\text{ }^\circ$), and the presence of rain.

3 FTS retrievals of O_3 , CO and HCHO

3.1 Retrieval strategy

The SFIT4 (version 0.9.4.4) algorithm is used in the profile retrieval (Supplement section A; <https://www2.acom.ucar.edu/irwg/links>, last access on 23 May 2018). The retrieval settings for O_3 , CO, and HCHO are listed in Table 1. All spectroscopic line parameters are adopted from HITRAN 2008 (Rothman et al., 2009). A priori profiles of all gases except H_2O are from a dedicated WACCM (Whole Atmosphere Community Climate Model) run. A priori profiles of pressure, temperature and H_2O are interpolated from the National Centers for Environmental Protection and National Center for Atmospheric Research (NCEP/NCAR) reanalysis (Kalnay et al., 1996). For O_3 and CO, we follow the NDACC standard convention with respect to micro windows (MW) selection and the interfering gases consideration (<https://www2.acom.ucar.edu/irwg/links>, last access on 23 May 2018). HCHO is not yet an official NDACC species but has been retrieved at a few stations with different retrieval settings (Albrecht et al., 2002; Vigouroux et al., 2009; Jones et al., 2009; Viatte et al., 2014; Franco et al., 2015). The four MWs used in the current study are chosen from a harmonization project taking place in view of future satellite validation (Vigouroux et

al., 2018). They are centered at around 2770 cm^{-1} and the interfering gases are CH_4 , O_3 , N_2O , and HDO .

We assume measurement noise covariance matrices \mathbf{S}_e to be diagonal, and set its diagonal elements to the inverse square of the signal to noise ratio (SNR) of the fitted spectra and its non-diagonal elements to zero. For all gases, the diagonal elements of *a priori* profile covariance matrices \mathbf{S}_a are set to standard deviation of a dedicated WACCM run from 1980 to 2020, and its non-diagonal elements are set to zero.

We regularly used a low-pressure HBr cell to monitor the instrument line shape (ILS) of the instrument and included the measured ILS in the retrieval (Hase et al., 2012; Sun et al., 2018).

3.2 Profile information in the FTS retrievals

The sensitive range for CO and HCHO is mainly tropospheric, and for O_3 is both tropospheric and stratospheric (Figure S2). The typical degrees of freedom (DOFS) over the total atmosphere obtained in Hefei for each gas are included in Table 2: they are about 4.8, 3.5, and 1.2 for O_3 , CO, and HCHO, respectively. In order to separate independent partial column amounts in the retrieved profiles, we have chosen the altitude limit for each independent layer such that the DOFS in each associated partial column is not less than 1.0. The retrieved profiles of O_3 , CO, and HCHO can be divided into four, three, and one independent layers, respectively (Figure S3). The troposphere is well resolved by O_3 , CO, and HCHO, where CO exhibits the best vertical resolution with more than two independent layers in the troposphere.

In this study, we have chosen the same upper limit for the tropospheric columns for all gases, which is about 3 km lower than the mean value of the tropopause (~ 15.1 km). In this way we ensured the accuracies for the tropospheric O_3 , CO, and HCHO retrievals, and minimized the influence of transport from stratosphere, i.e., the so called STE process (stratosphere-troposphere exchange).

3.3 Error analysis

The results of the error analysis presented here based on the average of all measurements that fulfill the screening scheme, which is used to minimize the impacts of significant weather events or instrument problems (Supplement section B). In the troposphere, the dominant systematic error for O_3 and CO is the smoothing error, and for HCHO is the line intensity error (Figure S4). The dominant random error for O_3

and HCHO is the measurement error, and for CO is the zero baseline level error (Figure S5). Taken all error items into account, the summarized errors in O₃, CO, and HCHO for 0–12 km tropospheric partial column and for the total column are listed in Table 3. The total errors in the tropospheric partial columns for O₃, CO, and HCHO, have been evaluated to be 8.7%, 6.8%, and 10.2%, respectively.

4 Tropospheric O₃ seasonal evolution

4.1 Tropospheric O₃ seasonal variability

Figure 1(a) shows the tropospheric O₃ column time series recorded by the FTS from 2014 to 2017, where we followed Gardiner’s method and used a second-order Fourier series plus a linear component to determine the annual variability (Gardiner et al., 2008). While it failed to determine the secular trend of tropospheric O₃ column probably because the time series is much shorter than those in Gardiner et al. (2008), the observed seasonal cycle of tropospheric O₃ variations is well captured by the bootstrap resampling method (Gardiner et al., 2008). As commonly observed, high levels of tropospheric O₃ occur in spring and summer (hereafter MAM/JJA). Low levels of tropospheric O₃ occur in autumn and winter (hereafter SON/DJF). Day-to-day variations in MAM/JJA are generally larger than those in SON/DJF (Figure 1(b)). At the same time, it shows that the tropospheric O₃ column roughly increases over time at the first half of the year and reaches the maximum in June, and then decreases during the second half of the year. Tropospheric O₃ columns in June were, on average, 0.5×10^{18} molecules*cm⁻² (47.6%) higher than those in December which have a mean value of 1.05×10^{18} molecules*cm⁻².

Vigouroux et al. (2015) studied the O₃ trends and variabilities at eight NDACC FTS stations that have a long-term time series of O₃ measurements, namely, Ny-Ålesund (79 °N), Thule (77 °N), Kiruna (68 °N), Harestua (60 °N), Jungfraujoch (47 °N), Izaña (28 °N), Wollongong (34 °S) and Lauder (45 °S). All these stations were located in non-polluted or relatively clean areas. The results showed a maximum tropospheric O₃ column in spring at all stations except at Jungfraujoch where it extended into summer. This is because the STE process is most effective during late

winter and spring (Vigouroux et al. 2015). In contrast, we observed a broader maximum in Hefei which extends over MAM/JJA season, and the values are higher than those studied in Vigouroux et al. (2015). This is because the observed tropospheric O₃ levels in MAM/JJA are more influenced by air masses originated from densely populated and industrialized areas (see section 4.2), and the MAM/JJA meteorological conditions are more favorable to photochemical O₃ production (see 6). The selection of tropospheric limits 3 km below the tropopause minimized but cannot avoid the influence of transport from stratosphere, the STE process may also contribute to high level of tropospheric O₃ column in spring. Particularly, there is no stronger signature of summer O₃ enhancements in Hefei is most probably because the STE process is weaker in summer than in spring (Vigouroux et al. 2015).

4.2 Regional contribution to tropospheric O₃ levels

In order to determine where the air masses came from and thus contributed to the observed tropospheric O₃ levels, we have used the HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) model to calculate the three-dimensional kinematic back trajectories that coincide with the FTS measurements from 2014 - 2017 (Draxler et al., 2009). In the calculation, the GDAS (University of Alaska Fairbanks GDAS Archive) meteorological fields were used with a spatial resolution of 0.25 °× 0.25 °, a time resolution of 6 h and 22 vertical levels from the surface to 250 mbar. All daily back trajectories at 12:00 UTC, with a 24 h pathway arriving at Hefei site at 1500 m a.s.l., have been grouped into clusters, and divided into MAM/JJA and SON/DJF seasons (Stunder, 1996). The results showed that air pollution in Jiangsu and Anhui Province in eastern China, Hebei and Shandong Province in northern China, Shaanxi, Henan and Shanxi Province in northwestern China, Hunan and Hubei Province in central China contributed to the observed tropospheric O₃ levels.

In MAM/JJA season (Figure 2(a)), 28.8% of air masses are east origin and arrived at Hefei through the southeast of Jiangsu Province and east of Anhui Province; 41.0% are southwest origin and arrived at Hefei through the northeast of Hunan and Hubei Province, and southwest of Anhui Province; 10.1% are northwest origin and arrived at

Hefei through the southeast of Shanxi and Henan Province, and northwest of Anhui Province; 10.1% are north origin and arrived at Hefei through the south of Shandong Province and north of Anhui Province; 10.1% are local origin generated in south of Anhui Province. As a result, air pollution from megacities such as Shanghai, Nanjing, Hangzhou and Hefei in eastern China, Changsha and Wuhan in central-southern China, Zhenzhou and Taiyuan in northwest China, and Jinan in north China could dominate the contribution to the observed tropospheric O₃ levels.

In SON/DJF season, air masses are generally longer and originated in the northwest of the MAM/JJA ones (Figure 2(b)). The direction of east origin air masses shifts from the southeast to northeast of Jiangsu Province, and that of local origin air masses shifts from the south to the northwest of Anhui province. Trajectories of east origin, west origin, and north origin air masses in SON/DJF are 6.5%, 13.1%, and 0.7% smaller than the MAM/JJA ones, respectively. As a result, the air pollution outside Anhui province have 20.2% smaller contribution to the observed tropospheric O₃ levels in SON/DJF than in MAM/JJA. In contrast, trajectories of local origin air masses in SON/DJF are 20.2% larger than the MAM/JJA ones, indicating a more significant contribution of the air pollution inside Anhui province in SON/DJF.

The majority of the Chinese population lives in the eastern part of China, especially in the three most developed regions, the Jing-Jin-Ji (Beijing-Tianjin-Hebei), the Yangtze River Delta (YRD; including Shanghai-Jiangsu-Zhejiang-Anhui), and the Pearl River Delta (PRD; including Guangzhou, Shenzhen, and Hong Kong). These regions consistently have the highest emissions of anthropogenic precursors (Figure S6), which have led to severe region-wide air pollution. Particularly, the Hefei site located in the central-western corner of the YRD, where the population in the southeastern area is typically denser than the northwestern area. Specifically, the southeast of Jiangsu province and the south of Anhui province are two of the most developed areas in YRD, and human activities therein are very intense. Therefore, when the air masses originated from these two areas, O₃ level is usually very high. Overall, compared with SON/DJF season, the more southeastern air masses transportation in MAM/JJA indicated that the observed tropospheric O₃ levels could

be more influenced by the densely populated and industrialized areas, which can be broadly accounting for higher O₃ level and variability in MAM/JJA.

5 Tropospheric O₃ production regime

5.1 Meteorological dependency

Photochemistry in polluted atmospheres, particularly the formation of O₃, depends not only on pollutant emissions, but also on meteorological conditions (Lei et al., 2008; Wang et al., 2016; Coates et al., 2016). In order to investigate meteorological dependency of O₃ production regime in the observed area, we analyzed the correlation of the tropospheric O₃ with the coincident minutely-averaged surface meteorological data. Figure 3 shows time series of temperature, pressure, humidity, wind direction, wind speed, and solar radiation recorded by the surface weather station. The seasonal dependencies of all these coincident meteorological elements show no clear dependencies except for the temperature and pressure which show clear reverse seasonal cycles. Generally, the temperatures are higher and the pressures are lower in MAM/JJA than those in SON/DJF. The correlation plots between FTS tropospheric O₃ column and each meteorological element are shown in Figure 4. The tropospheric O₃ column shows positive correlations with solar radiation and temperature, and negative correlations with pressure, humidity, wind direction and wind speed.

High temperature and strong sunlight primarily affects O₃ production in Hefei in two ways: speeding up the rates of many chemical reactions and increasing emissions of VOCs from biogenic sources (BVOCs) (Sillman and Samson, 1995b). While emissions of anthropogenic VOCs (AVOCs) are generally not dependent on temperature, evaporative emissions of some AVOCs do increase with temperature (Rubin et al., 2006; Coates et al., 2016). Elevated O₃ concentration generally occurs on days with dry condition, low pressure and low winds in Hefei probably because these conditions favor the accumulation of O₃ and its precursors. Wind direction is also important because it affects pollution transport, giving rise to high O₃ in downwind locations (Wang et al., 2016). The city downtown locates in eastern of the

observation site and the majority of the Chinese population lives in the eastern part of China, easterly winds (direction less than 180°) could generally transport more pollutants to the observe area than westerly winds (direction larger than 180°), resulting in a higher O_3 level. Overall, MAM/JJA meteorological conditions are more favorable to O_3 production (higher sun intensity, higher temperature, lower pressure, and more easterly winds) than SON/DJF, which consolidates the fact that tropospheric O_3 in MAM/JJA are larger than those in SON/DJF.

5.2 PO_3 relative to CO, HCHO, and NO_2 changes

In order to determine the relationship between tropospheric O_3 production and its precursors, the chemical sensitivity of PO_3 relative to tropospheric CO, HCHO, and NO_2 changes was investigated. Figure 5 shows time series of tropospheric CO, HCHO, and NO_2 columns stay at present tropospheric O_3 counterparts, where tropospheric NO_2 was deduced from OMI product selected within the $\pm 0.7^\circ$ latitude/longitude rectangular area around Hefei site. The retrieval uncertainty for tropospheric column of is less than 30% (https://disc.gsfc.nasa.gov/datasets/OMNO2_V003/). Similar as tropospheric O_3 , tropospheric HCHO exhibits a clear seasonal cycle and has a minimum in winter and a maximum in summer. Pronounced tropospheric CO and NO_2 variations were observed but the seasonal cycles are not evident probably because of air pollution which is not constant over season or season dependent.

Figure 6 shows the correlation plot between the FTS tropospheric O_3 column and the coincident tropospheric CO, HCHO, and NO_2 columns. The tropospheric O_3 column shows positive correlations with tropospheric CO, HCHO, and NO_2 columns. Generally, the higher the tropospheric CO concentration, the higher the tropospheric O_3 , and both VOCs and NO_x reductions decrease O_3 production. As an indicator of regional air pollution, the good correlation between O_3 and CO (Figure 6(a)) indicates that the enhancement of tropospheric O_3 is highly associated with the photochemical reactions which occurred in polluted conditions rather than due to the STE process. Since the sensitivity of PO_3 to VOCs and NO_x is different under different limitation regimes, the relative weaker overall correlations to HCHO (Figure 6 (b)) and NO_2

(Figure 6 (c)) indicates that the O₃ pollution in Hefei can neither be fully attributed to NO_x pollution nor VOCs pollution.

5.3 O₃-NO_x-VOCs sensitivities

5.3.1 Transition/ambiguous range estimation

Referring to previous studies, the chemical sensitivity of PO₃ in Hefei was investigated using the column HCHO/NO₂ ratio (Martin et al., 2004; Duncan et al., 2010; Witte et al., 2011; Choi et al., 2012; Jin and Holloway, 2015; Mahajan et al., 2015; Schroeder et al., 2017; Jin et al., 2017). The methods have been adapted to the particular conditions in Hefei. In particular the findings of Schroeder et.al (2017) have been taken into account.

First, previous studies either based on space or airborne column HCHO/NO₂ ratios (Martin et al., 2004; Duncan et al., 2010; Witte et al., 2011; Schroeder et al., 2017), both ground-based remote sensing (O₃, CO, and HCHO) and results measured from space (NO₂) were used here. Both products have the same viewing geometry, i.e. they measure the whole troposphere. The ground-based products in Hefei are verified to be robust in troposphere (section 3) and the HCHO product is dedicated to future satellite validation (Vigouroux et al., 2018).

Second, while in most previous studies tropospheric NO₂ and total HCHO have been chosen as the proxy (Martin et al., 2004; Duncan et al., 2010; Witte et al., 2011; Jin and Holloway, 2015; Jin et al., 2017), we used the same tropospheric limits for all gases to calculate tropospheric columns. The AVK's of the measurements show, that all three gases are sensitive throughout the troposphere (compare figure S2).

Third, most previous studies used chemical transport model to estimate the transition threshold (Martin et al., 2004a; Duncan et al., 2010; Witte et al., 2011; Jin and Holloway, 2015; Schroeder et al., 2017; Jin et al., 2017). We used the observation results plus an empirical iterative scheme to calculate the transition threshold (Su et al., 2017). Schroeder et al. (2017) showed, that the transition threshold depends on the particular conditions of the site under study and no global value can be obtained.

Since the measurement tools for O₃ and HCHO, the pollution characteristic and

the meteorological condition in this study were not the same as those of previous studies, the transition thresholds estimated in either previous studies were not straightly applied here (Martin et al., 2004a; Duncan et al., 2010; Witte et al., 2011; Choi et al., 2012; Jin and Holloway, 2015; Mahajan et al., 2015; Schroeder et al., 2017; Jin et al., 2017). In order to determine transition thresholds applicable in Hefei, China, we iteratively altered the column HCHO/NO₂ ratio threshold and judged whether the sensitivities of tropospheric O₃ to HCHO or NO₂ changed abruptly. For example, in order to estimate the VOC-limited threshold, we first fitted tropospheric O₃ to HCHO that lies within column HCHO/NO₂ ratios < 2 (an empirical start point) to obtain the corresponding correlation/slope, and then we decreased the threshold by 0.1 (an empirical step size) and repeated the fit, i.e., only fitted the data pairs with column HCHO/NO₂ ratios < 1.9. This has been done iteratively. Finally, we sorted out the transition ratio which shows an abrupt change in correlation/slope, and regarded this as the VOC-limited threshold. Similarly, the NO_x-limited threshold was determined by iteratively increasing the column HCHO/NO₂ ratio threshold till the sensitivity of tropospheric O₃ to NO₂ changed abruptly.

The transition threshold estimation using this scheme exploits the fact that O₃ production is more sensitive to VOCs if it is VOCs-limited and is more sensitive to NO_x if it is NO_x limited, and it exists a transition point near the threshold (Martin et al., 2004). Su et al. (2017) used this scheme to investigate the O₃-NO_x-VOCs sensitivities during the 2016 G20 conference in Hangzhou, China, and argued that this diagnosis of PO₃ could reflect the overall O₃ production conditions.

5.3.2 PO₃ limitations in Hefei

The FTS retrievals within ± 1 h of OMI overpass time (13:30 local time (LT)) were used for investigation of PO₃ limitations. While the FTS instrument can measure throughout the whole day, if not cloudy, OMI measures only during midday. For Hefei, this coincidence criterion is a balance between the accuracy and the number of data points. Through the above empirical iterative calculation, we observed a VOC-limited regime with column HCHO/NO₂ ratios < 1.3, a NO_x-limited regime

with column HCHO/NO₂ ratios > 2.8, and a mix VOC-NO_x-limited regime with column HCHO/NO₂ ratios between 1.3 and 2.8. Schroeder et. al. (2017) argued, the column measurements from space have to be used with care because of the high uncertainty and the inhomogeneity of the satellite measurements. This has been mitigated in this study by the following:

The FTIR measurements have a much smaller footprint than the satellite measurements. Also we concentrate on measurements recorded during midday, when the mixing layer has largely been dissolved.

The measurements are more sensitive to the lower parts of the troposphere, which can be inferred from the normalized AVK's. This reason is simply, that the AVK's show the sensitivity to the column, but the column per altitude decreases with altitude.

Figure 7 shows time series of column HCHO/NO₂ ratios which varied over a wide range from 1.0 to 9.0. The column HCHO/NO₂ ratios in summer are typically larger than those in winter, indicating that the PO₃ is mainly NO_x limited in summer and mainly VOC limited or mix VOC-NO_x limited in winter. Based on the calculated transition criteria, 106 days of observations that have coincident O₃, HCHO, and NO₂ counterparts in the reported period are classified, where 57 days (53.8%) are in MAM/JJA season and 49 days (46.2%) are in SON/DJF season. Table 4 listed the statistics for the 106 days of observations, which shows that NO_x limited, mix VOC-NO_x limited, and VOC limited PO₃ accounts for 60.3% (64 days), 28.3% (30 days), and 11.4% (12 days), respectively. The majority of NO_x limited (70.3%) PO₃ lies in MAM/JJA season, while the majorities of mix VOC-NO_x limited (70%) and VOC limited (75%) PO₃ lie in SON/DJF season. As a result, reductions in NO_x and VOC could be more effective to mitigate O₃ pollution in MAM/JJA and SON/DJF season, respectively. Furthermore, considering most of PO₃ are NO_x limited or mix VOC-NO_x limited, reductions in NO_x would reduce most O₃ pollution in eastern China.

6 Conclusion

We investigated the seasonal evolution and photochemical production regime of

tropospheric O₃ in eastern China from 2014 – 2017 by using tropospheric O₃, CO and HCHO columns derived from Fourier transform infrared spectrometry (FTS), tropospheric NO₂ column deduced from Ozone Monitoring Instrument (OMI), the surface meteorological data, and a back trajectory cluster analysis technique. A pronounced seasonal cycle for tropospheric O₃ is captured by the FTS, which roughly increases over time at the first half year and reaches the maximum in June, and then it decreases over time at the second half year. Tropospheric O₃ columns in June are, on average, 0.50×10^{18} molecules*cm⁻² (47.6%) higher than those in December which has a mean value of 1.05×10^{18} molecules*cm⁻². A broad maximum within both spring and summer (MAM/JJA) is observed and the day-to-day variations in MAM/JJA are generally larger than those in autumn and winter (SON/DJF). This differs from tropospheric O₃ measurements in Vigouroux et al. (2015). However, Vigouroux et al. (2015) used measurements at relatively clean sites.

Back trajectories analysis showed that air pollution in Jiangsu and Anhui Province in eastern China, Hebei and Shandong Province in northern China, Shaanxi, Henan and Shanxi Province in northwest China, Hunan and Hubei Province in central China dominate the contributions to the observed tropospheric O₃ levels. Compared with SON/DJF season, the observed tropospheric O₃ levels in MAM/JJA are mainly influenced by transport of air masses from densely populated and industrialized areas while the broad and high O₃ level and variability in MAM/JJA is determined by the photochemical O₃ production. The tropospheric column HCHO/NO₂ ratio is used as a proxy to investigate the chemical sensitivity of O₃ production rate (PO₃). The results show that the PO₃ is mainly nitrogen oxide (NO_x) limited in MAM/JJA, while it is mainly VOC or mix VOC-NO_x limited in SON/DJF. Reductions in NO_x and VOC could be more effective to mitigate O₃ pollution in MAM/JJA and SON/DJF season, respectively. Considering most of PO₃ are NO_x limited or mix VOC-NO_x limited, reductions in NO_x would reduce most O₃ pollution in eastern China.
