

28 heterogeneous hydrolysis at higher altitude air masses aloft could be an important
29 source for haze formation in the urban airshed during wintertime. Accurately
30 describing the formation and development of reactive air masses aloft is a critical task
31 for improving current chemical transport models.

32

33 **1. Introduction**

34 Winter particulate matters (PM) pollution events occur frequently in China, and have
35 drawn widespread and sustained attention in recent years (Guo et al., 2014; Zhang et
36 al., 2015; Huang et al., 2014). PM pollution reduced visibility (Lei and Wuebbles,
37 2013) and had harmful effects on public health (Cao et al., 2012). Particulate nitrate
38 (pNO_3^-) is an important component of secondary inorganic aerosols, and contributed
39 to 15–40% of the $\text{PM}_{2.5}$ mass concentration in China (Sun et al., 2013, 2015a, 2015b;
40 Chen et al., 2015; Zheng et al., 2015; Wen et al., 2015). The main atmospheric
41 pathways of nitrate formation are (1) the reaction of OH with NO_2 and (2) N_2O_5
42 heterogeneous hydrolysis (Seinfeld and Pandis, 2006). The first reaction ($\text{OH} + \text{NO}_2$)
43 was a daytime pathway since OH is severely limited at night, and N_2O_5 uptake was
44 refer to a nighttime pathway as NO_3 and N_2O_5 is easily photo-labile.

45 Nitrate formation via N_2O_5 heterogeneous hydrolysis was proved efficient by
46 ground based observation in summer in North China (H.C. Wang et al., 2017b; Z.
47 Wang et al., 2017), which is comparable with or even high than the daytime formation.
48 Several model studies showed N_2O_5 hydrolysis is responsible for nocturnal pNO_3^-
49 enhancement in Beijing (Pathak et al., 2009, 2011; H.C. Wang et al., 2017a). Although
50 the pNO_3^- formation via N_2O_5 uptake is significant in summertime, the importance of
51 this pathway in wintertime was not well characterized. As there are many differences
52 of N_2O_5 chemistry between winter and summer. First, as the key precursor of NO_3 and
53 N_2O_5 , O_3 level are much lower in winter than in summer due to short daytime length
54 and weak solar radiation. Second, colder temperatures and high NO_2 levels favor
55 partitioning towards N_2O_5 . Third, nighttime lasts much longer in winter, making N_2O_5
56 heterogeneous hydrolysis potentially more important in pNO_3^- formation. Finally,

57 N_2O_5 uptake coefficient, the most important parameter in N_2O_5 heterogeneous
58 hydrolysis, is likely very different from that in summer. Since the particle
59 characteristics and meteorological conditions (e.g. organic compounds, particle nitrate,
60 liquid water contents, solubility, viscosity and relative humidity) are different in
61 summer and winter (Chen et al., 2015; Zhang et al., 2007). These differences would
62 result in the N_2O_5 uptake coefficient has large variation (Wahner et al., 1998; Mentel
63 et al., 1999; Kane et al., 2001; Hallquist et al., 2003; Thornton et al., 2003; Bertram
64 and Thornton, 2009; Grzanic et al., 2015; Wagner et al., 2013).

65 In addition to seasonal differences, previous studies have also shown a potential
66 altitude dependence in pNO_3^- production. In the evening, vertical mixing is strong
67 suppressed in nocturnal boundary layer (NBL) due to the reduction of sunlight
68 diminishes the heating of the earth's surface, leading to vertical layer occur with NO_3
69 and N_2O_5 gradient (Brown et al., 2007), as well as the particle compounds percentage
70 and size distribution (Ferrero et al., 2010; 2012). On nights when NO_3 radical
71 production in the surface layer is negligible due to high NO emissions, N_2O_5 uptake
72 may still be active aloft without NO titration (Pusede et al., 2016; Baasandorj et al.,
73 2017). The N_2O_5 uptake aloft leads to elevated pNO_3^- formed in the upper layer with
74 effective NO_x removal (Watson et al., 2002; S.G. Brown et al., 2006; Lurmann et al.,
75 2006), which was reported with field observations at a high altitude site in Kleiner
76 Feldberg, Germany (Crowley et al., 2010a), London British Telecommunications
77 tower, UK (Benton et al., 2010), Boulder Atmospheric Observatory (BAO) tower in
78 Colorado, USA (Wagner et al., 2013) and so on. Model studies also proposed nitrate
79 formation varied in different height (Kim et al., 2014; Ying, 2011; Su et al., 2017).
80 The mass fraction and concentration of pNO_3^- in Beijing was reported higher aloft
81 (260 m) than at the ground in Beijing (Chan et al., 2005; Sun et al., 2015b), and they
82 explained the favorable gas-particle partitioning aloft under lower temperature
83 conditions.

84 To explore the possible sources of pNO_3^- and the dependence of altitude in
85 wintertime, we conducted vertical profile measurements of NO, NO_2 , and O_3 with a
86 tower platform in combination with simultaneous ground measurements of these

87 parameters in urban Beijing. A box model was used to investigate the reaction rate of
88 N_2O_5 heterogeneous hydrolysis and impact on pNO_3^- formation at different altitudes
89 during a heavy haze episode over urban Beijing. Additionally, the dependence of
90 pNO_3^- formation on the N_2O_5 uptake coefficient was probed.

91

92 2. Methods

93 2.1 Field measurement

94 Ground measurement (15 m above the ground) was carried out in the campus of
95 Peking University (PKU, 39°59'21"N, 116°18'25"E) in Beijing, China. The location
96 of the PKU site was shown in Fig. 1, as well as the vertical measurement site (IAP,
97 introduced below). At PKU site, dry-state mass concentration of $\text{PM}_{2.5}$ was measured
98 by a TEOM 1400A analyzer. NO_x was measured by chemiluminescence analyzer
99 (Thermo Scientific, TE-42i-TR) and O_3 was measured by a UV photometric O_3
100 analyzer (Thermo Scientific, TE-49i). Dry state particle number and size distribution
101 (PNSD) was measured from 0.01 to 0.6 μm with a Scanning Mobility Particle Sizer
102 (SMPS, TSI Inc. 3010). These parameters were listed in Table S1. The data were
103 collected from December 16 to 22, 2016. Additionally, relative humidity (RH),
104 temperature (T), wind direction and speed were available during the measurement
105 period.

106 Vertical profile measurements were conducted from December 18 to 20, 2016 at the
107 tower-based platform (maximum height: 325 m) on the campus of the Institute of
108 Atmospheric Physics, Chinese Academy of Sciences (IAP, 39°58'28"N, 116°22'16"E),
109 during a heavy PM pollution episode. The IAP site is just with 4 km distance from the
110 PKU site. The measurement instruments were installed on board a movable cabin on
111 the tower. The ambient NO_x and O_3 concentrations were measured with two
112 low-power, light-weight instruments (Model 405 nm and Model 106-L; 2B
113 Technologies, USA). The Model 405 nm instrument measures NO_2 directly based on
114 the absorbance at 405 nm, and NO is measured by adding excess O_3 (conversion
115 efficiency ~100%). The limit of detection of both NO and NO_2 is 1 part per billion

116 volume (ppbv), with an accuracy of 2 ppbv or 2% of the reading, and the time
117 resolution is 10 s. The Model 106-L instrument measures O₃ based on the absorbance
118 at 254 nm with a precision of 1 ppbv or 2% of the reading and a limit of detection of 3
119 ppbv. Height information was retrieved from the observed atmospheric pressure
120 measured by Model 405 nm instrument. The cabin ascended and descended at a rate
121 of 10 m min⁻¹, with a height limit of 260 m at daytime and 240 m at night. The cabin
122 stopped after reaching the peak and parameters were measured continually for the last
123 10 min of each cycle. One vertical cycle lasted for approximately 1 h. We measured
124 two cycles per day, one in the morning and the other in the evening.

125

126 2.2 Box model simulation

127 A box model was used to model the NO₃ and N₂O₅ mixing ratios and the nitrate
128 formation potential in vertical scale at IAP site. A simple chemical mechanism (see
129 R1-R5) is used to model the nighttime NO₃ and N₂O₅ chemistry in NO free air masses,
130 and the physical mixing, dilution, deposition, or interruption during the transport of
131 the air mass were not considered. Here *f* represents the ClNO₂ yield from N₂O₅ uptake.
132 Homogeneous hydrolysis of N₂O₅ and NO₃ heterogeneous are neglected in this
133 analysis because there is little absolute humidity and extremely low NO₃
134 concentration during wintertime (Brown and Stutz, 2012). The corresponding rate
135 constants of R1- R3 are those reported by Sander et al., (2011).

141 Following the work of Wagner et al., (2013), the box model can be solved by four
142 equations (Eq. 1-4). In the framework, O₃ only losses via the reaction of NO₂+O₃ and
143 the change of the O₃ concentration can express as Eq. 1. Since the ratio of N₂O₅ to
144 NO₃ was calculated to be larger than 150:1 in a typical urban region in wintertime

145 ($\text{NO}_2 = 15$ ppbv, nighttime temperature = 0°C), N_2O_5 is proposed to be dominate the
 146 NO_3 loss, than means two molecules of NO_2 lost (convert to nitrate or ClNO_2) for one
 147 molecule NO_3 formed (Eq. 2). In the model we need to know the mixing ratio of NO_2
 148 and O_3 at time zero (here set to sunset). According to Eq. 1 and Eq. 2, the NO_2 ($t=0$)
 149 and O_3 ($t=0$) concentration can derived from the duration time and the vertical
 150 measured NO_2 and O_3 at each height. Assuming the equilibrium between NO_3 and
 151 N_2O_5 is maintained after a time period, the sum concentration of NO_3 and N_2O_5 can
 152 be described by Eq. 3. Using the temperature dependent equilibrium rate constant (k_{eq})
 153 and the modeled NO_2 at a certain time, Eq. 4 can be used to determine the ratio of
 154 N_2O_5 and NO_3 . Combined, Eq. 1-4 allow for the calculation of N_2O_5 concentrations,
 155 given a constant of NO_3 and N_2O_5 rate constant (k_{NO_3} and $k_{\text{N}_2\text{O}_5}$). Modeled N_2O_5
 156 concentrations and given $k_{\text{N}_2\text{O}_5}$ are then used to estimate pNO_3^- formation, here the
 157 HNO_3 produced in R4 is not accounted, as a large part of the products are organic
 158 nitrates (Brown and Stutz, 2012). Here k_{NO_3} and $k_{\text{N}_2\text{O}_5}$ denotes the pseudo first order
 159 reaction rate constant of the total NO_3 reactivity caused by ambient volatile organic
 160 compounds (VOCs) and N_2O_5 heterogeneous uptake, respectively. $k_{\text{N}_2\text{O}_5}$ is given in
 161 Eq. 5. S_a is aerosol surface area, C is the mean molecular speed of N_2O_5 , and $\gamma_{\text{N}_2\text{O}_5}$ is
 162 N_2O_5 uptake coefficient. The model is run from sunset to sunrise, where the length of
 163 night was about 14.5 h.

$$164 \quad (\text{Eq. 1}) \quad \frac{d[\text{O}_3]}{dt} = -k_{\text{NO}_2+\text{O}_3}[\text{O}_3][\text{NO}_2]$$

$$165 \quad (\text{Eq. 2}) \quad \frac{d[\text{NO}_2]}{dt} = -2 \times k_{\text{NO}_2+\text{O}_3}[\text{O}_3][\text{NO}_2]$$

$$166 \quad (\text{Eq. 3}) \quad \frac{d[\text{NO}_3+\text{N}_2\text{O}_5]}{dt} = k_{\text{NO}_2+\text{O}_3}[\text{O}_3][\text{NO}_2] - k_{\text{N}_2\text{O}_5}[\text{N}_2\text{O}_5] - k_{\text{NO}_3}[\text{NO}_3]$$

$$167 \quad (\text{Eq. 4}) \quad \frac{[\text{N}_2\text{O}_5]}{[\text{NO}_3]} = k_{\text{eq}}[\text{NO}_2]$$

$$168 \quad (\text{Eq. 5}) \quad k_{\text{N}_2\text{O}_5} = \frac{C \times S_a \times \gamma_{\text{N}_2\text{O}_5}}{4}$$

169 Dry-state S_a at PKU site was calculated based on the PNSD measurement, which
 170 was corrected to ambient (wet) S_a for particle hygroscopicity by a growth factor (Liu
 171 et al., 2013). The uncertainty of the wet S_a was estimated to be ~30%, which was
 172 associated from the error from dry PNSD measurement (~20%) and the growth factor

173 (~20%). Nighttime averaged S_a on the night of December 19 is about $3000 \mu\text{m}^2 \text{cm}^{-3}$.
174 PM measurements by National Monitoring Sites proved this heavy haze pollution
175 episode was a typical regional event (Fig. S1). Furthermore, synchronous study on the
176 night of December 19, 2016 shown small variation of vertical particle number
177 concentration, with the boundary layer height below 340 m (Zhong et al., 2017).
178 Therefore, the S_a at PKU site is representative to the urban Beijing conditions and
179 applied in the model is reasonable.

180 N_2O_5 uptake coefficient was regard as the main uncertainty of the N_2O_5 loss, along
181 with the ClNO_2 yield lead to the uncertainties in the estimation of particulate nitrate
182 formation (Thornton et al., 2010; Riedel et al., 2013; Wagner et al., 2013; Phillips et
183 al., 2016). Wagner et al., (2013) shows the significant particular nitrate suppression
184 aloft in the wintertime in Denver, USA, with the uptake coefficient of about 0.005
185 when particulate nitrate fraction in the $\text{PM}_{2.5}$ mass concentration about 40%.
186 Considered the high particle nitrate content in North China in wintertime is similar to
187 that in Denver (Sun et al., 2013, 2015a; Chen et al., 2015; Zheng et al., 2015; Wen et
188 al., 2015), here we used a constant uptake coefficient of 0.005 as the model initial
189 input in the base case, and the uncertainty of N_2O_5 uptake coefficients will be
190 discussed later. Since the model input of ClNO_2 yield only affect the value of
191 produced particulate nitrate concentration, and would not change the modeled N_2O_5
192 concentration, here we set the initial f_{ClNO_2} to zero. The impact of ClNO_2 yield will be
193 further discussed later.

194 Respect to k_{NO_3} , the average value in summertime was estimated to be 0.024 s^{-1} in
195 2006 (H.C. Wang et al., 2017a). While in wintertime, the k_{NO_3} should be smaller as
196 the intensity of plant emissions reduced in the lower temperature and weak solar
197 radiation. The model input $k(\text{NO}_3)$ was set to an relative moderate value of 0.02 s^{-1}
198 (equivalent to 0.2 ppbv isoprene + 40 pptv monoterpene + 1.0 ppbv cis-2-butene). A
199 series of sensitivity tests were conducted to study the uncertainties to the model
200 simulation, and the detailed test set were listed in Table 1, included the test of N_2O_5
201 uptake coefficient and k_{NO_3} . The $\gamma_{\text{N}_2\text{O}_5}$ sensitivity tests were set to a lower limit of
202 0.001 to a upper limit of 0.05, as well as the k_{NO_3} set to 0.001, 0.01 and 0.1 s^{-1} .

203 3. Results and discussion

204 3.1 Ground-based observations.

205 A severe winter PM pollution event was captured from the ground observations from
206 December 16 to 22, 2016 in Beijing. Figure 2a shown the mass concentration of PM_{2.5}
207 began to increase on December 16 and reached the maximum value of 480 $\mu\text{g m}^{-3}$
208 December on 20. A fast PM growth event happened on the night of December 19–20
209 (colored red in Fig. 2a), the PM_{2.5} mass concentration increased continuously
210 throughout the night, with an overall increment of 100 $\mu\text{g m}^{-3}$. During the episode, the
211 meteorological condition is featured with high RH (50% \pm 16%) and low temperature
212 (2 \pm 3 °C). The slow surface wind (< 3 m s⁻¹) indicated the atmosphere was static
213 stabilized (Fig. 2c, 2d). The daytime O₃ concentration was low due to high NO
214 emission and weak solar radiation. After sunset, O₃ was rapidly titrated to zero by the
215 elevated NO. The presence of high NO concentrations would have strongly
216 suppressed the concentration of NO₃, and further suppressed N₂O₅ near the ground.
217 Figure 2b depicted large amounts of NO and NO₂ were observed throughout the
218 whole PM pollution episode, suggesting that pNO₃⁻ production via N₂O₅ uptake was
219 not important near the ground during the winter haze episode.

220

221 3.2 Tower observations.

222 Six vertical measurements of Ox (< 50 m) was consist with that measured at ground
223 level and shown in Fig. S2, confirmed the two sites are comparable at ground level at
224 last. On the night of December 20 (Fig. 3a), the NO₂ and NO from 0-240 m were
225 abundant and conservative around 21:00, with the concentration of 80 ppbv and 100
226 ppbv, respectively. The O₃ concentrations keep zero during the nighttime (Fig. 3b).
227 The vertical profile on December 20 suggests that at least below 240 m, the N₂O₅
228 chemistry is also not important like ground level as mentioned above. The case on the
229 night of December 18 is similar to the night of December 20.

230 The vertical measurement on December 19 did not like those happened on

231 December 18 and 20. Figure 4a shows the vertical profiles around 21:00 on December
232 19 that NO was abundant from the ground to 100 m, then gradually decreased to zero
233 from 100 m to 150 m, and stay zero above 150 m. The observed NO₂ concentration
234 was 85 ± 2 ppbv below 100 m, which gradually decreased from 100 m to 150 m, and
235 was 50 ± 2 ppbv from 150 m to 240 m. The observed O₃ concentrations were below
236 the instrument limit of detection below 150 m (Fig. 4b). Above 150 m, the O₃
237 concentration was 20 ± 2 ppbv, corresponding to the greatly diminished NO
238 concentration. With respect to the total oxidants (Ox = O₃ + NO₂), the mixing ratio of
239 Ox was 85 ± 2 ppbv at lower altitudes, while the Ox concentration at higher altitudes
240 was 15 ppbv lower than that at lower altitude (Fig. 4b). The O_x missing at the higher
241 altitude air mass indicated an additionally nocturnal removal of Ox aloft.

242 Figure 5 depicted the vertical measurement at 09:30 on the morning of December
243 20 has similar features with those observed at 21:00 on December 19, and the NBL
244 still not be broken. The O_x missing aloft in the morning increased to 25 ppbv at
245 240–260 m, demonstrated that an additional 25 ppbv of Ox was removed or converted
246 to other compounds at higher altitudes than surface layer on the night of December
247 19–20. Figure S3 shows the vertical profiles of NO, NO₂, O₃ and Ox at ~12:00 on
248 December 18, when the solar radiation is strong enough to drive the trace gas mixing
249 well in vertical direction. NO_x and O₃ were observed well mixed indeed, with small
250 variation from ground level to 260 m.

251

252 3.3 Particulate nitrate formation aloft.

253 N₂O₅ uptake is one of the two most important pathways of the ambient NO_x losses,
254 and is consequently an important pathway of pNO₃⁻ formation (Wagner et al., 2013;
255 Stutz et al., 2010; Tsai et al., 2014). At higher altitudes (e.g. > 150 m), NO₃ and N₂O₅
256 chemistry can be initiated in the co-presence of high NO₂ and significant O₃ levels.
257 Therefore, N₂O₅ uptake could represent a plausible explanation for the observed O_x
258 missing in the higher-altitude air masses on the night of December 19. To explore this
259 phenomenon, a time-step box model was used to simulate the NO₃ and N₂O₅

260 chemistry based on the observed vertical profiles of NO_2 and O_3 on the night of
261 December 19.

262 In the base case, the modeled N_2O_5 concentration is zero below 150 m, as the high
263 level NO consumed NO_3 formation fast. While the modeled N_2O_5 concentrations at
264 21:00 were in the range of 400-600 parts per trillion volume (pptv) above 150 m (Fig.
265 5a). pNO_3^- accumulation via N_2O_5 heterogeneous hydrolysis from sunset to the
266 measurement time was significant, yielding a maximum of $24 \mu\text{g m}^{-3}$ within 4.5 hours
267 after sunset (Fig. 5(b)).

268 The box model enabled the analysis of the integrated pNO_3^- and ClNO_2 via N_2O_5
269 uptake over the whole night. As shown in Fig. 5c, the modeled integrated pNO_3^- went
270 up to as high as $50 \mu\text{g m}^{-3}$. The integrated pNO_3^- at sunrise was equal to the loss of 27
271 ppbv O_x , shows a good agreement with the observed O_x missing aloft at the morning
272 hours. During the nighttime, the formed pNO_3^- aloft via N_2O_5 uptake would lead to
273 the particle nitrate concentration much higher than that in the surface layer, which has
274 been reported many field observations (Watson et al., 2002; S.G. Brown et al., 2006;
275 Lurmann et al., 2006; Ferrero et al., 2012; Sun et al., 2015b). In addition, during the
276 morning time when NBL was broken, the elevated pNO_3^- aloft will vertically mixed
277 and enhanced the PM concentration at surface layer, this phenomenon also been
278 observed in previous studies (Watson et al., 2002; S.G. Brown et al., 2006; Lurmann
279 et al., 2006). In this case, the planetary boundary layer (PBL) height during the
280 daytime is about 340 m on December 20 (Zhong et al., 2017). Assuming that the
281 height of NBL and planetary boundary layer (PBL) are the same, and the air mass was
282 well mixed in the following morning in the PBL. The nighttime N_2O_5 uptake aloft
283 would be enhanced the ground pNO_3^- mass concentration significantly with $28 \mu\text{g m}^{-3}$
284 in the morning, which is in good agreement with the observed PM peak in the
285 morning on December 20, with the PM enhancement of $\sim 60 \mu\text{g m}^{-3}$. The result
286 demonstrated that the nocturnal N_2O_5 uptake aloft and downward transportation are
287 really importance in understanding the PM growth process.

288

289 3.4 Sensitivity studies.

290 Previous studies have emphasized that the N_2O_5 uptake coefficient varies greatly
291 (0.001–0.1) in different ambient conditions (Brown and Stutz, 2012; H.C. Wang et al.,
292 2016), which is the main source of uncertainties in the model. Sensitivity tests
293 illustrate that the modeled N_2O_5 concentration varied from 3 ppbv to 60 pptv when the
294 N_2O_5 uptake coefficients were varied from 0.001 to 0.05 (Fig. 6a), the N_2O_5
295 concentration is very sensitivity to the loss from heterogeneous reaction. Compared
296 with the base case, the accumulated pNO_3^- is evidently lower at $\gamma = 0.001$ with the
297 accumulated pNO_3^- of $44 \mu\text{g m}^{-3}$, the low N_2O_5 uptake coefficient condition is
298 corresponding to several kinds of aerosols, such as secondary organic aerosol (Gross
299 et al., 2009), humic acid (Badger et al., 2006)) and certain solid aerosols (Gross et al.,
300 2008). When the N_2O_5 uptake coefficient enlarges from 0.005 to 0.05 (Fig. 6b, c), the
301 integral pNO_3^- almost not change with negligible increasing, indicating that the
302 conversion capacity of N_2O_5 uptake to pNO_3^- was almost maximized at certain ClNO_2
303 yield, the convert capacity of NO_x to nitrate was not limited by N_2O_5 heterogeneous
304 reaction rate, but the formation of NO_3 by the reaction of NO_2 with O_3 .

305 For describing the nocturnal NO_x convert capacity to particulate nitrate via N_2O_5
306 uptake coefficient, here we defined the particle nitrate convert efficiency (ϵ) as Eq. 6.
307 The Δt represents the time duration from time zero at sunset till the ending time at
308 sunrise.

$$309 \text{ (Eq. 6)} \quad \epsilon = \frac{\sum_0^{\Delta t} k_{\text{N}_2\text{O}_5} [\text{N}_2\text{O}_5]}{\sum_0^{\Delta t} 2 \times k_{\text{NO}_2 + \text{O}_3} [\text{O}_3] [\text{NO}_2]}$$

310 In the case, S_a is set to $3000 \mu\text{m}^2 \text{cm}^{-3}$, the ClNO_2 yield is zero and k_{NO_3} is 0.02 s^{-1} .
311 Figure 7 shows the dependence of the particle nitrate convert efficiency varied from
312 10^{-5} to 0.1. When $\gamma_{\text{N}_2\text{O}_5}$ is lower than 0.0017, the particle nitrate formation enhanced
313 rapidly with the increasing of N_2O_5 uptake coefficient, here we defined as the $\gamma_{\text{N}_2\text{O}_5}$
314 sensitive region when $\gamma_{\text{N}_2\text{O}_5} < 1.7 \times 10^{-3}$. While $\gamma_{\text{N}_2\text{O}_5} \geq 1.7 \times 10^{-3}$ is defined as $\gamma_{\text{N}_2\text{O}_5}$
315 insensitive region, since the convert efficient is over 90% and not sensitive to the
316 variation of N_2O_5 uptake coefficient. According to Eq. 3 and Eq. 5, higher aerosol
317 surface concentration, higher NO_x , lower k_{NO_3} and temperature would further

318 enlarging the insensitivity region with lower $\gamma_{\text{N}_2\text{O}_5}$ value, and make the N_2O_5 uptake
319 more easily located in the $\gamma_{\text{N}_2\text{O}_5}$ insensitive region. Here the critical value of the N_2O_5
320 uptake coefficient (1.7×10^{-3}) is relative low compared with that IUPAC (International
321 Union of Pure and Applied Chemistry) recommended on the surface of mineral dust
322 (0.013, 290-300K) (Crowley et al., 2010b) or determined in many field experiments
323 (e.g. S.S. Brown et al., 2006; 2009; Wagner et al., 2013; Morgan et al., 2015; Phillips
324 et al., 2016; Z. Wang et al., 2017; Brown et al., 2016; H.C. Wang et al., 2017b; X.F.
325 Wang et al., 2017), suggesting the particulate nitrate formation via N_2O_5 uptake was
326 easily maximized in polluted episode, and further worsen the PM pollution.

327 In the base case, the modeled particulate nitrate formation via N_2O_5 uptake is an
328 upper limit result, as the ClNO_2 yield set to zero. Since large coral combustion
329 emitted chloride into the atmosphere in the heating period in Beijing (Sun et al., 2013),
330 associated with the emission by power plants in North China. The enhanced
331 anthropogenic emission of chloride provides abundant chloride-containing aerosol to
332 form ClNO_2 via N_2O_5 uptake aloft, implying that significant ClNO_2 formed in the
333 upper layer of NBL (Tham et al., 2016; Z. Wang et al., 2017). Assuming the ClNO_2
334 yield is the average value of 0.28 determined at high altitude in North China (Z. Wang
335 et al., 2017), the produced pNO_3^- throughout the whole night will decreased $7 \mu\text{g m}^{-3}$.
336 The ClNO_2 formation aloft throughout the night reach up to 2.5 ppbv, which is
337 comparable with that observed in the field measurement in North China (Tham et al.,
338 2016; Z. Wang et al., 2017; X.F. Wang et al., 2017). As the error of pNO_3^- formation
339 simulation was subject to the ClNO_2 yield, higher yield would increase the model
340 uncertainty directly, probing the ClNO_2 yield are warranted in future studies. As for
341 NO_3 reactivity, Figure 7 shows sensitivity tests of the integral pNO_3^- formation in the
342 whole night at $k_{\text{NO}_3} = 0.001 \text{ s}^{-1}$, 0.01 s^{-1} , 0.02 s^{-1} , 0.05 s^{-1} . The integral pNO_3^-
343 formation was decreased when k_{NO_3} vary from 0.001 s^{-1} to 0.1 s^{-1} , but the variation
344 ratio to base case was within $\pm 5\%$. The result shows the NO_3 - N_2O_5 loss via NO_3 react
345 with VOCs in polluted wintertime is not important, which may only lead to relative
346 small uncertainties to the integral pNO_3^- formation calculation. Nevertheless, if N_2O_5
347 uptake was extremely low (e.g. $\gamma_{\text{N}_2\text{O}_5} < 10^{-4}$), the uncertainty cased by NO_3 oxidation

348 will be enlarged significantly.

349

350 **4. Conclusion**

351 During the wintertime, ambient O₃ is often fully titrated to be zero at the ground of
352 urban Beijing due to fast reaction with NO emissions. Consequently, the near surface
353 air masses were chemically inert. Nevertheless, the chemical information of the air
354 masses at higher altitudes was indicative of a reactive layer above urban Beijing,
355 which potentially drives fast pNO₃⁻ production via N₂O₅ uptake. In this study, we
356 evidenced of an additional Ox missing aloft with 25 ppb throughout the night. Based
357 on model simulation, we found the particulate nitrate formed above 150 m can reach
358 up to 50 μg m⁻³, and enhance the surface level PM concentration significantly with 28
359 μg m⁻³ after NBL breaking. Our study also demonstrated that during heavy PM
360 pollution period, the particulate nitrate formation capacity via N₂O₅ uptake is easily
361 maximized in the upper layer, even N₂O₅ uptake is as low as 1.7×10⁻³, indicating the
362 mixing ratio of NO₂ aloft are directly linked to nitrate formation, and reduction of
363 NO_x is helpful to decrease nocturnal nitrate formation. Overall, this study highlights
364 the importance of the interplay between chemical formation aloft and dynamic
365 processes for probing the ground level PM pollution problem. In the future, direct
366 observations of N₂O₅ and associated parameters should be performed to explore the
367 physical and chemical properties of this overhead nighttime reaction layer, and
368 reached a better understanding of the winter haze formation.

580

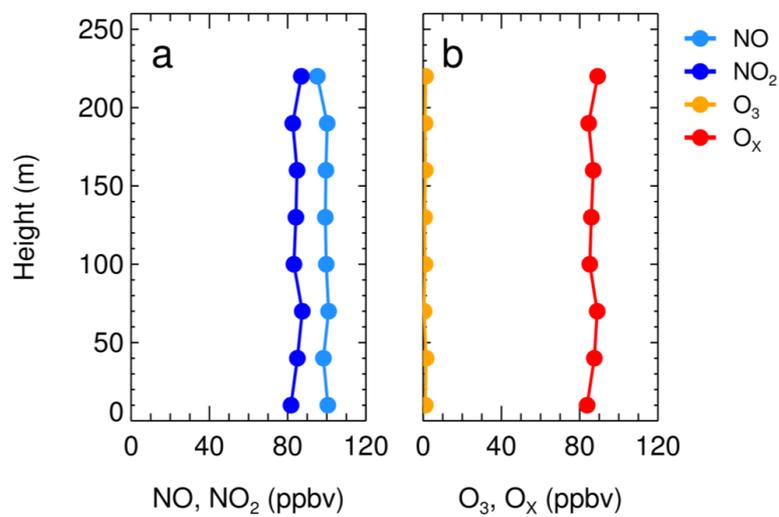

581 **Figure 1.** Location of the monitoring sites used in this study, including PKU (red
582 diamond), IAP (blue diamond), and other National Monitoring Sites (green circles).
583 Vertical profiles of NO_x and O₃ were collected at a tower at the IAP. Measurements of
584 particle number and size distribution (used to calculate N₂O₅ and particle nitrate
585 formation) were collected from a ground site at PKU. Additional measurements on
586 PM_{2.5} concentrations were continuously measured at national monitoring sites
587 throughout Beijing.

588

589

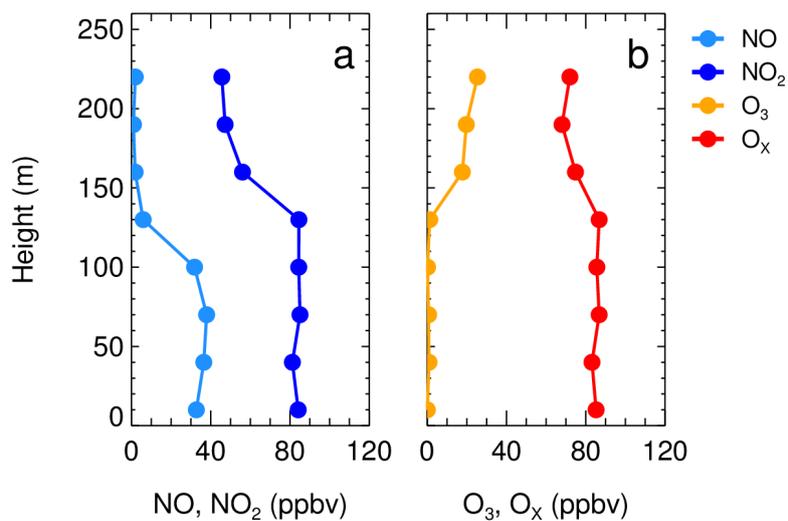

590 **Figure 2.** Time series of (a) $PM_{2.5}$ and O_3 , (b) NO and NO_2 , (c) temperature (T) and
591 relative humidity (RH), (d) wind direction (WD) and wind speed (WS) from
592 December 16 to 22, 2016 (CNST, Chinese National Standard Time) at PKU site in
593 Beijing, China. The shaded region represents the nighttime periods. Red line in panel
594 (a) shows an example of fast $PM_{2.5}$ enhancement on the night of December 19, and
595 the green lines are the time periods when the vertical measurements conducted in IAP
596 site.

597

598 **Figure 3.** Vertical profiles of NO and NO₂ (a), O₃ and O_x (b) at 20:38-21:06 on the
599 night of December 20, 2016.

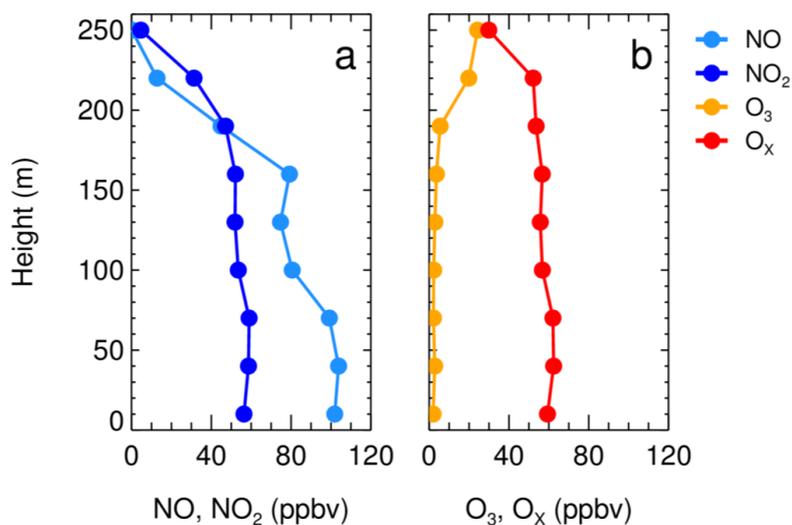

600

601

602 **Figure 4.** O_x missing case presented by the vertical profiles of (a) NO and NO₂, (b)
603 O₃ and O_x at 20:38-21:13 on the night of December 19, 2016.

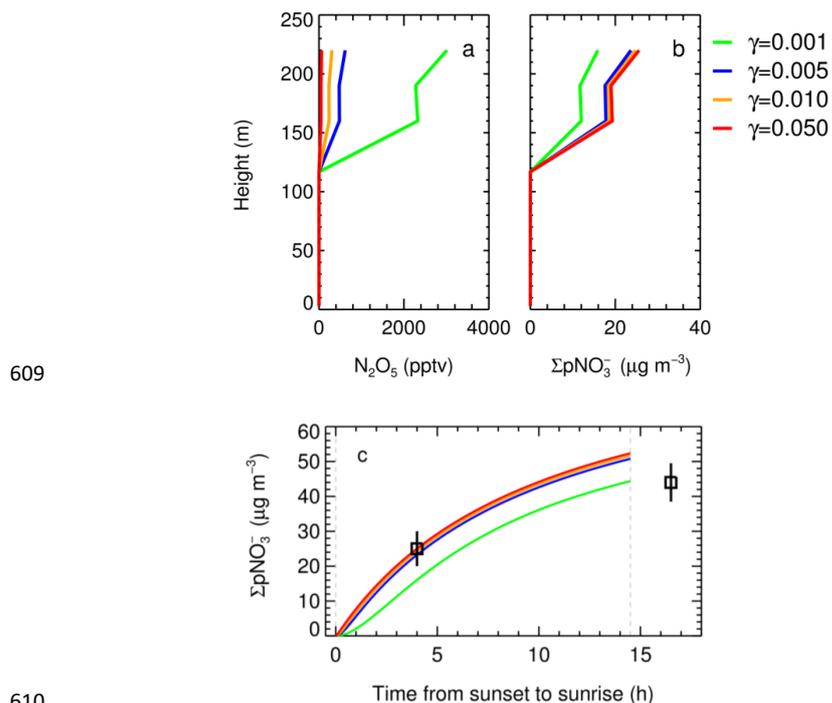

604

605

606 **Figure 5.** Vertical profiles of (a) NO and NO₂, (b) O₃ and O_x at 09:06-09:34 in the
607 morning of December 20, 2016.

608

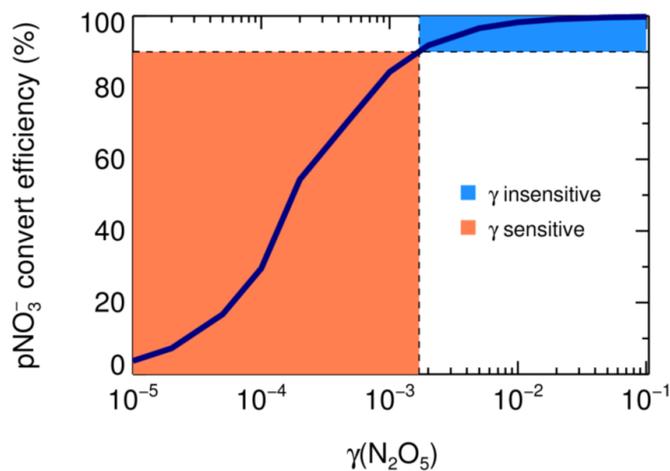

609

610

611 **Figure 6.** Base case ($\gamma=0.005$) and sensitivity tests of the vertical profile on the night
612 of December 19 at different N_2O_5 uptake coefficients, including (a) the mixing ratio
613 of N_2O_5 at 21:00, (b) the integral pNO_3^- production from sunset to 21:00, (c) the time
614 series of the integral pNO_3^- formed at 240 m via N_2O_5 uptake from sunset (17:00) to
615 sunrise (07:30, nighttime length = 14.5 h), the squares represents the pNO_3^- equivalent
616 weight from the observed O_x missing in the two vertical measurements ~21:00 and
617 ~09:30 in the following morning.

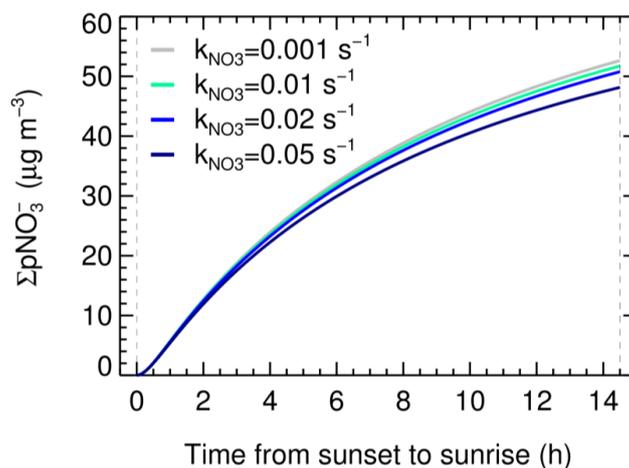

618

619

620 **Figure 7.** The dependence of pNO_3^- convert efficiency by N_2O_5 uptake on $\gamma_{\text{N}_2\text{O}_5}$. The
621 initial S_a set to $3000 \mu\text{m}^2 \text{cm}^{-3}$, the ClNO_2 yield is zero and k_{NO_3} is 0.02 s^{-1} . The orange
622 region shows the convert efficiency is sensitive when $\gamma < 0.0017$, while the blue
623 region shows the convert efficiency is over 90% and insensitive when $\gamma \geq 0.0017$.

624

625

626

627

628

629

Figure 8. Base case ($k_{\text{NO}_3}=0.02 \text{ s}^{-1}$) and sensitivity tests of the integral pNO_3^- formed at 240 m via N_2O_5 uptake at different NO_3 reactivity (0.001 s^{-1} , 0.01 s^{-1} , 0.05 s^{-1}) on the whole night of December 19, 2016.

630

Table 1. List of the parameter sets in base case and sensitivity tests.

Cases	k_{NO_3} (s^{-1})	$\gamma_{\text{N}_2\text{O}_5}$
Base case	0.02	0.005
k_{NO_3} test 1	0.001	0.005
k_{NO_3} test 2	0.01	0.005
k_{NO_3} test 3	0.05	0.005
$\gamma_{\text{N}_2\text{O}_5}$ test 1	0.02	0.001
$\gamma_{\text{N}_2\text{O}_5}$ test 2	0.02	0.01
$\gamma_{\text{N}_2\text{O}_5}$ test 3	0.02	0.05
