19 **Abstract:**

20 The seasonal evolution of O₃ and its photochemical production regime in a
21 polluted region of eastern China between 2014 and 2017 has been investigated using
22 observations. We used tropospheric ozone (O₃), carbon monoxide (CO) and
23 formaldehyde (HCHO, a marker of VOCs (volatile organic compounds)) partial
24 columns derived from high resolution Fourier transform spectrometry (FTS),
25 tropospheric nitrogen dioxide (NO₂, a marker of NO_x (nitrogen oxides)) partial
26 column deduced from Ozone Monitoring Instrument (OMI), surface meteorological
27 data, and a back trajectory cluster analysis technique. A broad O₃ maximum during
28 both spring and summer (MAM/JJA) is observed; the day-to-day variations in
29 MAM/JJA are generally larger than those in autumn and winter (SON/DJF).

Correspondence to: Cheng Liu (chliu81@ustc.edu.cn) or Youwen Sun (ywsun@aiofm.ac.cn)

30 Tropospheric O₃ columns in June are 1.55×10^{18} molecules*cm⁻² (56 DU (Dobson
31 Units)) and in December are 1.05×10^{18} molecules*cm⁻² (39 DU). Tropospheric O₃
32 columns in June were ~ 50% higher than those in December. Compared with
33 SON/DJF season, the observed tropospheric O₃ levels in MAM/JJA are more
34 influenced by transport of air masses from densely populated and industrialized areas,
35 and the high O₃ level and variability in MAM/JJA is determined by the photochemical
36 O₃ production. The tropospheric column HCHO/NO₂ ratio is used as a proxy to
37 investigate the photochemical O₃ production rate (PO₃). The results show that the PO₃
38 is mainly nitrogen oxides (NO_x) limited in MAM/JJA, while it is mainly VOC or mix
39 VOC-NO_x limited in SON/DJF. Statistics show that NO_x limited, mix VOC-NO_x
40 limited, and VOC limited PO₃ accounts for 60.1%, 28.7%, and 11% of days,
41 respectively. Considering most of PO₃ are NO_x limited or mix VOC-NO_x limited,
42 reductions in NO_x would reduce O₃ pollution in eastern China.

43 **1 Introduction**

44 Human health, terrestrial ecosystems, and materials degradation are impacted by
45 poor air quality resulting from high photochemical ozone (O₃) levels (Wennberg and
46 Dabdub, 2008; Edwards et al., 2013; Schroeder et al., 2017). In polluted areas,
47 tropospheric O₃ generates from a series of complex reactions in the presence of
48 sunlight involving carbon monoxide (CO), nitrogen oxides (NO_x ≡ NO (nitric oxide)
49 + NO₂ (nitrogen dioxide)), and volatile organic compounds (VOCs) (Oltmans et al.,
50 2006; Schroeder et al., 2017). Briefly, VOCs first react with the hydroxyl radical (OH)
51 to form a peroxy radical (HO₂ + RO₂) which increases the rate of catalytic cycling of
52 NO to NO₂. O₃ is then produced by photolysis of NO₂. Subsequent reactions between
53 HO₂ or RO₂ and NO lead to radical propagation (via subsequent reformation of OH).
54 Radical termination proceeds via reaction of OH with NO_x to form nitric acid (HNO₃)
55 (reaction (1), referred to as LNO_x) or by radical-radical reactions resulting in stable
56 peroxide formation (reactions (2) – (4), referred to as LRO_x, where RO_x ≡ RO₂ +
57 HO₂) (Schroeder et al., 2017):

62 Typically, the relationship between these two competing radical termination processes
63 (referred to as the ratio $\text{LRO}_x/\text{LNO}_x$) can be used to evaluate the photochemical
64 regime. In high-radical, low- NO_x environments, reactions (2) – (4) remove radicals at
65 a faster rate than reaction (1) (i.e., $\text{LRO}_x \gg \text{LNO}_x$), and the photochemical regime is
66 regarded as “ NO_x limited”. In low-radical, high- NO_x environments the opposite is
67 true (i.e., $\text{LRO}_x \ll \text{LNO}_x$) and the regime is regarded as “VOC limited”. When the
68 rates of the two loss processes are comparable ($\text{LNO}_x \approx \text{LRO}_x$), the regime is said to
69 be at the photochemical transition/ambiguous point, i.e., mix VOC- NO_x limited
70 (Kleinman et al., 2005; Sillman et al., 1995a; Schroeder et al., 2017).

71 Understanding the photochemical regime at local scales is a crucial piece of
72 information for enacting effective policies to mitigate O_3 pollution (Jin et al., 2017;
73 Schroeder et al., 2017). In order to determine the regime, the total reactivity with OH
74 of the myriad of VOCs in the polluted area has to be estimated (Sillman, 1995a; Xing
75 et al., 2017). In the absence of such information, the formaldehyde (HCHO)
76 concentration can be used as a proxy for VOC reactivity because it is a short-lived
77 oxidation product of many VOCs and is positively correlated with peroxy radicals
78 (Schroeder et al., 2017). Sillman (1995a) and Tonnesen and Dennis (2000) found that
79 in situ measurements of the ratio of HCHO (a marker of VOCs) to NO_2 (a marker of
80 NO_x) could be used to diagnose local photochemical regimes. Over polluted areas,
81 both HCHO and tropospheric NO_2 have vertical distributions that are heavily
82 weighted toward the lower troposphere, indicating that tropospheric column
83 measurements of these gases are fairly representative of near surface conditions.
84 Many studies have taken advantage of these favorable vertical distributions to
85 investigate surface emissions of NO_x and VOCs from space (Boersma et al., 2009;
86 Martin et al., 2004a; Millet et al., 2008; Streets et al., 2013). Martin et al. (2004a) and
87 Duncan et al. (2010) used satellite measurements of column HCHO/ NO_2 ratio to
88 explore tropospheric O_3 sensitivities from space and disclosed that this diagnosis of
89 O_3 production rate (PO_3) is consistent with previous finding of surface photochemistry.

90 Witte et al. (2011) used the similar technique to estimate changes in PO_3 to the strict
91 emission control measures (ECMs) during Beijing Summer Olympic Games period in
92 2008. Recent papers have applied the findings of Duncan et al. (2010) to observe O_3
93 sensitivity in other parts of the world (Choi et al., 2012; Witte et al., 2011; Jin and
94 Holloway, 2015; Mahajan et al., 2015; Jin et al., 2017).

95 With in situ measurements, Tonnesen and Dennis (2000) observed a
96 radical-limited environment with HCHO/NO_2 ratios < 0.8 , a NO_x -limited
97 environment with HCHO/NO_2 ratios > 1.8 , and a transition environment with
98 HCHO/NO_2 ratios between 0.8 and 1.8. With 3-d chemical model simulations,
99 Sillman (1995a) and Martin et al. (2004b) estimated that the transition between the
100 VOC - and NO_x -limited regimes occurs when the HCHO/NO_2 ratio is ~ 1.0 . With a
101 combination of regional chemical model simulations and the Ozone Monitoring
102 Instrument (OMI) measurements, Duncan et al. (2010) concluded that O_3 production
103 decreases with reductions in VOCs at column HCHO/NO_2 ratio < 1.0 and NO_x at
104 column HCHO/NO_2 ratio > 2.0 ; both NO_x and VOCs reductions decrease O_3
105 production when column HCHO/NO_2 ratio lies in between 1.0 and 2.0. With a 0-D
106 photochemical box model and airborne measurements, Schroeder et al. (2017)
107 presented a thorough analysis of the utility of column HCHO/NO_2 ratios to indicate
108 surface O_3 sensitivity and found that the transition/ambiguous range estimated via
109 column data is much larger than that indicated by in situ data alone. Furthermore,
110 Schroeder et al. (2017) concluded that many additional sources of uncertainty
111 (regional variability, seasonal variability, variable free tropospheric contributions,
112 retrieval uncertainty, air pollution levels and meteorological conditions) may cause
113 transition threshold vary both geographically and temporally, and thus the results from
114 one region are not likely to be applicable globally.

115 With the rapid increase in fossil fuel consumption in China over the past three
116 decades, the emission of chemical precursors of O_3 (NO_x and VOCs) has increased
117 dramatically, surpassing that of North America and Europe and raising concerns about
118 worsening O_3 pollution in China (Tang et al., 2011; Wang et al., 2017; Xing et al.,
119 2017). Tropospheric O_3 was already included in the new air quality standard as a

120 routine monitoring component (<http://www.mep.gov.cn>, last access on 23 May 2018),
121 where the limit for the maximum daily 8 h average (MDA8) O₃ in urban and
122 industrial areas is 160µg/m³ (~ 75 ppbv at 273 K, 101.3 kPa). According to air quality
123 data released by the Chinese Ministry of Environmental Protection, tropospheric O₃
124 has replaced PM_{2.5} as the primary pollutant in many cities during summer
125 (<http://www.mep.gov.cn/>, last access on 23 May 2018). A precise knowledge of O₃
126 evolution and photochemical production regime in polluted troposphere in China has
127 important policy implications for O₃ pollution controls (Tang et al., 2011; Xing et al.,
128 2017; Wang et al., 2017).

129 In this study, we investigate O₃ seasonal evolution and photochemical production
130 regime in the polluted troposphere in eastern China with tropospheric O₃, CO and
131 HCHO derived from ground-based high resolution Fourier transform spectrometry
132 (FTS) in Hefei, China, tropospheric NO₂ deduced from the OMI satellite
133 (<https://aura.gsfc.nasa.gov/omi.html>, last access on 23 May 2018), surface
134 meteorological data, and a back trajectory cluster analysis technique. Considering the
135 fact that most NDACC (Network for Detection of Atmospheric Composition Change)
136 FTS sites are located in Europe and Northern America, whereas the number of sites in
137 Asia, Africa, and South America is very sparse, and there is still no official NDACC
138 FTS station that covers China (<http://www.ndacc.org/>, last access on 23 May 2018),
139 this study can not only improve our understanding of regional photochemical O₃
140 production regime, but also contributes to the evaluation of O₃ pollution controls.

141 This study concentrates on measurements recorded during midday, when the
142 mixing layer has largely been dissolved. All FTS retrievals are selected within ± 30
143 min of OMI overpass time (13:30 local time (LT)). While the FTS instrument can
144 measure throughout the whole day, if not cloudy, OMI measures only during midday.
145 For Hefei, this coincidence criterion is a balance between the accuracy and the
146 number of data points.

147 **2 Site description and instrumentation**

148 The FTS observation site (117°10'E, 31°54'N, 30 m a.s.l. (above sea level)) is

149 located in the western suburbs of Hefei city (the capital of Anhui Province, 8 million
150 population) in central-eastern China (Figure S1). Detailed description of this site and
151 its typical observation scenario can be found in Tian et al. (2018). Similar to other
152 Chinese megacities, serious air pollution is common in Hefei throughout the whole
153 year (<http://mep.gov.cn/>, last access on 23 May 2018).

154 Our observation system consists of a high resolution FTS spectrometer
155 (IFS125HR, Bruker GmbH, Germany), a solar tracker (Tracker-A Solar 547, Bruker
156 GmbH, Germany), and a weather station (ZENO-3200, Coastal Environmental
157 Systems, Inc., USA). The near infrared (NIR) and middle infrared (MIR) solar spectra
158 were alternately acquired in routine observations (Wang et al., 2017). The MIR
159 spectra used in this study are recorded over a wide spectral range (about 600 – 4500
160 cm^{-1}) with a spectral resolution of 0.005cm^{-1} . The instrument is equipped with a KBr
161 beam splitter & MCT detector for O_3 measurements and a KBr beam splitter & InSb
162 detector for other gases. The weather station includes sensors for air pressure (\pm
163 0.1hpa), air temperature ($\pm 0.3^\circ\text{C}$), relative humidity ($\pm 3\%$), solar radiation ($\pm 5\%$),
164 wind speed ($\pm 0.2\text{ m/s}$), wind direction ($\pm 5^\circ$), and the presence of rain.

165 **3 FTS retrievals of O_3 , CO and HCHO**

166 **3.1 Retrieval strategy**

167 The SFIT4 (version 0.9.4.4) algorithm is used in the profile retrieval (Supplement
168 section A; <https://www2.acom.ucar.edu/irwg/links>, last access on 23 May 2018). The
169 retrieval settings for O_3 , CO, and HCHO are listed in Table 1. All spectroscopic line
170 parameters are adopted from HITRAN 2008 (Rothman et al., 2009). A priori profiles
171 of all gases except H_2O are from a dedicated WACCM (Whole Atmosphere
172 Community Climate Model) run. A priori profiles of pressure, temperature and H_2O
173 are interpolated from the National Centers for Environmental Protection and National
174 Center for Atmospheric Research (NCEP/NCAR) reanalysis (Kalnay et al., 1996). For
175 O_3 and CO, we follow the NDACC standard convention with respect to micro
176 windows (MW) selection and the interfering gases consideration ([https://www2.acom.
177 ucar.edu/irwg/links](https://www2.acom.ucar.edu/irwg/links), last access on 23 May 2018). HCHO is not yet an official
178 NDACC species but has been retrieved at a few stations with different retrieval

179 settings (Albrecht et al., 2002; Vigouroux et al., 2009; Jones et al., 2009; Viatte et al.,
180 2014; Franco et al., 2015). The four MWs used in the current study are chosen from a
181 harmonization project taking place in view of future satellite validation (Vigouroux et
182 al., 2018). They are centered at around 2770 cm^{-1} and the interfering gases are CH_4 ,
183 O_3 , N_2O , and HDO .

184 We assume measurement noise covariance matrices \mathbf{S}_e to be diagonal, and set its
185 diagonal elements to the inverse square of the signal to noise ratio (SNR) of the fitted
186 spectra and its non-diagonal elements to zero. For all gases, the diagonal elements of
187 *a priori* profile covariance matrices \mathbf{S}_a are set to standard deviation of a dedicated
188 WACCM run from 1980 to 2020, and its non-diagonal elements are set to zero.

189 We regularly used a low-pressure HBr cell to monitor the instrument line shape
190 (ILS) of the instrument and included the measured ILS in the retrieval (Hase et al.,
191 2012; Sun et al., 2018).

192 **3.2 Profile information in the FTS retrievals**

193 The sensitive range for CO and HCHO is mainly tropospheric, and for O_3 is both
194 tropospheric and stratospheric (Figure S2). The typical degrees of freedom (DOFS)
195 over the total atmosphere obtained at Hefei for each gas are included in Table 2: they
196 are about 4.8, 3.5, and 1.2 for O_3 , CO, and HCHO, respectively. In order to separate
197 independent partial column amounts in the retrieved profiles, we have chosen the
198 altitude limit for each independent layer such that the DOFS in each associated partial
199 column is not less than 1.0. The retrieved profiles of O_3 , CO, and HCHO can be
200 divided into four, three, and one independent layers, respectively (Figure S3). The
201 troposphere is well resolved by O_3 , CO, and HCHO, where CO exhibits the best
202 vertical resolution with more than two independent layers in the troposphere.

203 In this study, we have chosen the same upper limit (12 km) for the tropospheric
204 columns for all gases (Table 2), which is about 3 km lower than the mean value of the
205 tropopause (~ 15.1 km). In this way we ensured the accuracies for the tropospheric O_3 ,
206 CO, and HCHO retrievals, and minimized the influence of transport from stratosphere,
207 i.e., the so called STE process (stratosphere-troposphere exchange).

208 **3.3 Error analysis**

209 The results of the error analysis presented here based on the average of all
210 measurements that fulfill the screening scheme, which is used to minimize the impacts

211 of significant weather events or instrument problems (Supplement section B). In the
212 troposphere, the dominant systematic error for O₃ and CO is the smoothing error, and
213 for HCHO is the line intensity error (Figure S4). The dominant random error for O₃
214 and HCHO is the measurement error, and for CO is the zero baseline level error
215 (Figure S5). Taken all error items into account, the summarized errors in O₃, CO, and
216 HCHO for 0–12 km tropospheric partial column and for the total column are listed in
217 Table 3. The total errors in the tropospheric partial columns for O₃, CO, and HCHO,
218 have been evaluated to be 8.7%, 6.8%, and 10.2%, respectively.

219 **4 Tropospheric O₃ seasonal evolution**

220 **4.1 Tropospheric O₃ seasonal variability**

221 Figure 1(a) shows the tropospheric O₃ column time series recorded by the FTS
222 from 2014 to 2017, where we followed Gardiner's method and used a second-order
223 Fourier series plus a linear component to determine the annual variability (Gardiner et
224 al., 2008). The analysis did not indicate a significant secular trend of tropospheric O₃
225 column probably because the time series is much shorter than those in Gardiner et al.
226 (2008), the observed seasonal cycle of tropospheric O₃ variations is well captured by
227 the bootstrap resampling method (Gardiner et al., 2008). As commonly observed, high
228 levels of tropospheric O₃ occur in spring and summer (hereafter MAM/JJA). Low
229 levels of tropospheric O₃ occur in autumn and winter (hereafter SON/DJF).
230 Day-to-day variations in MAM/JJA are generally larger than those in SON/DJF
231 (Figure 1(b)). At the same time, the tropospheric O₃ column roughly increases over
232 time at the first half of the year and reaches the maximum in June, and then decreases
233 during the second half of the year. Tropospheric O₃ columns in June are 1.55×10^{18}
234 molecules*cm⁻² (56 DU (Dobson Units)) and in December are 1.05×10^{18}
235 molecules*cm⁻² (39 DU). Tropospheric O₃ columns in June were ~ 50% higher than
236 those in December.

237 Vigouroux et al. (2015) studied the O₃ trends and variabilities at eight NDACC
238 FTS stations that have a long-term time series of O₃ measurements, namely,
239 Ny-Ålesund (79 °N), Thule (77 °N), Kiruna (68 °N), Harestua (60 °N), Jungfraujoch
240 (47 °N), Izaña (28 °N), Wollongong (34 °S) and Lauder (45 °S). All these stations

241 were located in non-polluted or relatively clean areas. The tropospheric columns at
242 these stations are of the order of 0.7×10^{18} molecules* cm^{-2} to 1.1×10^{18} molecules* cm^{-2} .
243 The results showed a maximum tropospheric O₃ column in spring at all these stations
244 except at the high altitude stations Jungfrauoch and Izaña where it extended into early
245 summer. This is because the STE process is most effective during late winter and
246 spring (Vigouroux et al. 2015). In contrast, we observed a broader maximum at Hefei
247 which extends over MAM/JJA season, and the values are ~ 35% higher than those
248 studied in Vigouroux et al. (2015). This is because the observed tropospheric O₃ levels
249 in MAM/JJA are more influenced by air masses originated from densely populated
250 and industrialized areas (see section 4.2), and the MAM/JJA meteorological
251 conditions are more favorable to photochemical O₃ production (see section 5.1). The
252 selection of tropospheric limits 3 km below the tropopause minimized but cannot
253 avoid the influence of transport from stratosphere, the STE process may also
254 contribute to high level of tropospheric O₃ column in spring.

255 **4.2 Regional contribution to tropospheric O₃ levels**

256 In order to determine where the air masses came from and thus contributed to the
257 observed tropospheric O₃ levels, we have used the HYSPLIT (Hybrid Single-Particle
258 Lagrangian Integrated Trajectory) model to calculate the three-dimensional kinematic
259 back trajectories that coincide with the FTS measurements from 2014 - 2017 (Draxler
260 et al., 2009). In the calculation, the GDAS (University of Alaska Fairbanks GDAS
261 Archive) meteorological fields were used with a spatial resolution of $0.25^\circ \times 0.25^\circ$, a
262 time resolution of 6 h and 22 vertical levels from the surface to 250 mbar. All daily
263 back trajectories at 12:00 UTC, with a 24 h pathway arriving at Hefei site at 1500 m
264 a.s.l., have been grouped into clusters, and divided into MAM/JJA and SON/DJF
265 seasons (Stunder, 1996). The results showed that air masses in Jiangsu and Anhui
266 Province in eastern China, Hebei and Shandong Province in northern China, Shaanxi,
267 Henan and Shanxi Province in northwestern China, Hunan and Hubei Province in
268 central China contributed to the observed tropospheric O₃ levels.

269 In MAM/JJA season (Figure 2(a)), 28.8% of air masses are east origin and arrived

270 at Hefei through the southeast of Jiangsu Province and east of Anhui Province; 41.0%
271 are southwest origin and arrived at Hefei through the northeast of Hunan and Hubei
272 Province, and southwest of Anhui Province; 10.1% are northwest origin and arrived at
273 Hefei through the southeast of Shanxi and Henan Province, and northwest of Anhui
274 Province; 10.1% are north origin and arrived at Hefei through the south of Shandong
275 Province and north of Anhui Province; 10.1% are local origin generated in south of
276 Anhui Province. As a result, air pollution from megacities such as Shanghai, Nanjing,
277 Hangzhou and Hefei in eastern China, Changsha and Wuhan in central-southern
278 China, Zhenzhou and Taiyuan in northwest China, and Jinan in north China could
279 contribute to the observed tropospheric O₃ levels.

280 In SON/DJF season, trajectories are generally longer and originated in the
281 northwest of the MAM/JJA ones (Figure 2(b)). The direction of air masses originating
282 in the eastern sector shifts from the southeast to northeast of Jiangsu Province, and
283 that of local air masses shifts from the south to the northwest of Anhui province.
284 Trajectories of east origin, west origin, and north origin air masses in SON/DJF are
285 6.5%, 13.1%, and 0.7% less frequent than the MAM/JJA ones, respectively. As a
286 result, the air masses outside Anhui province have 20.2% smaller contribution to the
287 observed tropospheric O₃ levels in SON/DJF than in MAM/JJA. In contrast,
288 trajectories of local origin air masses in SON/DJF are 20.2% more frequent than the
289 MAM/JJA ones, indicating a more significant contribution of air masses inside Anhui
290 province in SON/DJF.

291 The majority of the Chinese population lives in the eastern part of China,
292 especially in the three most developed regions, the Jing-Jin-Ji (Beijing-Tianjin-Hebei),
293 the Yangtze River Delta (YRD; including Shanghai-Jiangsu-Zhejiang-Anhui), and the
294 Pearl River Delta (PRD; including Guangzhou, Shenzhen, and Hong Kong). These
295 regions consistently have the highest emissions of anthropogenic precursors (Figure
296 S6), which have led to severe region-wide air pollution. Particularly, the Hefei site
297 located in the central-western corner of the YRD, where the population in the
298 southeastern area is typically denser than the northwestern area. Specifically, the
299 southeast of Jiangsu province and the south of Anhui province are two of the most

300 developed areas in YRD, and human activities therein are very intense. Therefore,
301 when the air masses originated from these two areas, O₃ level is usually very high.
302 Overall, compared with SON/DJF season, the more southeastern air masses
303 transportation in MAM/JJA indicated that the observed tropospheric O₃ levels could
304 be more influenced by the densely populated and industrialized areas, broadly
305 accounting for higher O₃ level and variability in MAM/JJA.

306 **5 Tropospheric O₃ production regime**

307 **5.1 Meteorological dependency**

308 Photochemistry in polluted atmospheres, particularly the formation of O₃,
309 depends not only on pollutant emissions, but also on meteorological conditions (Lei et
310 al., 2008; Wang et al., 2016; Coates et al., 2016). In order to investigate
311 meteorological dependency of O₃ production regime in the observed area, we
312 analyzed the correlation of the tropospheric O₃ with the coincident surface
313 meteorological data. Figure 3 shows time series of temperature, pressure, humidity,
314 and solar radiation recorded by the surface weather station. The seasonal
315 dependencies of all these coincident meteorological elements show no clear
316 dependencies except for the temperature and pressure which show clear reverse
317 seasonal cycles. Generally, the temperatures are higher and the pressures are lower in
318 MAM/JJA than those in SON/DJF. The correlation plots between FTS tropospheric O₃
319 column and each meteorological element are shown in Figure 4. The tropospheric O₃
320 column shows positive correlations with solar radiation, temperature, and humidity,
321 and negative correlations with pressure.

322 High temperature and strong sunlight primarily affects O₃ production in Hefei in
323 two ways: speeding up the rates of many chemical reactions and increasing emissions
324 of VOCs from biogenic sources (BVOCs) (Sillman and Samson, 1995b). While
325 emissions of anthropogenic VOCs (AVOCs) are generally not dependent on
326 temperature, evaporative emissions of some AVOCs do increase with temperature
327 (Rubin et al., 2006; Coates et al., 2016). Elevated O₃ concentration generally occurs
328 on days with wet condition and low pressure in Hefei probably because these

329 conditions favor the accumulation of O₃ and its precursors. Overall, MAM/JJA
330 meteorological conditions are more favorable to O₃ production (higher sun intensity,
331 higher temperature, wetter condition, and lower pressure) than SON/DJF, which
332 consolidates the fact that tropospheric O₃ in MAM/JJA are larger than those in
333 SON/DJF.

334 **5.2 PO₃ relative to CO, HCHO, and NO₂ changes**

335 In order to determine the relationship between tropospheric O₃ production and its
336 precursors, the chemical sensitivity of PO₃ relative to tropospheric CO, HCHO, and
337 NO₂ changes was investigated. Figure 5 shows time series of tropospheric CO, HCHO,
338 and NO₂ columns that are coincident with O₃ counterparts. The tropospheric NO₂ was
339 deduced from OMI product selected within the $\pm 0.7^\circ$ latitude/longitude rectangular
340 area around Hefei site. The retrieval uncertainty for tropospheric column of is less
341 than 30% (https://disc.gsfc.nasa.gov/datasets/OMNO2_V003/). Tropospheric HCHO
342 and NO₂ show clear reverse seasonal cycles. Generally, tropospheric HCHO are higher
343 and tropospheric NO₂ are lower in MAM/JJA than those in SON/DJF. Pronounced
344 tropospheric CO was observed but the seasonal cycle is not evident probably because
345 CO emission is not constant over season or season dependent.

346 Figure 6 shows the correlation plot between the FTS tropospheric O₃ column and
347 the coincident tropospheric CO, HCHO, and NO₂ columns. The tropospheric O₃
348 column shows positive correlations with tropospheric CO, HCHO, and NO₂ columns.
349 Generally, the higher the tropospheric CO concentration, the higher the tropospheric
350 O₃, and both VOCs and NO_x reductions decrease O₃ production. As an indicator of
351 regional air pollution, the good correlation between O₃ and CO (Figure 6(a)) indicates
352 that the enhancement of tropospheric O₃ is highly associated with the photochemical
353 reactions which occurred in polluted conditions rather than due to the STE process.
354 The relative weaker overall correlations of O₃ with HCHO (Figure 6 (b)) and NO₂
355 (Figure 6 (c)) are partly explained by different lifetimes of these gases, i.e., several
356 hours to 1 day in summer for NO₂ and HCHO, several days to weeks for O₃. So older
357 O₃ enhanced air masses easily loose trace of NO₂ or HCHO. Since the sensitivity of

358 PO₃ to VOCs and NO_x is different under different limitation regimes, the relative flat
359 overall slopes indicates that the O₃ pollution in Hefei can neither be fully attributed to
360 NO_x pollution nor VOCs pollution.

361 **5.3 O₃-NO_x-VOCs sensitivities**

362 **5.3.1 Transition/ambiguous range estimation**

363 Referring to previous studies, the chemical sensitivity of PO₃ in Hefei was
364 investigated using the column HCHO/NO₂ ratio (Martin et al., 2004; Duncan et al.,
365 2010; Witte et al., 2011; Choi et al., 2012; Jin and Holloway, 2015; Mahajan et al.,
366 2015; Schroeder et al., 2017; Jin et al., 2017). The methods have been adapted to the
367 particular conditions in Hefei. In particular the findings of Schroeder et.al (2017) have
368 been taken into account.

369 Since the measurement tools for O₃ and HCHO, the pollution characteristic and
370 the meteorological condition in this study were not the same as those of previous
371 studies, the transition thresholds estimated in either previous studies were not
372 straightly applied here (Martin et al., 2004a; Duncan et al., 2010; Witte et al., 2011;
373 Choi et al., 2012; Jin and Holloway, 2015; Mahajan et al., 2015; Schroeder et al.,
374 2017; Jin et al., 2017). In order to determine transition thresholds applicable in Hefei,
375 China, we iteratively altered the column HCHO/NO₂ ratio threshold and judged
376 whether the sensitivities of tropospheric O₃ to HCHO or NO₂ changed abruptly. For
377 example, in order to estimate the VOC-limited threshold, we first fitted tropospheric
378 O₃ to HCHO that lies within column HCHO/NO₂ ratios < 2 (an empirical start point)
379 to obtain the corresponding slope, and then we decreased the threshold by 0.1 (an
380 empirical step size) and repeated the fit, i.e., only fitted the data pairs with column
381 HCHO/NO₂ ratios < 1.9. This has been done iteratively. Finally, we sorted out the
382 transition ratio which shows an abrupt change in slope, and regarded this as the
383 VOC-limited threshold. Similarly, the NO_x-limited threshold was determined by
384 iteratively increasing the column HCHO/NO₂ ratio threshold till the sensitivity of
385 tropospheric O₃ to NO₂ changed abruptly.

386 The transition threshold estimation with this scheme exploits the fact that O₃

387 production is more sensitive to VOCs if it is VOCs-limited and is more sensitive to
388 NO_x if it is NO_x limited, and it exists a transition point near the threshold (Martin et
389 al., 2004). Su et al. (2017) used this scheme to investigate the O₃-NO_x-VOCs
390 sensitivities during the 2016 G20 conference in Hangzhou, China, and argued that this
391 diagnosis of PO₃ could reflect the overall O₃ production conditions.

392 **5.3.2 PO₃ limitations in Hefei**

393 Through the above empirical iterative calculation, we observed a VOC-limited
394 regime with column HCHO/NO₂ ratios < 1.3, a NO_x-limited regime with column
395 HCHO/NO₂ ratios > 2.8, and a mix VOC-NO_x-limited regime with column
396 HCHO/NO₂ ratios between 1.3 and 2.8. Column measurements sample a larger
397 portion of the atmosphere, and thus their spatial coverage are larger than in situ
398 measurements. So the photochemical scene disclosed by column measurement is
399 larger than the in-situ measurement. Specifically, this study reflects the mean
400 photochemical condition of the troposphere.

401 Schroeder et. al. (2017) argued, the column measurements from space have to be
402 used with care because of the high uncertainty and the inhomogeneity of the satellite
403 measurements. This has been mitigated in this study by the following:

404 The FTIR measurements have a much smaller footprint than the satellite
405 measurements. Also we concentrate on measurements recorded during midday, when
406 the mixing layer has largely been dissolved.

407 The measurements are more sensitive to the lower parts of the troposphere, which
408 can be inferred from the normalized AVK's. This reason is simply, that the AVK's
409 show the sensitivity to the column, but the column per altitude decreases with altitude.

410 Figure 7 shows time series of column HCHO/NO₂ ratios which varied over a
411 wide range from 1.0 to 9.0. The column HCHO/NO₂ ratios in summer are typically
412 larger than those in winter, indicating that the PO₃ is mainly NO_x limited in summer
413 and mainly VOC limited or mix VOC-NO_x limited in winter. Based on the calculated
414 transition criteria, 106 days of observations that have coincident O₃, HCHO, and NO₂
415 counterparts in the reported period are classified, where 57 days (53.8%) are in

416 MAM/JJA season and 49 days (46.2%) are in SON/DJF season. Table 4 listed the
417 statistics for the 106 days of observations, which shows that NO_x limited, mix
418 VOC-NO_x limited, and VOC limited PO₃ accounts for 60.3% (64 days), 28.3% (30
419 days), and 11.4% (12 days), respectively. The majority of NO_x limited (70.3%) PO₃
420 lies in MAM/JJA season, while the majorities of mix VOC-NO_x limited (70%) and
421 VOC limited (75%) PO₃ lie in SON/DJF season. As a result, reductions in NO_x and
422 VOC could be more effective to mitigate O₃ pollution in MAM/JJA and SON/DJF
423 season, respectively. Furthermore, considering most of PO₃ are NO_x limited or mix
424 VOC-NO_x limited, reductions in NO_x would reduce O₃ pollution in eastern China.

425 **6 Conclusion**

426 We investigated the seasonal evolution and photochemical production regime of
427 tropospheric O₃ in eastern China from 2014 – 2017 by using tropospheric O₃, CO and
428 HCHO columns derived from Fourier transform infrared spectrometry (FTS),
429 tropospheric NO₂ column deduced from Ozone Monitoring Instrument (OMI), the
430 surface meteorological data, and a back trajectory cluster analysis technique. A
431 pronounced seasonal cycle for tropospheric O₃ is captured by the FTS, which roughly
432 increases over time at the first half year and reaches the maximum in June, and then it
433 decreases over time at the second half year. Tropospheric O₃ columns in June are
434 1.55×10^{18} molecules*cm⁻² (56 DU (Dobson Units)) and in December are 1.05×10^{18}
435 molecules*cm⁻² (39 DU). Tropospheric O₃ columns in June were ~ 50% higher than
436 those in December. A broad maximum within both spring and summer (MAM/JJA) is
437 observed and the day-to-day variations in MAM/JJA are generally larger than those in
438 autumn and winter (SON/DJF). This differs from tropospheric O₃ measurements in
439 Vigouroux et al. (2015). However, Vigouroux et al. (2015) used measurements at
440 relatively clean sites.

441 Back trajectories analysis showed that air pollution in Jiangsu and Anhui
442 Province in eastern China, Hebei and Shandong Province in northern China, Shaanxi,
443 Henan and Shanxi Province in northwest China, Hunan and Hubei Province in central
444 China contributed to the observed tropospheric O₃ levels. Compared with SON/DJF

445 season, the observed tropospheric O₃ levels in MAM/JJA are more influenced by
446 transport of air masses from densely populated and industrialized areas, and the high
447 O₃ level and variability in MAM/JJA is determined by the photochemical O₃
448 production. The tropospheric column HCHO/NO₂ ratio is used as a proxy to
449 investigate the chemical sensitivity of O₃ production rate (PO₃). The results show that
450 the PO₃ is mainly nitrogen oxide (NO_x) limited in MAM/JJA, while it is mainly VOC
451 or mix VOC-NO_x limited in SON/DJF. Reductions in NO_x and VOC could be more
452 effective to mitigate O₃ pollution in MAM/JJA and SON/DJF season, respectively.
453 Considering most of PO₃ are NO_x limited or mix VOC-NO_x limited, reductions in
454 NO_x would reduce O₃ pollution in eastern China.

637 Figure 1. (a): FTS measured and bootstrap resampled tropospheric O₃ columns at Hefei site. The
638 linear trend and the residual are also shown. Detailed description of the bootstrap method can be
639 found in Gardiner et al., 2008. (b): Tropospheric O₃ column monthly means derived from (a).

641

642

643

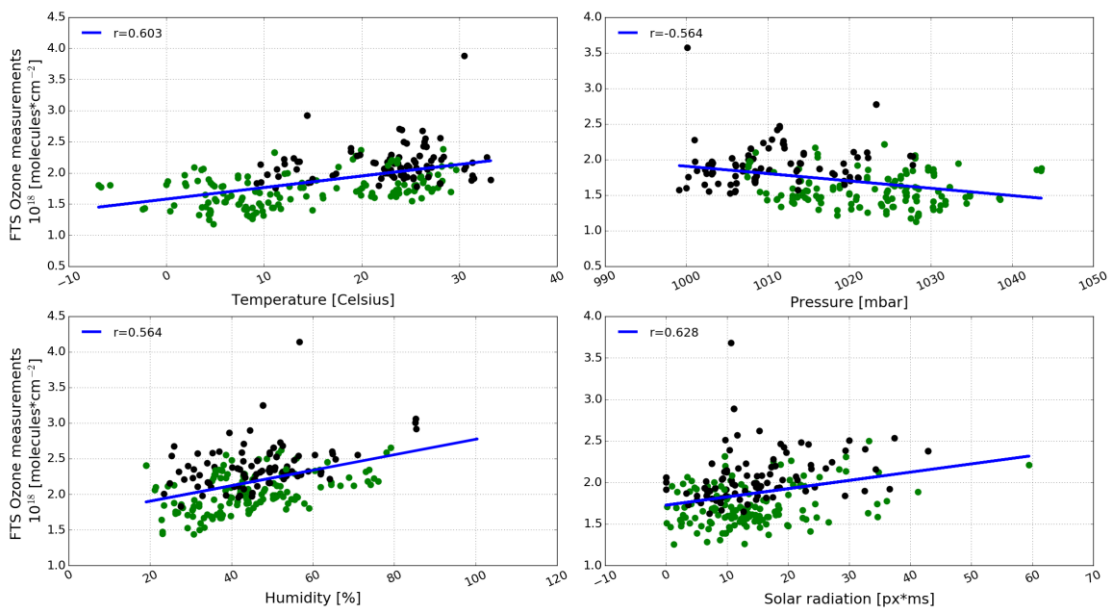

644 Figure 2. One-day HYSPLIT back trajectory clusters arriving at Hefei at 1500 m a.s.l that are
 645 coincident with the FTS measurements from 2014 - 2017. (a) Spring and summer (MAM/JJA),
 646 and (b) Autumn and winter (SON/DJF) season. The base map was generated using the TrajStat
 647 1.2.2 software (<http://www.meteothinker.com>).

648

649 Figure 3. Minutely averaged time series of temperature, pressure, humidity, and solar radiation

650 recorded by the surface weather station.

651

652 Figure 4. Correlation plot between the FTS tropospheric O₃ column and the coincident surface

653 meteorological data. Black dots are data pairs within MAM/JJA season and green dots are data

654 pairs within SON/DJF season.

655

656 Figure 5. Time series of tropospheric CO, HCHO, and NO₂. Tropospheric CO and HCHO were
 657 derived from FTS observations which is the same as tropospheric O₃ and tropospheric NO₂ is
 658 derived from OMI data.

659

660

661

662

663

664 Figure 6. Correlation plot between the FTS tropospheric O₃ column and coincident tropospheric
665 CO (upper), HCHO (middle), and NO₂ (bottom) columns. The CO and HCHO data are retrieved
666 from FTS observations and the NO₂ data were deduced from OMI product.

667

668 Figure 7. Time series of column HCHO/NO₂ ratios.

669

670 **Tables**

671

Table 1. Summary of the retrieval parameters used for O₃, CO, and HCHO. All micro windows (MW) are given in cm⁻¹.

672

Gases		O ₃	CO	HCHO
Retrieval code		SFIT4 v 0.9.4.4	SFIT4 v 0.9.4.4	SFIT4 v 0.9.4.4
Spectroscopy		HITRAN2008	HITRAN2008	HITRAN2008
P, T, H ₂ O profiles		NCEP	NCEP	NCEP
A priori profiles for target/interfering gases except H ₂ O		WACCM	WACCM	WACCM
MW for profile retrievals		1000-1004.5	2057.7-2058 2069.56-2069.76 2157.5-2159.15	2763.42-2764.17 2765.65-2766.01 2778.15-2779.1 2780.65-2782.0
Retrieved interfering gases		H ₂ O, CO ₂ , C ₂ H ₄ , ⁶⁶⁸ O ₃ , ⁶⁸⁶ O ₃	O ₃ , N ₂ O, CO ₂ , OCS, H ₂ O	CH ₄ , O ₃ , N ₂ O, HDO
SNR for de-weighting		None	500	600
Regularization	S _a	Diagonal: 20% No correlation	Diagonal: 11% ~ 27% No correlation	Diagonal: 10% No correlation
	S _e	Real SNR	Real SNR	Real SNR
ILS		LINEFIT145	LINEFIT145	LINEFIT145
Error analysis		Systematic error: -Smoothing error (smoothing) -Errors from other parameters: Background curvature (curvature), Optical path difference (max_opd), Field of view (omega), Solar line strength (solstrnth), Background slope (slope), Solar line shift (solshft), Phase (phase), Solar zenith angle(sza), Line temperature broadening (linetair_gas), Line pressure broadening (linepair_gas), Line intensity(lineint_gas) Random error: -Interference errors: retrieval parameters (retrieval_parameters), interfering species (interfering_species) -Measurement error (measurement) - Errors from other parameters: Temperature (temperature), Zero level (zshift)

675

676

677

678 Table 2. Typical degrees of freedom for signal (DOFs) and sensitive range of the retrieved O₃, CO, and HCHO
 679 profiles at Hefei site.

Gas	Total column DOFs	Sensitive range (km)	Tropospheric partial column (km)	Tropospheric DOFs
O ₃	4.8	Ground - 44	Ground - 12	1.3
CO	3.5	Ground - 27	Ground - 12	2.7
HCHO	1.2	Ground - 18	Ground - 12	1.1

680

681 Table 3. Errors in % of the column amount of O₃, CO, and HCHO for 0 –12 km tropospheric partial column and
 682 for the total column.

Gas	O ₃		CO		HCHO	
	Altitude (km)	Total column	Altitude (km)	Total column	Altitude (km)	Total column
Total random	0 – 12	0.59	0 – 12	0.66	0 – 12	0.97
Total systematic	3.2	4.86	3.8	3.9	3.3	5.7
Total errors	8.1	5.0	5.7	3.95	9.6	5.8

683

684

685 Table 4. Chemical sensitivities of PO₃ for the selected 106 days of observations that have coincident O₃, HCHO,
 686 and NO₂ counterparts

Items	Proportion		Autumn and winter		Spring and summer	
	days	percentage	days	percentage	days	percentage
NOx limited	64	60.3%	19	29.7%	45	70.3%
Mix VOC-NOx limited	30	28.3%	21	70%	9	30%
VOC limited	12	11.4%	9	75%	3	25%
Sum	106	100%	49	46.2%	57	53.8%
