Abstract. Peroxy acids might contribute significantly to particle toxicity and were recently found to be involved in new particle formation in the atmosphere. However, a lack of suitable analytical methods for the detection and characterization of peroxy acids in the particle phase is currently hindering the quantitative investigation of their contribution to these important atmospheric processes. Further development of appropriate techniques and relevant standards is therefore urgently needed. In this study, we synthesized three peroxydic acids, developed a liquid chromatography separation method and characterised them with tandem mass spectrometry. The observed fragmentation patterns clearly distinguish the different peroxydic acids from both the acid and each other, showing several neutral losses previously already observed for other peroxy acids. Both monoperoxydic acids were found to be present in secondary organic aerosol generated from ozonolysis of α -pinene in laboratory experiments. The yield of monoperoxydic acid formation was not influenced by humidity. Monoperoxydic acid quickly degrades on the filter, with about 60% lost within the first 5 hours. This fast degradation shows that time delays in traditional off-line analysis will likely lead to severe underestimates of peroxy compound concentrations in ambient particles.

20 **1 Introduction**

In recent years, organic peroxy compounds have emerged as important particle phase constituents of secondary organic aerosol (SOA). They are discussed as components of a family of compounds summarised as highly oxygenated molecules (HOMs), important in new particle formation (Ehn et al., 2014; Rissanen et al., 2015), and they could be involved in particle toxicity due to their oxidising properties, contributing to overall particle-bound reactive oxygen species (ROS) concentrations (Arashiro et al., 2017; Jiang et al., 2017). Multiple studies have shown that exposure to atmospheric aerosols is correlated with a wide variety of negative health outcomes (Brunekreef and Holgate, 2002; Dockery et al., 1993; Hoek et al., 2013; Nel, 2005). While it is not yet known which particle constituents are the main cause of particle toxicity, ROS, which summarises various oxygen-containing species with strong oxidative capacities, are implicated as a potential main contributor (Dellinger et al., 2001; Li et al., 2003; Tao et al., 2003).

In addition, it was recently shown that molecules with multiple hydroperoxy and peroxy acid groups, HOMs, which are formed through autoxidation in the gas phase, are highly relevant for the initial stages of SOA formation (Ehn et al., 2014; Rissanen et al., 2014). Therefore, the characterization and quantification of peroxy compounds in the particle phase has become an important issue. However, there is currently a lack of suitable analytical methods, which is exacerbated by the lack of appropriate standards for method development and validation. One subgroup of peroxy compounds are peroxy acids, which, apart from their relevance for atmospheric chemistry, are widely used as chemical reagents, disinfectants and bleaching agents (Holah et al., 1990; Luukkonen and Pehkonen, 2017; Milne, 1998; Ramirez, 2008; Reinhardt and Borchers, 2009). Due to their widespread practical applications, several methods have been developed both for the quantification of overall peracid content (Davies and Deary, 1988; Greenspan and MacKellar, 1948), as well as separation and detection of specific peracids (Cairns et al., 1975; Effkemann et al., 1998; Kirk et al., 1992). These methods use relatively unspecific detectors such as flame ionization, electrochemical and UV/VIS detectors. This poses a problem for the analysis of ambient particles, as they can contain several thousands of organic species, especially given the lack of available standards. Mass spectrometry, in particular coupled with chromatography, provides a method to characterize and identify specific peroxyacids. In a previous paper, we synthesized one cyclic and several linear aliphatic peroxy acids and showed their separation and detection with liquid chromatography-tandem mass spectrometry (HPLC-MS/MS) (Steimer et al., 2017). This study revealed that all investigated peroxy acids show common and specific mass spectrometry fragmentation patterns, which could be used as diagnostics to identify unknown peroxy acids in complex organic mixtures. However, as all structures synthesised in Steimer et al. (2017) are likely not prominent in secondary organic aerosol, we expand in this study the characterisation of peroxy acids towards structures that are likely present in atmospheric SOA particles. Monoperoxy-pinonic acid has been suggested as a potential product of α -pinene and β -pinene ozonolysis (Docherty et al., 2005) and has been tentatively identified in α -pinene and β -pinene SOA using online MS/MS (Reinnig et al., 2009). In this study, we have synthesized three peroxy-pinonic acids, characterised their MS/MS spectra and investigated their presence and stability in α -pinene SOA generated in laboratory experiments under varying conditions.

2 Experimental section

2.1 Chemicals and Synthesis

Sulphuric acid (H_2SO_4 , 95-98%), hydrogen peroxide (H_2O_2 , 50%, stabilized), α -pinene ($\text{C}_{10}\text{H}_{16}$, $\geq 98\%$), pinonic acid, bromine, dioxane, diethyl ether and hydrochloric acid were bought from Sigma-Aldrich. D(+)-Camphoric acid ($\text{C}_{10}\text{H}_{16}\text{O}_4$, $\geq 99\%$) was purchased from Acros Organics. Dichloromethane was bought from Carl-Roth, sodium sulfate was supplied by Acros, sodium hydroxide was purchased from Merck and charcoal pellets were provided by Fluka. Water, formic acid (0.1% in water) and acetonitrile, all in OPTIMA® LC/MS grade, were purchased from Fisher Scientific.

Pinic acid was synthesized using a similar procedure described by Moglioni et al. (2000). 2.84 g pinonic acid was dissolved in 50 mL dioxane. 8.2 g sodium hydroxide was dissolved in 196 mL water and loaded with 7.49 g bromine (0°C). The prepared sodium hydrobromite solution was added dropwise to the pinonic acid solution (30 min, -15°C). After 2 h of stirring at 0°C and over night (approx. 16 h) at room temperature, the resulting solution has been extracted three times each with 20 mL dichloromethane. 60 mL of a 40% sodium hydrogensulfate solution, prepared by solving sodium sulfate in water, was added to the watery phase. The pH was set to 1 using hydrochloric acid. This solution was extracted 5 times using 5 x 40 mL diethyl ether. The collected etheric phases were dried using 1 g sodium sulfate. After filtration and evaporation, the slightly yellow powder was cleaned by dissolving it in 2 mL diethyl ether and addition of 5 pellets of charcoal. After subsequent filtration followed by evaporation, the yield was estimated to be 2.54 g (88%). ¹H NMR (CDCl₃) 1.01 (s, 3H), 1.25 (s, 3H), 1.95 (complex absorption, 1H), 2.14 (complex absorption, 1H), 2.39 (complex absorption, 3H), 2.79 (dd, J = 10.2 Hz, J' = 7.55 Hz, 1H).

A mixture of diperoxy-pinic acid (C₉H₁₄O₆) and two different monoperoxy-pinic acids (C₉H₁₄O₅) was synthesized from pinic acid (C₉H₁₄O₄) using a procedure adapted from Parker et al. (1957), who describes the synthesis of various aliphatic diperoxy acids. The structures of the synthesized compounds are shown in Fig. 1. For the synthesis, 10 mg of pinic acid was dissolved in 22 μL of concentrated sulphuric acid and the resulting solution was cooled to 10-15°C in an ice water bath. Under constant stirring, 13 μL of 50% H₂O₂ was slowly added dropwise to the solution. After 180 min reaction time, 100 μL of ammonium sulphate solution (350 mg·ml⁻¹, 4°C) was added to the product solution. Since no precipitate was formed, the solution was mixed with 0.5 ml 20:80 water:acetonitrile and stored in a freezer (-22°C) until further analysis. The product solution consists of two phases, of which the upper one (acetonitrile phase) was used for analysis.

2.2 Flow tube experiments

An aerosol flow tube (2.5 L) was used to produce α-pinene SOA. An overview of the setup for sampling under humid conditions is shown in Fig. 2. Ozone (O₃) was produced by irradiating a flow of synthetic air (200 mL/min) with a UV-lamp (185/254 nm, Appleton Woods®). The resulting average O₃ concentrations were 21-22 ppm under dry conditions and 16-19 ppm under humid conditions as some of the ozone was removed in the Gore-Tex tube of the humidifier (see Fig. 2). Gaseous α-pinene was introduced into the flow tube by passing N₂ (200 mL/min) over 500 μL of liquid α-pinene (about 300 ppm initial concentration), resulting in a reaction time of approximately 6.25 min. For the experiments at higher humidity (~85%), a humidifier was added to the setup. A scanning mobility particle sizer (SMPS) was used to monitor the concentration of produced SOA before and after sample collection. The SMPS consists of a TSI 3080 differential mobility analyser (DMA) connected to a TSI 3775 condensation particle counter (CPC). The average particle mass concentration in the flow tube was about 5·10⁴ μg·m³, assuming a density of 1 g·cm³, with a mode of 200 nm for the number concentration. The produced α-pinene SOA was collected on Durapore® membrane filters (0.1 μm pore size, 47 mm diameter, Merck) for a sampling period of 45 minutes. After sample collection, 100 μL of a 0.60 mg/L camphoric acid solution (20:80 H₂O:ACN) was added to each filter as an internal standard. The filters were extracted by vortexing in 1.5 mL ACN for 5 min. The

extracts were then evaporated down to a volume of 300 μL at 30°C under a steady flow of nitrogen. As a final step, 1.2 mL of 0.1% formic acid in water was added to better match initial mobile phase conditions of the HPLC analysis.

To investigate the influence of humidity on the formation of monoperoxy-pinic acid, a total of 13 filter samples were collected: 7 under dry conditions ($\leq 3\%$ RH), and 6 for α -pinene oxidation at $\sim 85\%$ RH. The average filter mass loading was 0.87 mg for the dry and 0.55 mg for the humid oxidation. All filters were extracted immediately after sampling. Three LC-MS/MS runs were conducted for each filter extract.

The degradation of peroxy-pinic acid in α -pinene SOA was investigated by subsequently collecting SOA on four filters under dry conditions. After collection of the final filter sample, the filters were cut into quarters and divided into four identical composite samples, containing one quarter from each filter. The first composite sample was extracted immediately, following the procedure described in the introduction to section 2.3. The three additional composite samples were extracted after being stored in their filter boxes at room temperature for up to 70 h. All extracts were analysed by HPLC-MS/MS multiple (2-5) times.

2.3 HPLC-MS/MS Analysis

All samples were analysed via HPLC-ESI-MS/MS. An Accela system (Thermo Scientific, San Jose, USA) equipped with a T3 Atlantis C18 column (3 μm ; 3.0 \times 150 mm; Waters, Milford, USA) was used for the chromatographic separation. The detector was a high-resolution LTQ Orbitrap Velos mass spectrometer (Thermo Scientific, Bremen, Germany) with a heated electrospray ionization (HESI) source. All data were analysed with Thermo Xcalibur 2.2.

For analysis of the synthesized standard, 10 μL of the product mixture were diluted with 1 mL of an 80:20 water:acetonitrile mixture. For the flow tube experiments, filters were extracted according to the procedure described in the previous section and measured without further sample processing.

Pinic acid and its synthesized peroxy acids were separated using gradient elution at a flow rate of 200 $\mu\text{L}/\text{min}$. The mobile phase was composed of a mixture of 0.1% formic acid in water (solvent A) and acetonitrile (solvent B). The initial concentration of 20% B was kept constant for two minutes and then increased to 23% over the course of 20 min. After this, it was further increased to 90% within the next 6 min. Over the next 5 min, it was then decreased back to 20% and subsequently kept at this concentration for an additional 10 min, resulting in a method of 43 min total length.

The mass spectrometer was calibrated using Pierce® ESI Negative Ion Calibration Solution (Thermo Scientific, Rockford, USA). All samples were analysed in negative ionization mode, using the following source parameters: spray voltage -3.3 kV, source heater temperature 250°C, capillary temperature 275°C, sheath gas flow 40 arbitrary units, auxiliary gas flow 10 arbitrary units, no sweep gas flow and S-lens RF level 70%. Mass spectra were collected in full scan mode over a mass range of m/z 100–650, using the lock mass of the deprotonated dimer of formic acid at m/z 91.0037 and a resolution of 100 000 at m/z 400. For the majority of measurements, alternating MS/MS scans were performed using a global mass list including the masses of deprotonated pinic, monoperoxy-pinic and diperoxy-pinic acid as well as deprotonated camphoric acid, which was used as an internal standard in the flow tube experiments. The MS/MS scans were performed with a

5 resolution of 60 000, an isolation width of 4 and a mass range that was m/z 50–220 for pinic acid and its derivatives and 50–210 for camphoric acid. The collision energy was 27% for pinic acid and its derivatives and 22% for camphoric acid. A few additional runs were performed with isolation width 1.5, leading to a strongly reduced signal of monoperoxy-pinic acid isomer I. For investigation of the monoperoxyacid dimeric adduct, alternating MS^3 scans were performed instead with the mass of the deprotonated monoperoxy-pinic acids selected for the second fragmentation. In this case, the collision energy was 27% for both fragmentation steps, the resolution was 60 000, the mass range was m/z 55–410 and the isolation width was 4 for the first fragmentation and 2.5 for the second fragmentation. In all cases, collision-induced dissociation (CID) was used to induce fragmentation.

2.4 Evaluation of MS/MS spectra

10 Elemental compositions were assigned with a mass tolerance of 6 ppm, including only the elements carbon, oxygen and hydrogen. The list of MS/MS fragments contains all m/z smaller than the precursor ion which have a relative abundance above the chosen threshold of >1%. The same procedure was repeated with a background subtracted version of the spectrum. The final list of product ions is based on the background subtracted mass list, but additionally excludes m/z which did not have an assigned elemental composition, which could be dismissed as product ions based on their assigned elemental
15 composition or whose extracted ion chromatogram showed a poor overlap with the base peak chromatogram of the MS/MS measurement. While product ions and their relative abundances were selected based on the background subtracted mass list, the masses themselves were taken from the raw data as they showed higher mass accuracy. Since the chromatographic peaks of the two monoperoxy acids overlap (see Fig. 3), special care was taken to separate the two spectra. Only the third of the chromatographic peaks furthest removed from their neighbour was used for the evaluation. In addition to the monomers,
20 there were also dimeric adducts of monoperoxy-pinic acid detected at the same chromatographic peaks. Since they have the same retention time as the monomers, these compounds are ESI artefacts and not actually present in the sample. MS^3 spectra were taken for the mass of the dimeric monoperoxy-pinic acid adduct (m/z 403.16159), which is more prominent for isomer I. The resulting MS^3 spectrum of the dimeric adduct from the isomer I peak shows the same fragments as the MS/MS spectrum of the monomer, but with lower abundances of fragments which the two isomers have in common. It was therefore taken to
25 be closer to the pure spectrum of isomer I and used to characterise MS/MS fragmentations of that compound. Similarly, initial MS/MS conditions lead to low isolation efficiency of the isomer I quasimolecular ion so that the MS/MS spectrum for isomer II was not significantly influenced by isomer I.

2.5 Data analysis of flow tube measurements

To investigate the presence of peroxy-pinic acid in the samples, extracted ion chromatograms of the peracid main fragments
30 were selected. If a peak was found at the appropriate retention time, its MS/MS spectra was compared to that of the corresponding standard. The integrated peak of the extracted ion chromatogram of m/z 183.06 was used for the quantitative

analysis of monoperoxy-pinic acid isomer II. It was normalized to the peak area of the main fragment of camphoric acid, m/z 155.10, and to the mass loading of the filter.

3 Results & discussion

3.1 Liquid chromatography separation of the synthesized standards

5 The chromatogram shows pinic acid and its peroxy acid derivatives, synthesised as described above, elute from the HPLC column in order of decreasing polarity, with pinic acid eluting first, followed by the two monoperoxy pinic acids and finally diperoxy-pinic acid (Fig. 3). While the acid and diperoxy acid are clearly separated from the monoperoxy acids, the two monoperoxy-pinic acids strongly overlap due to similar polarities. Peaks were assigned based on deprotonated analyte ions ($[M-H]^-$), as well as the occurrence of different fragmentations for the two monoperoxy-pinic acid isomers.

10 3.2 Mass spectrometry of pinic acid and the synthesized standards

All four analytes were detected as quasimolecular $[M-H]^-$ ions. In the case of pinic acid and the two monoperoxy-pinic isomers, the quasimolecular ion is dominant in the chromatographic peak. In contrast, the mass spectrum of diperoxy-pinic acid was dominated by $[M-H]^-$ ions of pinic and monoperoxy-pinic acid, which were about an order of magnitude more abundant than the diperoxy-pinic acid $[M-H]^-$ ion. As described in previous papers (Harman et al., 2006; Steimer et al., 2017),
15 this likely indicates an electrochemical reduction of the analyte (i.e., diperoxy-pinic acid) in the ion source. The pinic acid quasimolecular ion was also present in the monoperoxy-pinic acid spectra, although about an order of magnitude less abundant than the monoperoxy-pinic acid quasimolecular ion, which follows the trend of less efficient electroreduction of monoperoxy vs. diperoxy acids observed in our previous paper (Steimer et al., 2017). Tandem mass spectrometry was performed on all four analyte $[M-H]^-$ ions, the results of which are summarized in Tab. 1. The fragments observed for the
20 pinic acid MS/MS are in line with results from previous studies (Glasius et al., 1999; Yasmeen et al., 2011), where loss of CO_2 was observed as the main fragmentation process.

All neutral loss fragments observed for pinic acid also occurred for both of the monoperoxy-pinic acid isomers. However, as previously observed for aliphatic peroxy acids, there are additional loss processes present compared to the acid (Steimer et al., 2017), four of which are shared between the two isomers. Two of the resulting fragment ion types, $[M-CH_2O_2]^-$ and $[M-CH_4O_4]^-$, were observed in our previous study for linear monoperoxydicarboxylic acids, while $[M-C_2H_2O_4]^-$ was also
25 observed for the only measured cyclic monoperoxydicarboxylic acid (monoperoxy-camphoric acid) and $[M-C_2H_2O_3]^-$ was not detected for any of the peroxy acids investigated in our previous study (Steimer et al., 2017).

The MS/MS spectra of the two isomers can be easily distinguished. While the main difference lies in the relative abundances of the various fragment ions, the spectrum of isomer I also shows several fragments not present for isomer II. Using, this
30 information, it was possible to determine that electroreduction of diperoxy-pinic acid in the ion source predominantly leads to formation of isomer II.

The diperoxy-pinic acid spectrum is dominated by loss of CHO_3 , a process which was also observed for monoperoxy-camphoric acid and monoperoxy-pinic acid isomer I. Two other relatively abundant neutral losses are peracid-specific fragments: H_2O_2 , which was previously also observed in linear diperoxy acids, and $\text{C}_2\text{H}_2\text{O}_5$, which gives a minor contribution to the spectrum of monoperoxy-pinic acid isomer I.

- 5 In summary, the three peroxy acids synthesised here showed unique trends in fragmentation patterns for mono- and diperoxy acids, respectively. Some of these fragmentations were also observed for the 15 peroxy acids we characterised earlier (Steimer et al., 2017). The consistent fragmentation patterns of peroxy acids suggests that they might be suitable to identify unknown peroxy acids in SOA, e.g. as HOMs or ROS markers.

3.3 Flow tube experiments

- 10 The formation of peroxy-pinic acids in SOA formed through ozonolysis of α -pinene was investigated using the flow tube set up detailed above. The MS/MS spectra of the filter extracts showed presence of both monoperoxy-pinic acid isomers (both suggested to form during α -pinene ozonolysis (Docherty et al., 2005; Reinnig et al., 2009)), while there was no evidence of diperoxy-pinic acid formation. While both monoperoxy-pinic acid isomers were formed during α -pinene oxidation, the peak of isomer I was often too small for reliable integration, so that only isomer II was chosen for the following quantitative
15 analyses. Even though isomer II could be reliably detected, it is only a minor product of the α -pinene oxidation, with about 1/5500 the peak area of pinic acid.

3.3.1 Humid vs. dry conditions

- The relative yields of monoperoxy-pinic acid under dry and humid ozonolysis conditions were investigated experimentally and *via* the AtChem box model (<https://atchem.leeds.ac.uk>). The complete reaction scheme for the degradation of α -pinene
20 was extracted from the Master Chemical Mechanism (MCM) v3.3.1 (Jenkin et al., 1997; Saunders et al., 2003) via the MCM website (<http://mcm.leeds.ac.uk/MCM>). Gas-phase only simulations were performed for dark ozonolysis with $[\alpha\text{-pinene}]_0 = 300$ ppm and $[\text{O}_3]_0 = 20$ ppm. The yield of monoperoxy-pinic acid per O_3 molecule was $\sim 6 \times 10^{-5}$ (~ 1.2 ppb) under dry conditions. This relative yield was insensitive to RH (0-100%) and initial precursor concentrations (1-300 ppm), suggesting an unimportant role for water vapour in the gas-phase mechanism. The yield of monoperoxy-pinic acid was $\sim 1/500$ that of
25 pinic acid in the simulations, compared to the experimental estimate above ($\sim 1/5500$).

- In the condensed phase, however, the formation of peracids from the carboxylic acid is reversible, with presence of liquid water shifting the equilibrium towards the acid (d'Ans and Frey, 1912; Parker et al., 1955). Increased humidity, leading to an increased fraction of water in the particle phase, could therefore lead to less peroxy-pinic acid in α -pinene ozonolysis SOA. We proceeded with experiments to investigate whether humidity-dependent gas-particle partitioning and/or condensed-phase
30 reactions, not accounted for in the model, could influence peroxy acid yields.

The concentration of monoperoxy-pinic acid isomer II in SOA was compared under dry ($\leq 3\%$ RH) and humid ($\sim 85\%$ RH) conditions. The results of the comparison are shown in Fig. 4. Within the current limits of uncertainty, no difference in

monoperoxyipinic acid production was found for the two reaction conditions. This indicates that hydrolysis of monoperoxyipinic acid is not a significant loss process under the studied conditions (i.e. reactant concentrations and reaction time). Available studies of the hydrolysis of peracetic acid show that its hydrolysis kinetics strongly depend on the reaction conditions, such as temperature and pH (Dul'neva and Moskvina, 2005; Yuan et al., 1997), leading to large variations in decomposition rates. The main factors limiting precision of the measurement are low signal intensity, uncertainty of the measurement of filter mass loading and peroxyipinic acid degradation on the filter, as described in the following section.

3.3.2 Peroxy acid degradation over time

We investigated the stability of monoperoxyipinic acid isomer II in SOA over time when the filter was stored at room temperature after collection. In many studies characterising SOA composition in detail on a molecular level, filter samples, especially from field campaigns, are collected many hours to days or weeks before analysis. While these samples usually kept at low temperatures for long-term storage, they are collected at room temperature, which can take longer than 24 h and there is often significant delay between sampling and storage. For thermally unstable compounds such as peroxides and peroxy acids, this might result in decomposition prior to analysis and thus risks underestimating the abundance of such compounds.

Monitoring of the amount of peroxy acid on the collected filters over almost three days clearly shows that this compound significantly degrades (Fig. 5). About 60% of monoperoxyipinic acid is lost within the first five hours. Given that the measured samples were composites of four subsequently collected filters, the average age of the SOA sample before extraction is ca. 100 min. Therefore, a significant amount of monoperoxyipinic acid will already have been lost at the time of analysis. Repeated measurements of the extracts over 22 hours showed that there is also a change in concentration over time in the liquid phase, however significantly less pronounced with a maximum of factor two difference to the initial measurement. We therefore attempted to measure all extracts as soon as possible after extraction, using the same number of repeats. This was not always possible for the experiment shown as purple diamonds in Fig. 5, contributing to the uncertainty of the results.

4 Conclusions

In this study, we successfully synthesized three peroxyipinic acids and showed that they can be distinguished from each other and the analogous carboxylic acid via their retention times in HPLC-MS and their specific MS/MS spectra. This technique can therefore be used to identify peroxyipinic acids in SOA samples. We have shown that one of the peroxyipinic acids, monoperoxyipinic acid isomer II, was present in laboratory-generated α -pinene SOA. There was no observed effect of humidity on the production of monoperoxyipinic acid from α -pinene, i.e. the reaction times in our flow tube set up were possibly too short to observe any potential decay due to hydrolysis. It was shown that monoperoxyipinic acid quickly degrades, with about 60% lost within the first 5 hours. This demonstrates that filters need to be analysed as soon as possible

after collection to avoid serious underestimation for such compounds, which presents a major problem particularly during field campaigns, where such immediate analysis is often not feasible. Ideally online techniques would need to be developed to quantify such unstable compounds in atmospheric aerosols.

Table 1: MS/MS fragmentations of [M-H]⁻ ions from pinic acid and its peroxyacid analogues.

Compound	Deprotonated molecule [M-H] ⁻	<i>m/z</i> (Δ ppm)	Product ion <i>m/z</i> (rel. abund.) ^a	Neutral loss(es)
Pinic acid	C ₉ H ₁₃ O ₄ ⁻	185.08193 (-0.002)	141.09194 (100) 167.07127 (16) 123.08155 (4)	CO ₂ H ₂ O CH ₂ O ₃
Monoperoxy-pinic acid isomer I	C ₉ H ₁₃ O ₅ ⁻	201.07706 (1.060)	111.08149 (100) 155.07127 (38) 139.07639 (37) 140.08423 (10) 157.08694 (8) 183.06619 (8) 127.07643 (5) 84.02166 (3) 115.00367 (3) 129.05568 (3) 99.04513 (2) 111.04514 (2) 121.06583 (2) 184.07401 (1) 95.08662 (1)	C ₂ H ₂ O ₄ CH ₂ O ₂ CH ₂ O ₃ CHO ₃ CO ₂ H ₂ O C ₂ H ₂ O ₃ C ₃ H ₉ O ₃ C ₃ H ₁₀ O C ₃ H ₄ O ₂ C ₄ H ₆ O ₃ C ₃ H ₆ O ₃ CH ₄ O ₄ OH C ₂ H ₂ O ₅
Monoperoxy-pinic acid isomer II	C ₉ H ₁₃ O ₅ ⁻	201.07711 (1.293)	183.06605 (100) 157.08678 (35) 139.07625 (31) 155.07116 (10) 111.08142 (5) 127.07635 (2) 121.06577 (2)	H ₂ O CO ₂ CH ₂ O ₃ CH ₂ O ₂ C ₂ H ₂ O ₄ C ₂ H ₂ O ₃ CH ₄ O ₄

^a Average of three MS/MS spectra, with exception of monoperoxy-pinic acid isomer I (average of two MS³ spectra, see section 2.4 for discussion)

Diperoxy-pinic acid	$C_9H_{13}O_6^-$	217.07232 (2.573)	156.07910 (100)	CHO_3
			155.07132 (16)	CH_2O_3
			111.08152 (13)	$C_2H_2O_5$
			183.06628 (7)	H_2O_2
			171.06625 (3)	CH_2O_2
			173.08189 (2)	CO_2
			199.06122 (1)	H_2O
			74.00093 (1)	$C_7H_{11}O_3$
			127.07646 (1)	$C_2H_2O_4$

Figure 1 Structures of pinic acid and its peroxy acid derivatives synthesised and characterised in this study.

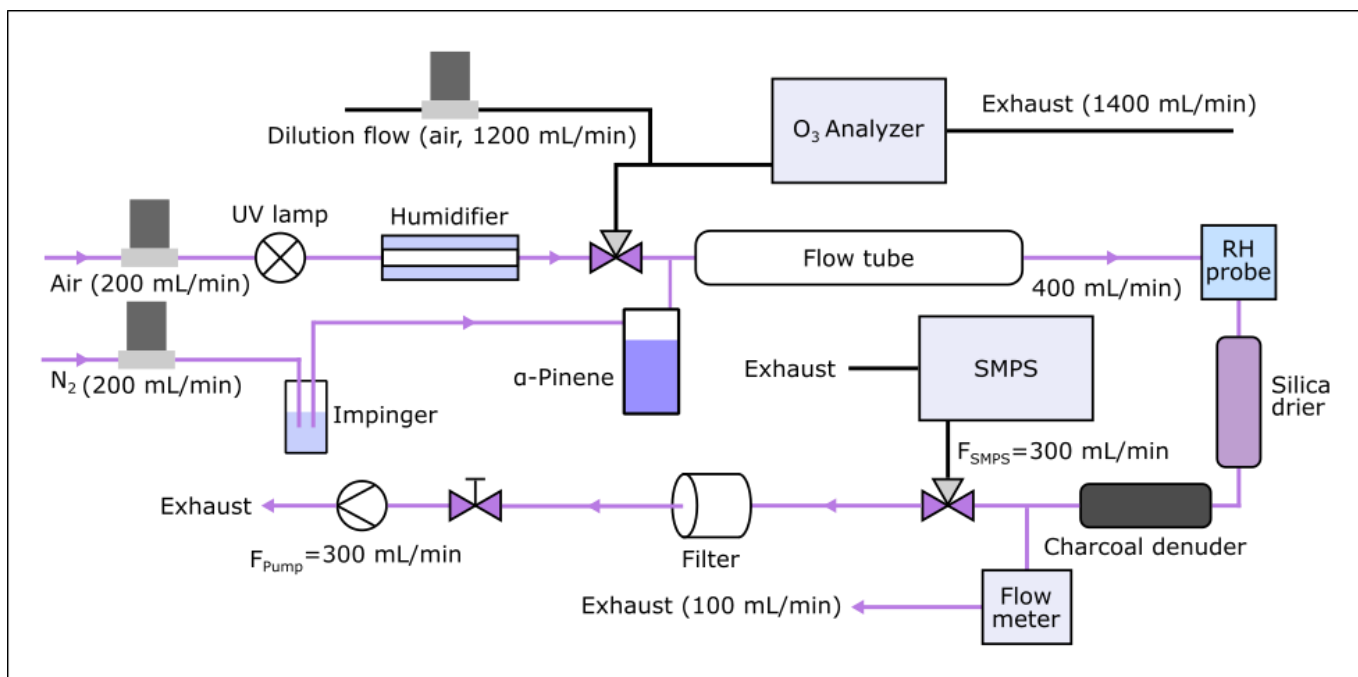

Figure 2: Flow tube setup for oxidation under humid conditions. The pink lines show the gas and aerosol flow path during sample collection, when O₃ analyser and SMPS are not connected.

5 Figure 3: Base peak chromatogram showing the separation of pinic acid (1), monoperoxy-pinic acid isomers I and II (2, 3) and diperoxy-pinic acid (4).

Figure 4: Monoperoxydic acid isomer II as a product of α -pinene oxidation under dry and humid conditions; error bars show the standard deviation between repeat measurements. The peak area was normalized to the peak area of the internal standard and the aerosol mass on the filter.

5

Figure 5 : Degradation of monoperoxydic acid isomer II on the filter illustrating its short lifetime of only a few hours.
