41 **Abstract**

42 Ambient air pollution from ozone and fine particulate matter is associated with
43 premature mortality. As emissions from one continent influence air quality over others,
44 changes in emissions can also influence human health on other continents. We estimate
45 global air pollution-related premature mortality from exposure to PM_{2.5} and ozone, and
46 the avoided deaths from 20% anthropogenic emission reductions from six source
47 regions, North America (NAM), Europe (EUR), South Asia (SAS), East Asia (EAS),
48 Russia/Belarus/Ukraine (RBU) and the Middle East (MDE), three global emission
49 sectors, Power and Industry (PIN), Ground Transportation (TRN) and Residential (RES)
50 and one global domain (GLO), using an ensemble of global chemical transport model
51 simulations coordinated by the second phase of the Task Force on Hemispheric
52 Transport of Air Pollution (TF-HTAP2), and epidemiologically-derived concentration-
53 response functions. We build on results from previous studies of the TF-HTAP by using
54 improved atmospheric models driven by new estimates of 2010 anthropogenic
55 emissions (excluding methane), with more source and receptor regions, new
56 consideration of source sector impacts, and new epidemiological mortality functions.
57 We estimate 290,000 (95% CI: 30,000, 600,000) premature O₃-related deaths and 2.8
58 million (0.5 million, 4.6 million) PM_{2.5}-related premature deaths globally for the
59 baseline year 2010. While 20% emission reductions from one region generally lead to
60 more avoided deaths within the source region than outside, reducing emissions from
61 MDE and RBU can avoid more O₃-related deaths outside of these regions than within,
62 and reducing MDE emissions also avoids more PM_{2.5}-related deaths outside of MDE
63 than within. Our findings that most avoided O₃-related deaths from emission reductions
64 in NAM and EUR occur outside of those regions contrast with those of previous studies,
65 while estimates of PM_{2.5}-related deaths from NAM, EUR, SAS and EAS emission
66 reductions agree well. In addition, EUR, MDE and RBU have more avoided O₃-related
67 deaths from reducing foreign emissions than from domestic reductions. For six regional
68 emission reductions, the total avoided extra-regional mortality is estimated as 6,000 (-
69 3,400, 15,500) deaths/year and 25,100 (8,200, 35,800) deaths/year through changes in
70 O₃ and PM_{2.5}, respectively. Interregional transport of air pollutants leads to more deaths
71 through changes in PM_{2.5} than in O₃, even though O₃ is transported more on
72 interregional scales, since PM_{2.5} has a stronger influence on mortality. For NAM and
73 EUR, our estimates of avoided mortality from regional and extra-regional emission
74 reductions are comparable to those estimated by regional models for these same
75 experiments. In sectoral emission reductions, TRN emissions account for the greatest

76 fraction (26-53% of global emission reduction) of O₃-related premature deaths in most
77 regions, in agreement with previous studies, except for EAS (58%) and RBU (38%)
78 where PIN emissions dominate. In contrast, PIN emission reductions have the greatest
79 fraction (38-78% of global emission reduction) of PM_{2.5}-related deaths in most regions,
80 except for SAS (45%) where RES emission dominates, which differs with previous
81 studies in which RES emissions dominate global health impacts. The spread of air
82 pollutant concentration changes across models contributes most to the overall
83 uncertainty in estimated avoided deaths, highlighting the uncertainty in results based
84 on a single model. Despite uncertainties, the health benefits of reduced intercontinental
85 air pollution transport suggest that international cooperation may be desirable to
86 mitigate pollution transported over long distances.

87

88 **1 Introduction**

89 Ozone (O₃) and fine particulate matter with aerodynamic diameter less than 2.5
90 μm (PM_{2.5}) are two common air pollutants with known adverse health effects.
91 Epidemiological studies have shown that both short-term and long-term exposures to
92 O₃ and PM_{2.5} are associated with elevated rates of premature mortality. Short-term
93 exposure to O₃ is associated with respiratory morbidity and mortality (Bell et al., 2005;
94 Bell et al., 2014; Gryparis et al., 2004; Ito et al., 2005; Levy et al., 2005; Stieb et al.,
95 2009) while long-term exposure to O₃ has been associated with premature respiratory
96 mortality (Jerrett et al., 2009, Turner et al., 2016). Short-term exposure to PM_{2.5} has
97 been associated with increases in daily mortality rates from all natural causes, and
98 specifically from respiratory and cardiovascular causes (Bell et al., 2014; Du et al.,
99 2016; Powell et al., 2015; Pope et al., 2011) while long-term exposure to PM_{2.5} can
100 have detrimental chronic health effects, including premature mortality due to
101 cardiopulmonary diseases and lung cancer (Brook et al., 2010; Burnett et al., 2014;
102 Hamra et al., 2014; Krewski et al., 2009; Lepeule et al., 2012; Lim et al., 2012). The
103 Global Burden of Disease Study 2015 (GBD 2015) estimated 254,000 deaths/year
104 associated with ambient O₃ and 4.2 million associated with ambient PM_{2.5} (Cohen et al.
105 2017). A comparable study using output from an ensemble of global chemistry–climate
106 models estimated 470,000 deaths/year associated with O₃ and 2.1 million premature
107 deaths/year associated with anthropogenic PM_{2.5} (Silva et al. 2013). These differences
108 in GBD estimates result mainly from differences in concentration response functions
109 and estimates of pollutant concentrations.

110 Numerous observational and modeling studies have shown that anthropogenic
111 emissions can affect O₃ and PM_{2.5} concentrations across continents (Dentener et al.,
112 2010; Heald et al., 2006; Leibensperger et al., 2011; Lin et al., 2012; Lin et al., 2017;

113 Liu et al., 2009a; West et al., 2009a; Wild and Akimoto, 2001; Yu et al., 2008). As
114 changes in emissions from one continent influence air quality over others, several
115 studies have estimated the premature mortality from intercontinental transport
116 (Anenberg et al., 2009; Anenberg et al., 2014; Bhalla et al., 2014; Duncan et al., 2008;
117 Im et al., 2018; Liu et al., 2009b; West et al., 2009b; Zhang et al., 2017). In 2005, the
118 Task Force on Hemispheric Transport of Air Pollution (TF-HTAP) was launched under
119 the United Nations Economic Commission for Europe (UNECE) Convention on Long-
120 Range Transboundary Air Pollution (LRTAP). One of its tasks is to investigate the
121 impacts of emission reductions on the intercontinental transport of air pollution, air
122 quality, health, ecosystem and climate effects, using a multi-model ensemble to
123 quantify uncertainties due to differences between models (Anenberg et al., 2009;
124 Anenberg et al., 2014; Fiore et al., 2009; Fry et al., 2012; Huang et al., 2017; Stjern et
125 al., 2016; Yu et al., 2013).

126 In the TF-HTAP Phase 1 (TF-HTAP1), human premature mortality due to 20%
127 anthropogenic emission reductions in four large source regions was investigated by
128 Anenberg et al. (2009 and 2014). They found that 20% foreign O₃ precursor emission
129 reductions contribute approximately 30% to >50% of the deaths avoided by reducing
130 precursor emissions in all four regions together (Anenberg et al., 2009). Similarly,
131 reducing emissions in NA and EU was found to avoid more O₃-related premature deaths
132 outside the source region than within (Anenberg et al., 2009), which agrees with other
133 studies that together show for the first time that emission reductions in NA and EU have
134 greater impacts on mortality outside the source region than within (Duncan et al., 2008;
135 West et al., 2009). In contrast, Anenberg et al. (2014) estimate that 93–97 % of PM_{2.5}-
136 related avoided deaths from reducing emissions in all four regions occurs within the
137 source region while 3–7 % occur outside the source region from transport between
138 continents. Despite the longer atmospheric lifetime of O₃ and its relatively larger scale
139 of influence, PM_{2.5} was found to cause more deaths from intercontinental transport
140 (Anenberg et al., 2009; 2014). These prior studies have consistently concluded that
141 most avoided O₃-related deaths from emission reductions in NAM and EUR occur
142 outside of those regions, while most avoided PM_{2.5}-related deaths occur within the
143 regions. Similarly, an ensemble of regional models in the third phase of the Air Quality
144 Modelling Evaluation International Initiative (AQMEII3) found that a 20% decrease of
145 emissions within the source region avoids 54,000 and 27,500 premature deaths in
146 Europe and the U.S. (from both O₃ and PM_{2.5}), while the reduction of foreign emissions
147 alone avoids ~1,000 and 2,000 premature deaths in Europe and the U.S. (Im et al., 2018).
148 Crippa et al (2017) used the TM5-FASST reduced-form model with HTAP2 emissions
149 to estimate a global sensitivity to 20 % emission reductions of PM_{2.5}-related premature
150 deaths of 401,000 globally, and 42,000 and 20,000 for Europe and the US respectively.

151 In addition, several studies have evaluated the relative importance of individual
152 emissions sectors (Barrett et al., 2010; Bhalla et al., 2014; Chafe et al., 2014; Chambliss
153 et al., 2014; Corbett et al., 2007) or multiple sectors (Lelieveld et al., 2015; Silva et al.,
154 2016a) to ambient air pollution–related premature mortality. Lelieveld et al. (2015)
155 estimated that residential energy use such as for heating and cooking has the largest
156 mortality impact globally (for PM_{2.5} and O₃ mortality combined), particularly in South
157 and East Asia. Silva et al (2016) likewise found that residential & commercial emissions
158 are most important for ambient PM_{2.5}-related mortality, but also found that land
159 transportation had the greatest impact on O₃-related mortality, particularly in North
160 America, South America, Europe, FSU and the Middle East. Understanding the impact
161 of different sectors on the global burden and the relative importance of each sector
162 among regions can help stimulate international efforts and region-specific air pollution
163 control strategies. Nevertheless, those studies were limited by using a single
164 atmospheric model, reflecting a need to understand whether results differ among
165 models and apportionment approaches.

166 In this study, we estimate the impacts of interregional transport and of source
167 sector emissions on human premature mortality from O₃ and PM_{2.5}, using an ensemble
168 of global chemical transport models coordinated by the Task Force on Hemispheric
169 Transport of Air Pollution Phase 2 (TF-HTAP2) (Galmarini et al., 2017; Huang et al.,
170 2017; Janssens-Maenhout et al., 2015; Stjern et al., 2016). Anthropogenic emissions
171 were reduced by 20% in six source regions: North America (NAM), Europe (EUR),
172 South Asia (SAS), East Asia (EAS), Russia/Belarus/Ukraine (RBU) and the Middle
173 East (MDE), three emission sectors: Power and Industry (PIN), Ground Transportation
174 (TRN) and Residential (RES), and one worldwide region (GLO). Human premature
175 mortality due to these reductions is calculated using a health impact function based on
176 a log-linear model for O₃ (Jerrett et al. 2009) and an integrated exposure-response
177 model for PM_{2.5} (Burnett et al. 2014), within the six source regions and elsewhere in
178 the world. We conduct a Monte Carlo simulation to estimate the overall uncertainty due
179 to uncertainties in relative risk, air pollutant concentrations (given by the spread of
180 results among different models), and baseline mortality rates.

181

182 **2 Method**

183 **2.1 Modeled O₃ and PM_{2.5} surface concentration**

184 Global numerical modelling experiments initiated by TF-HTAP2, the regional
185 experiments by the Air Quality Model Evaluation International Initiative (AQMEII)
186 over Europe and North America, and the Modelling Intercomparison Study-Asia
187 (MICS-Asia) were coordinated to perform consistent emission perturbation modelling

188 experiments across the global, hemispheric and continental/regional scales (Galmarini
189 et al., 2017). Simulation periods, meteorology, emission inventories, boundary
190 conditions, and model output are also consistent. The Joint Research Centre's (JRC)
191 EDGAR (Emission Data Base for Global Research) team in collaboration with regional
192 emission experts from the U.S. Environmental Protection Agency (US-EPA), European
193 Monitoring and Evaluation Programme (EMEP), Centre on Emission Inventories and
194 Projections (CEIP), Netherlands Organization for Applied Research (TNO), and the
195 MICS-Asia Scientific Community and Regional Emission Activity Asia (REAS)
196 provide a global emission inventory at $0.1^{\circ} \times 0.1^{\circ}$ resolution for TF-HTAP2 modeling
197 experiments (Janssens-Maenhout et al., 2015). The emissions dataset was constructed
198 for SO_2 , NO_x , CO, NMVOC, NH_3 , PM_{10} , $\text{PM}_{2.5}$, BC and OC and seven emission sectors
199 (shipping, aircraft, land transportation, agriculture, residential, industry and energy) for
200 the year 2010 (Fig. S1).

201 This study uses outputs from 14 global models / model versions (Table S1)
202 participating in TF-HTAP2. Overall, TF-HTAP2 model resolutions are finer than in TF-
203 HTAP1. In TF-HTAP2, each model performed a baseline simulation and sensitivity
204 simulations where the anthropogenic emissions in a defined source region or sector
205 were perturbed (reduced by 20% in most cases). Based on the number of models that
206 simulated different experiments, we choose to focus on emission reductions from six
207 source regions, three emission sectors, and one global domain. More specifically, all
208 anthropogenic emissions are reduced by 20% in the North America (NAM), Europe
209 (EUR), South Asia (SAS), East Asia (EAS), Russia/Belarus/Ukraine (RBU) and the
210 Middle East (MDE) continental regions, in the Power and Industry (PIN), Ground
211 Transportation (TRN) and Residential (RES) emission sectors globally, and in one
212 global domain (GLO) (Fig. S2). Unlike TF-HTAP1 (Dentener et al., 2010) which
213 defined rectangular regions that included ocean or some sparsely inhabited regions, TF-
214 HTAP2 regions are defined by geopolitical boundaries.

215 We selected output from the models that provided temporally resolved volume
216 mixing ratios of O_3 and mass mixing ratios of $\text{PM}_{2.5}$ ("mmrpm2p5") for the baseline
217 and at least one regional or sectoral emission reduction scenario. Among the 14 models,
218 11 models reported O_3 and 8 reported $\text{PM}_{2.5}$ for regional emission perturbation
219 scenarios, 4 models reported O_3 and 4 reported $\text{PM}_{2.5}$ for sectoral emission perturbation
220 scenarios, and 10 models reported O_3 and 8 reported $\text{PM}_{2.5}$ for the global emission
221 perturbation. All models used prescribed meteorology for the year 2010, although this
222 meteorology was derived from different (re-)analysis products and not uniform across
223 models. Modeled concentrations are processed by calculating metrics consistent with
224 the underlying epidemiological studies to estimate premature mortality. For O_3 , we
225 calculate the average of daily 1-h maximum O_3 concentration for the 6 consecutive

226 months with the highest concentrations in each grid cell (Jerrett et al., 2009), for the
227 baseline and each 20% emission reduction scenario. While some models reported
228 hourly O₃ metrics, others only reported daily or monthly O₃. We include these models
229 by first calculating the ratio of the 6-month average of daily 1-h maximum O₃ to the
230 annual average of O₃ in individual grid cells, for models reporting hourly O₃, and then
231 applying that ratio to the annual average of ozone for those models that only report
232 daily or monthly O₃, following Silva et al. (2013; 2016b). For PM_{2.5}, we calculate the
233 annual average PM_{2.5} concentration in each cell using the monthly total PM_{2.5}
234 concentrations reported by each model (“mmrpm2p5”). Model results for these two
235 metrics are then regridded from each model’s native grid resolution (varying from
236 0.5°×0.5° to 2.8°×2.8°) to a consistent 0.5°×0.5° resolution used in mortality estimation.
237 We estimate regional and sectoral multi-model averages for each 20% emission
238 reduction scenario in the year 2010, but for each perturbation case, we only include
239 models that report both the baseline and perturbation cases.

240

241 **2.2 Model evaluation**

242 Measurements from multiple observation networks are employed in this study to
243 evaluate the model performance around the world. We evaluate model performance for
244 the 2010 baseline simulation for 11 TF-HTAP2 models for O₃ and 8 for PM_{2.5} (Table
245 S1). For O₃, we use ground level measurements from 2010 at 4,655 sites globally,
246 collected by the Tropospheric Ozone Assessment Report (TOAR) (Schultz et al., 2017;
247 Young et al., 2018). The TOAR dataset identifies stations as urban, rural and
248 unclassified sites (Schultz et al., 2017). Model performance is evaluated for the average
249 of daily 1-h maximum O₃ concentrations for the 3 consecutive months (3m1hmaxO₃)
250 with the highest concentrations in each grid cell, including models that only report daily
251 or monthly O₃ as described above. This metric for O₃ differs slightly from the 6-month
252 average of daily 1-h maximum metric used for health impact assessment, and is chosen
253 because TOAR reports the 3-month metric but not the 6-month metric. For PM_{2.5}, we
254 compare the annual average PM_{2.5}, using PM_{2.5} observations from 2010 at 3,157 sites
255 globally selected for analysis by the Global Burden of Disease 2013 (GBD2013)
256 (Forouzanfar et al., 2016). Statistical parameters including the normalized mean bias
257 (NMB), normalized mean error (NME), and correlation coefficient (R) are selected to
258 evaluate model performance.

259 Table S2 and S3 present statistical parameters of model evaluation for O₃ and
260 PM_{2.5}, and Figures S3-S10 show the spatial O₃ and PM_{2.5} evaluation as NMB around
261 the world, and in North America, Europe and East Asia. For 3m1hmaxO₃, the model
262 ensemble mean shows good agreement with measurements globally with NMB of 7.3%
263 and NME of 13.2%, but moderate correlation with R of 0.53 (Table S2). For individual

264 models, 8 models (CAM-chem, CHASER_T42, CHASER_T106, EMEPrv48,
265 GEOSCHEMADJOINT, GEOS-Chem, GFDL_AM3 and HadGEM2-ES) overestimate
266 3m1hmaxO₃ with NMB of 9.2% to 23% while 3 models (C-IFS, OsloCTM3.v2 and
267 RAQMS) underestimate by -10.8% to -19.4% globally (Figure S3). In the 6
268 perturbation regions, the model ensemble mean is also in good agreement with the
269 measurements, with -11.2% to 25.3% for NMB, 9.8% to 25.3% for NME, and -0.09 to
270 0.98 for R. The ranges of NMB for individual models are -18.1% to 32.3%, -24.1% to
271 21.3%, -24.5% to 45.0%, -26.4% to 24.5%, -30.5% to 20.3%, -35.3% to 5.4%, in NAM,
272 EUR, SAS, EAS, MDE, and RBU, respectively (Figure S4-S6). Note that some regions
273 (SAS, MDE, and RBU) have very few observations for model evaluation, making the
274 comparison less robust. The underestimated O₃ in the western US and overestimated
275 O₃ in eastern US in most models is very close to the model performance result of Huang
276 et al. (2017) who compare 8 TF-HTAP2 models with CASTNET observations (Figure
277 S4), as well as earlier studies under HTAP1 (Fiore et al. 2009). Similarly, Dong et al.
278 (2018) find that O₃ is overestimated in EUR and EAS by 6 TF-HTAP2 models,
279 consistent with our ensemble mean result in these two regions (Figure S5-S6).

280 For PM_{2.5}, the model ensemble mean agrees well with measurements globally,
281 with NMB of -23.1%, NME of 35.4%, and R of 0.77 (Table S3). For individual models,
282 only 1 model (GEOSCHEMADJOINT) overpredicts PM_{2.5} by 20.3%, while the other
283 7 models underpredict PM_{2.5} by -60.9% to -7.4% around the world (Figure S7). In 6
284 perturbation regions, the model ensemble mean is also in good agreement with
285 measurements, with ranges of NMB of -49.7% to 19.4%, 21.2% to 49.7% for NME,
286 and 0.50 to 1.00 for R. The range of NMB for individual models are -46.6% to 13.9%,
287 -76.0% to 31.9%, -35.0% to 49.7%, -50.4% to 29.5%, -52.6% to 31.5%, and -74.1% to
288 -19.8%, in NAM, EUR, SAS, EAS, MDE, and RBU, respectively (Figure S8-S10).
289 Dong et al. (2018) shows that PM_{2.5} is underestimated in EUR and EAS by 6 TF-HTAP2
290 models, consistent with our ensemble mean result in these two regions (Figure S9-S10).
291 Note that many observations used are located in urban areas, and models with coarse
292 resolution may not be expected to have good model performance. Also several models
293 neglect some PM_{2.5} species, which may explain the tendency of models to
294 underestimate.

295

296 **2.3 Health impact assessment**

297 We use output from the TF-THAP2 model ensemble to estimate annual O₃- and
298 PM_{2.5}-related global cause-specific premature mortality and avoided mortality from the
299 20% regional and sectoral emission reductions, following the same methods used by
300 Silva et al. (2016a; 2016b). The annual O₃- and PM_{2.5}-related premature mortality is
301 calculated using a health impact function based on epidemiological relationships

302 between ambient air pollution concentration and mortality in each grid cell: $\Delta M =$
 303 $y_0 \times AF \times Pop$, where ΔM is premature mortality, y_0 is the baseline mortality rate
 304 (for the exposed population), $AF = 1 - 1/RR$ is the attributable fraction, where $RR = I$
 305 relative risk of death attributable to the change in air pollutant concentration ($RR = I$
 306 when there is no increased risk of death associated with a change in pollutant
 307 concentration), and Pop is the exposed population (adults aged 25 and older).

308 For O_3 mortality, we use a log-linear model for chronic respiratory mortality
 309 (RESP) from the American Cancer Society (ACS) study (Jerrett et al 2009), following
 310 recent studies including the GBD (Cohen et al., 2017), but Turner et al. (2016) recently
 311 published new results for chronic ozone mortality, and adoption of these results would
 312 lead to more ozone-related deaths overall (Malley et al., 2017). RR is calculated as:

$$313 \quad RR = e^{\beta \Delta x} \quad (1)$$

314 where β is the concentration-response factor, and Δx corresponds to the change in
 315 pollutant concentrations between simulations with perturbed emissions and the baseline
 316 simulation. For O_3 , $RR = 1.040$ (95% Confidence Interval, CI: 1.013-1.067) for a 10
 317 ppb increase in O_3 concentrations (Jerrett et al., 2009), which from eq. 1 gives values
 318 for β of 0.00392 (0.00129-0.00649). We estimate O_3 -related premature deaths due to
 319 respiratory disease (RESP) based on decreases or increases in O_3 concentration (i.e. Δx)
 320 due to 20% regional and sectoral emission reduction scenarios relative to the baseline.
 321 For regional and sectoral reductions, we do not assume a low-concentration threshold
 322 below which changes in O_3 have no mortality effects, as there is no clear evidence for
 323 such a threshold, following Anenberg et al (2009; 2010) and Silva et al. (2013; 2016a,
 324 b). However, we evaluate global O_3 premature mortality for the baseline 2010
 325 simulation, relative to a counterfactual concentration of 37.6 ppb (Lim et al. 2012), for
 326 consistency with GBD estimates (Cohen et al., 2017).

327 For $PM_{2.5}$ mortality, we apply the Integrated Exposure–Response (IER) model,
 328 which is intended to better represent the risk of exposure to $PM_{2.5}$ at locations with high
 329 ambient concentrations (Burnett et al., 2014). RR is calculated as:

$$330 \quad \text{For } z < z_{cf}, \quad RR_{IER}(z) = 1 \quad (2)$$

$$331 \quad \text{For } z \geq z_{cf}, \quad RR_{IER}(z) = 1 + \alpha \{1 - \exp[-\gamma(z - z_{cf})^\delta]\} \quad (3)$$

332 where z is the $PM_{2.5}$ concentration in $\mu g/m^3$ and z_{cf} is the counterfactual concentration
 333 below which no additional risk is assumed, and the parameters α , γ , and δ are used to
 334 fit the function for cause-specific RR (Burnett et al., 2014). The overall $PM_{2.5}$ -related
 335 cause-specific premature deaths related to ischemic heart disease (IHD),
 336 cerebrovascular disease (STROKE), chronic obstructive pulmonary disease (COPD)
 337 and lung cancer (LC) are estimated using RR s per age group for IHD and STROKE and
 338 RR s for all ages for COPD and LC. A uniform distribution from $5.8 \mu g/m^3$ to $8.8 \mu g/m^3$
 339 is used for z_{cf} as suggested by Burnett et al. (2014), which does not vary in space nor

340 time. For uncertainty analysis, we use results from 1,000 Monte Carlo simulations of
341 Burnett et al. (2014) to calculate RR in each grid cell by eq.2 or eq. 3. We estimate
342 avoided premature mortality in 20% emission perturbation experiments by taking the
343 difference in premature mortality estimates with the 2010 baseline. However, in the IER
344 model, the concentration–response function flattens off at higher PM_{2.5} concentrations,
345 yielding different estimates of avoided premature mortality for identical changes in air
346 pollutant concentrations from less-polluted vs. highly-polluted regions. That is, one unit
347 reduction of air pollution may have a stronger effect on avoided mortality in regions
348 where pollution levels are lower (e.g., Europe, North America) compared with highly
349 polluted regions (e.g., East Asia, India), which would not be the case for a log-linear
350 function (Jerrett et al., 2009; Krewski et al., 2009). Therefore, using the IER model in
351 this study may result in smaller changes in avoided mortality in highly polluted areas
352 than using the linear model.

353 For the exposed population, we use the Oak Ridge National Laboratory's Landscan
354 2011 Global Population Dataset at approximately 1 km resolution (30"x30") (Bright et
355 al., 2012). For the population of adults aged 25 and older, we use ArcGIS 10.2
356 geoprocessing tools to estimate the population per 5-year age group in each cell by
357 multiplying the country level percentage in each age group by the population in each
358 cell. We obtained cause-specific baseline mortality rates for 187 countries from the
359 GBD 2010 mortality dataset (IHME, 2013). The population and baseline mortality per
360 age group were regridded to the 0.5°×0.5° grid (Table S4 and Fig. S11). Cause-specific
361 baseline mortality rates vary geographically, e.g. RESP and COPD are relatively more
362 dominant in South Asia, IHD in Europe, STROKE in Russia, and LC in North America.

363 Finally, we conduct 1,000 Monte Carlo simulations to propagate uncertainty from
364 baseline mortality rates, modeled air pollutant concentrations, and the RRs in health
365 impact functions. We use the reported 95% CIs for cause-specific baseline mortality
366 rates, assuming lognormal distributions. For modeled O₃ and PM_{2.5} concentrations we
367 use the absolute value of the coefficient of variation among models in each grid cell,
368 for each 20% emission perturbation case minus the baseline, assuming a normal
369 distribution. For O₃ RRs, we use the reported 95% confidence intervals (CIs), assuming
370 a normal distribution. For PM_{2.5} RRs, we use the parameter values (i.e. α , γ , δ and z_{cf})
371 of Burnett et al. (2014) for 1,000 simulations. One should acknowledge that the range
372 of modeled air pollution concentrations in an ensemble is not a true reflection of the
373 uncertainty in emissions to concentration relationships. The mean health outcome of
374 the 1,000 Monte Carlo simulations (the “empirical mean”) may differ from the mean
375 when using the mean RR.

376 We also quantify the uncertainties in mortality due to the spread of air pollutant
377 concentrations across models, RRs, and baseline mortality rates, as contributors to the

378 overall uncertainty, expressed as a coefficient, of variation and compare the result with
379 the Monte-Carlo analysis estimate. To do so, we hold two variables at their mean values
380 and change the variable of interest within its uncertainty range; for example, using mean
381 RRs and baseline mortality rates, we analyze the spread of the model ensemble to
382 calculate the coefficient of variation caused by model uncertainty. Given that our
383 $0.5^\circ \times 0.5^\circ$ grid cell resolution can capture most of the population well in a given region,
384 uncertainty associated with population was assumed to be negligible. We estimate the
385 impacts of extra-regional emission reductions on mortality by using the Response to
386 Extra-Regional Emission Reduction (RERER) metric defined by TF-HTAP (Galmarini
387 et al., 2017):

$$388 \quad RERER_i = \frac{R_{global} - R_{region,i}}{R_{global}} \quad (4)$$

389 where for a given region i , R_{global} is the change in mortality in the global 20%
390 reduction simulation (GLO) relative to the base simulation, and $R_{region,i}$ is the change
391 in mortality in response to the 20% emission reduction from that same region i . A
392 RERER value near 1 indicates a strong relative influence of foreign emissions on
393 mortality within a region, while a value near 0 indicates a weak foreign influence. We
394 also estimate the total avoided extra-regional mortality from a source perspective as the
395 sum of avoided deaths outside of each of the 6 source regions, and from a receptor
396 perspective by summing $R_{global} - R_{region,i}$ for all 6 regions.

397

398 **3 Results**

399 **3.1 Response of O₃ and PM_{2.5} concentrations to 20% regional and sectoral** 400 **emission reductions**

401 Previous TF-HTAP studies reported area-averaged concentrations to quantify
402 source-receptor relationships averaging concentrations over a region (Doherty et al.,
403 2013; Fiore et al., 2009; Fry et al., 2012; Huang et al., 2017; Stjern et al., 2016; Yu et
404 al., 2013). Here, we present the population-weighted concentration over a region, which
405 is more relevant for health. Among six receptor regions, the population-weighted multi-
406 model mean O₃ concentrations range from 48.38 ± 8.05 ppb in EUR to 65.72 ± 10.08 ppb
407 in SAS with a global average of 53.74 ± 8.03 ppb, while the annual population-weighted
408 multi-model mean PM_{2.5} concentrations range from 9.36 ± 2.62 $\mu\text{g}/\text{m}^3$ in NAM to 39.27
409 ± 13.50 $\mu\text{g}/\text{m}^3$ in EAS with a global average of 25.98 ± 5.05 $\mu\text{g}/\text{m}^3$ (Table 1 and S5-S6
410 and Figs.S12-S13).

411 For 20% perturbation scenarios, in general the impact on the multi-model mean
412 change in surface O₃ and PM_{2.5} concentration is greater within the source region (i.e.,

413 domestic region) than outside of it (i.e., foreign region) (Figs. 1-2). This is also true for
414 individual model results (Figs. S14-S16). Among six source regions, the emission
415 reduction from SAS has the greatest impact on global population-weighted O₃
416 concentration (Tables 2 and S5), while that from EAS has greatest impact on PM_{2.5}
417 (Tables 3 and S6). The source-receptor pairs with the greatest changes in O₃ and PM_{2.5}
418 concentration reflect the geographical proximity between regions and the magnitude of
419 emissions (Table 2-3) – e.g., EUR→MDE (0.34±0.08 ppb), EUR→RBU (0.34
420 ppb±0.09), EAS→NAM (0.29±0.14 ppb), EAS→RBU (0.27±0.12 ppb), and
421 NAM→EUR (0.26±0.55 ppb) for O₃, and EUR→RBU (0.26±0.19 µg/m³), EUR→MDE
422 (0.18±0.08 µg/m³), MDE→SAS (0.12±0.06 µg/m³), SAS→EAS (0.08±0.08 µg/m³),
423 and EAS→SAS (0.08±0.07 µg/m³) for PM_{2.5}. Our ensemble shows similar ozone
424 responses in the western US to emission reductions from EAS (Figs. 1c) as those
425 modeled by Lin et al. (2012 and 2017), who show that a model can capture the measured
426 western US ozone increases due to rising Asian emissions.

427 For each receptor region, reducing foreign anthropogenic emissions by 20%
428 (estimated by global minus within-region reductions) can decrease population-
429 weighted O₃ concentrations by 29-74% of the change in O₃ concentration and 8–41 %
430 of the change in PM_{2.5} concentration (Tables 2-3). In some cases, regional emission
431 reductions cause small O₃ concentration increases within the source region or in foreign
432 receptors, reflecting O₃ nonlinear responses (Figs. S14). For instance, C-IFS_v2
433 predicts O₃ concentration increases in EUR by 0.04 ppb from domestic emission
434 reductions, which is in agreement with results from TF-HTAP1 (Anenberg et al. 2009).
435 Similarly, CMAchem shows more local O₃ increases, particularly in SAS, than other
436 models (Figs. S14). The change in O₃ concentration in foreign receptors is broader than
437 for PM_{2.5}, reflecting that O₃ has a longer atmospheric lifetime than PM_{2.5}.

438 For sectors, TRN emission reductions cause the greatest decrease in global
439 population-weighted O₃ by 1.13±0.19 ppb, while PIN emission reductions cause the
440 greatest decrease in surface PM_{2.5} by 1.46±0.56 µg/m³ globally (Tables 2-3 and Figs. 1-
441 2). The 20% emission reductions from individual sectors also have different effects in
442 different regions. Of the three sectors, emission reductions from TRN have the greatest
443 effect on population-weighted O₃ in NAM, EUR, SAS, MDE and MDE (40-50% of the
444 global emission reduction) while PIN emission reductions dominate in EAS (57%).
445 Emission reductions from PIN have the greatest effect on population-weighted PM_{2.5}
446 in NAM, EUR, EAS, MDE and MDE (41-84%) while RES emission reductions
447 dominate in SAS (43%). The response of PM_{2.5} concentration to sectoral emission
448 reductions differs significantly across models, which reflects in part the PM_{2.5} species
449 simulated by each model (Table S1 and Figs. S15-S17). For instance, we found that
450 models that simulate PM_{2.5} nitrate (i.e. CHASER_t42 and GEOSCHEMADJOIN)

451 predict a greater impact on PM_{2.5} concentration from TRN emission reduction than
452 those without nitrate (i.e. GOCARTv5 and SPRINTARS) (Fig. S17).

453

454 **3.2 Global mortality burden associated with anthropogenic air pollution**

455 Table 4 shows the annual multi-model mean O₃- and PM_{2.5}-related premature
456 deaths on 6 regions and globally for year 2010 baseline with 95% confidence intervals
457 (CI) based on Monte Carlo sampling. Tables S7-S8 show estimates of premature deaths
458 due to anthropogenic O₃ and PM_{2.5} from individual models. For the ensemble model
459 mean, we estimate 290,000 (30,000, 600,000) premature O₃-related deaths globally
460 using a 37.6 ppb counterfactual concentration, and 2.8 million (0.5 million, 4.6 million)
461 PM_{2.5}-related premature deaths using a uniform distribution of counterfactual
462 concentration from 5.8 µg/m³ to 8.8 µg/m³. Highly populated areas of India and East
463 Asia have the greatest O₃- and PM_{2.5}-related deaths, and those regions together account
464 for 82% and 66% of the global total O₃- and PM_{2.5}-related deaths. Compared with the
465 GBD 2015 (Cohen et al 2017), our global burden estimates are greater than the 254,000
466 (97,000, 422,000) premature deaths/year for O₃ from GBD, while less than 4.2 million
467 (3.7 million, 4.8 million) premature deaths for PM_{2.5}. Lelieveld et al (2015) estimate
468 142,000 (CI: 90,000, 208,000) O₃-related deaths and 3.2 million (1.5 million, 4.6
469 million) PM_{2.5}-related premature deaths for 2015. These differences can be explained
470 mainly by exposure estimates. Here we used a multi-model ensemble, whereas
471 Lelieveld et al. (2015) used a single model, and Cohen et al (2017) used a single model
472 for O₃ and a single model combined with surface and satellite observations for PM_{2.5}.
473 In addition, Cohen et al. (2017) use RRs for particulate matter for IHD and stroke
474 mortality that are modified from those used by Burnett et al (2014) and applied age
475 modification to the RRs, fitting the IER model for each age group separately. The
476 updated IER with estimated higher relative risks, together with greater global pollution
477 and baseline mortality rates in the low-income and middle-income countries in east and
478 south Asia leads to the higher absolute numbers of attributable deaths and disability-
479 adjusted life-years in GBD 2015 than estimated in GBD 2013 (Forouzanfar et al., 2016).
480 Also, GBD 2015 includes child lower respiratory infections estimate whereas we do
481 not. Our wider range of uncertainty for the global mortality reflects the uncertainty in
482 baseline rates, RRs and spread of air pollutant concentration across models whereas
483 Cohen et al (2017) consider national-level population-weighted mean concentrations
484 and uncertainty of IER function predictions at each concentration and Lelieveld et al.
485 (2015) only account for the statistical uncertainty of the parameters used in the IER
486 functions.

487

488 3.3 Effect of regional reductions on mortality

489 Reducing global anthropogenic emissions of air pollutant by 20% avoids 47,400
490 (11,300, 99,000) O₃-related deaths and 290,000 (67,100, 405,000) PM_{2.5}-related
491 premature deaths (Tables 5-6 and S9-S10). Most avoided air pollution-related deaths
492 were found within or close to the source region (Figs.3-76). Reducing anthropogenic
493 emissions by 20% from NAM, EUR, SAS, EAS, MDE and RBU can avoid 54%, 54%,
494 95%, 85%, 21%, and 22% of the global change in O₃-related deaths within the source
495 region (The number of avoided deaths within source region is divided by the number
496 of avoided deaths globally), and 93%, 81%, 93%, 94%, 32%, and 82% of the global
497 change in PM_{2.5}-related deaths, respectively (Table 5-6). Whereas the most O₃-related
498 premature deaths can be avoided by reducing SAS emissions (20,000 (3,600, 42,200)
499 deaths/year), reducing EAS emissions avoids more O₃-related premature deaths (1,700
500 (-1,300, 5,400)) outside of the source region than for any other region (500 (180, 870)
501 deaths/year to 1,300 (-1,200, 4,400) deaths/year (Table 5). Similarly, while reducing
502 EAS emissions avoids the most PM_{2.5}-related premature deaths (96,600 (3,500, 136,000)
503 deaths/year), reducing EUR emissions avoids more PM_{2.5}-related premature deaths
504 (7,400 (930, 9,500) deaths/year) outside of the source region than for any other region
505 (1,400 (-320, 2,300) deaths/year to 5,500 (3,000, 7,800) deaths/year) (Table 6). While
506 emission reductions from one region generally lead to more avoided deaths within the
507 source region than outside, 20% anthropogenic emission reductions from MDE (i.e.
508 79% and 68% of global avoided deaths outside of source region for O₃ and PM_{2.5},
509 respectively) and RBU (78% for O₃) can avoid more premature deaths outside of the
510 source region than within (Table 5-6). This result for RBU is in agreement with West et
511 al (2009). However, the results for NAM and EUR do not agree with previous studies
512 that found that emission reductions in these regions cause more O₃-related avoided
513 premature deaths outside of the source region than within (Anenberg et al., 2009;
514 Duncan et al., 2008; West et al., 2009). For PM_{2.5}, our results are comparable with
515 Anenberg et al. (2014) and Crippa et al. (2017) who found that for most regions, PM_{2.5}-
516 related avoided premature deaths are higher within the source region than outside. The
517 above difference in results with TF-HTAP1 may be in part because of the definition of
518 regions. Whereas the TF-HTAP2 regions are defined by geopolitical boundaries, the
519 TF-HTAP1 regions are defined by square domains which are larger and include more
520 ocean areas (Anenberg et al., 2009). In addition, updated atmospheric models and
521 emissions inputs, as well as different atmospheric dynamics in the single years chosen
522 in TF-HTAP1 vs. TF-HTAP2 may contribute to the differences.

523 Using individual models, different conclusions may result for the relative
524 importance of inter-regional transport. For example, for O₃, 8 models predict that NAM
525 emission reductions cause more O₃-related premature deaths within NAM (i.e CAM-

526 Chem, CHASER_T42, CHASER_T106, C-IFS, GEOSCHEMADJOINT, GEOS-
527 Chem, GFDL_AM3 and HadGEM2-ES), whereas 2 models predict more deaths outside
528 (i.e. EMEPrv48 and OsloCTM3.v2). 5 models suggest that EUR emission reductions
529 cause more O₃-related premature deaths within EUR (i.e. CAM-chem, CHASER_T42,
530 CHASER_T106, GFDL_AM3 and HadGEM2-ES), whereas 4 show more deaths
531 outside (i.e. C-IFS, GEOSCHEMADJOINT, EMEPrv48 and OsloCTM3.v2). Each
532 individual model shows that emission reductions from SAS and EAS avoid more O₃-
533 related premature deaths within than outside, and that those from MDE and RBU avoid
534 more O₃-related premature deaths outside than within (Fig. S18). For PM_{2.5}, each
535 individual model shows that emission reductions from NAM, EUR, SAS, EAS and
536 RBU avoid more PM_{2.5}-related premature deaths within than outside, while for
537 emission reductions from MDE, 3 models (EMEPrv48, GEOSCHEMADJOINT and
538 SPRINARS) show more PM_{2.5}-related premature deaths within, while 3
539 (CHASER_T42 GEOS5 and GOCART) show more PM_{2.5}-related premature deaths
540 outside (Fig. S19). The variation of health effect reflects the differences in processing
541 of natural emissions, atmospheric physical and chemical mechanisms, numerics etc
542 across models.

543 For each receptor region, reducing domestic anthropogenic emissions by 20%
544 contributes about 66%, 39%, 84%, 72%, 45% and 25% of the total O₃-related avoided
545 premature mortality (from the global reduction), and 90%, 78%, 87%, 87%, 58% and
546 66% of the total PM_{2.5}-related avoided premature mortality (from the global reduction)
547 in NAM, EUR, SAS, EAS, MDE and RBU, respectively (Table 5-6). Therefore,
548 reducing emissions from foreign regions avoids more O₃ premature deaths in EUR
549 (foreign emission account for 61% of total avoided deaths from the global reduction),
550 MDE (55%) and RBU (75%) than reducing domestic emissions (Table 5-6), in
551 agreement with the results for EUR from Anenberg et al (2009). Whereas EAS has the
552 greatest number of avoided O₃-related premature deaths due to foreign emission
553 reduction (3,800 (3,600, 3,900) deaths/year), RBU has the greatest fraction of O₃
554 mortality from foreign emission reductions (75%) (Table 5). Similarly, for PM_{2.5}, while
555 EAS has greatest number of avoided PM_{2.5}-related premature deaths due to foreign
556 emission reductions (13,600 (3,500, 18,800) deaths/year), MDE has the greatest
557 fraction of PM_{2.5} mortality from foreign emission reduction (42%) (Table 6).

558 Overall, adding results from all 6 regional reductions, interregional transport of air
559 pollution from extra-regional contributions is estimated to lead to more avoided deaths
560 through changes in PM_{2.5} (25,100 (8,200, 35,800) deaths/year) than in O₃ (6,000 (-3,400,
561 15,500) deaths/year), consistent with Anenberg et al. (2009; 2014). This result is due to
562 the greater influence of PM_{2.5} on mortality, despite the shorter atmospheric lifetime of
563 PM_{2.5} relative to O₃.

564 The contributions of different factors to the overall uncertainties in mortality are
565 shown in Tables S11-S12, considering uncertainties due to the spread of air pollutant
566 concentrations across models, RRs, and baseline mortality rates, expressed as
567 coefficients of variation. For both O₃ and PM_{2.5} mortality, the spread of model results
568 generally contributes most to the overall uncertainty, followed by uncertainty in RRs
569 and in baseline mortality rates, for most source-receptor pairs. The spread of model
570 results is generally wider for PM_{2.5} (14% to 3974% among source-receptor pairs) than
571 for O₃ (13% to 1065%). The uncertainty in RRs for O₃ mortality has constant value
572 (33% to 34%) due to the fixed uncertainty range of RRs from Jerrett et al. (2009),
573 whereas PM_{2.5} mortality leads to a wider range of uncertainty (1% to 247%) in RRs
574 because the uncertainty differs at different PM_{2.5} concentrations (Burnett et al., 2014).
575 Low uncertainty in baseline mortality rate was found for most source-receptor pairs
576 (<20%) except for the response of PM_{2.5} mortality in SAS to 20% reduction from RBU
577 (66%).

578

579 **3.4 Effect of sectoral reductions on mortality**

580 Reducing global anthropogenic emissions by 20% in 3 sectors (i.e. PIN, TRN and
581 RES) together avoids 48,500 (7,100, 108,000) O₃-related premature deaths and 243,000
582 (66,800, 357,000) PM_{2.5}-related premature deaths globally (Tables 5-6), with the
583 greatest avoided air pollution-related premature deaths located in highly populated
584 areas (e.g., North America, Europe, India, China, etc.) (Figs.3-6). For instance, reducing
585 anthropogenic emissions by 20% in 3 sectors together avoids the highest number of O₃-
586 related deaths in SAS (24,000 (6,000, 49,600) deaths/year) and PM_{2.5}-related deaths in
587 EAS (83,400 (29,400, 135,000) deaths/year). We compare our estimates of O₃ and
588 PM_{2.5}-related premature deaths attributable to PIN, TRN and RES emissions with
589 previous studies, by multiplying our results for 20% emission reductions by 5, and by
590 combining their sectors to nearly match each of the three sectors in this study (Table 7).
591 Compared with Silva et al (2016a), our estimate of O₃ and PM_{2.5}-related premature
592 deaths attributable to PIN and TRN are very comparable, but that to RES is lower here.
593 In comparison with Lelieveld et al (2015), we estimate greater O₃ and PM_{2.5}-related
594 premature deaths attributable to PIN and TRN, but less for RES.

595 Like Silva et al. (2016a) and Lelieveld et al. (2015), different locations show
596 relatively different mortality responses to changes in sectoral emissions. Whereas PIN
597 emission reductions cause the greatest number of avoided O₃-related premature deaths
598 globally (19,300 (1,400, 45,000) deaths/year), TRN emission reductions cause the
599 greatest fraction of avoided deaths in most of the six regions (26-53% of the global
600 emission reduction), except for EAS (58%) and RBU (38%) where the effect of
601 reducing PIN emissions dominates. In comparison with other studies (Table 7), our

602 conclusion that PIN emissions cause the most O₃-related deaths and TRN emissions
603 cause the greatest fraction of avoided deaths in most regions agrees well with Silva et
604 al (2016a). For PM_{2.5}, reducing PIN emissions avoids the most PM_{2.5}-related premature
605 deaths globally (128,000 (41,600, 179,000) deaths/year) and in most regions (38-78%
606 of the global emission reduction), except for SAS (45%) where the RES emission
607 dominates. Although these findings differ from those of Lelieveld et al (2015) and Silva
608 et al (2016), who find that Residential emissions have the greatest of impact on PM_{2.5}
609 mortality globally and in most regions, all studies agree that PIN emissions have the
610 greatest impact in NAM. Our result is also comparable with Crippa et al (2017) who
611 find that PIN emissions have the greatest health impact in most countries. Although
612 comparable emission inventories are used (i.e. Lelieveld et al (2015) and this study use
613 EDGAR emissions while Silva et al (2016) use RCP8.5 emissions), our lower mortality
614 estimate for RES emissions may be explained by our 20% reductions relative to the
615 zero-out method, and the different years simulated.

616 Considering results from individual models, we found that mortality from TRN
617 emission reductions show greater relative uncertainty than from PIN or RES (Table 5-
618 6 and Table S9-S10), reflecting a greater spread of results across models. Regional
619 impacts from individual model also differ from the ensemble mean result - e.g., for O₃,
620 GEOSCHEMADJOINT and OsloCTM3.v2 show that reducing PIN emissions causes
621 the greatest fraction of avoided O₃-related deaths in EUR, while
622 GEOSCHEMADJOINT, HadGM2-ES and OsloCTM3.v2 show that TRN emissions
623 have the greatest fraction of avoided O₃-related deaths in RBU (Figs. S20). For PM_{2.5},
624 CHASER_t42 and GEOSCHEMADJOINT show that reducing PIN emissions causes
625 the greatest fraction of avoided PM_{2.5}-related deaths in SAS (Figs. S21).

626

627 **4 Discussion**

628 We aggregate the avoided deaths attributable to 20% reductions from four
629 corresponding source regions (i.e. NAM, EUR, SAS and EAS), and compare with the
630 findings from TF-HTAP1. We estimate that these regional emission reductions are
631 associated with 36,000 (-1,500, 90,300) avoided deaths globally through the change in
632 O₃ and 207,000 (41,500, 304,000) avoided deaths through the change in PM_{2.5}, more
633 than those estimated by Anenberg et al. (2009 and 2014) – 21,800 (10,600, 33,400)
634 deaths for O₃ and 192,000 (146,000, 230,000) deaths for PM_{2.5}. This discrepancy might
635 be attributed to different health impact function, emissions data sets, region definitions,
636 updated population or baseline mortality rates. In particular, for O₃ respiratory mortality,
637 we use a log-linear model for chronic mortality (Jerrett et al 2009), instead of the short-
638 term O₃ mortality estimate based on a daily time-series study (Bell et al., 2004) used by

639 Anenberg et al., (2009). For PM_{2.5} mortality, Anenberg et al., (2014) only included the
640 simulated changes in BC, particulate organic matter (POM=primary organic
641 aerosol+secondary organic aerosol), and sulfate for PM_{2.5} concentration, while we use
642 the total model reported PM_{2.5} concentration which includes more species for some
643 models. We also apply the Integrated Exposure–Response (IER) model (Burnett et al.
644 2014) for PM_{2.5}, as opposed to the log-linear model of Krewski et al. (2009) used by
645 Anenberg et al., (2014).

646 For regional reductions, our multi-model average results suggest that NAM and
647 EUR emissions cause more deaths inside of those regions than outside, which disagrees
648 with previous studies (Anenberg et al., 2009; Duncan et al., 2008; West et al., 2009)
649 whereas similar regional impacts are found for EAS and SAS. Also, total avoided
650 deaths through interregional air pollution transport are estimated as 6,000 (-3,400,
651 15,500) deaths/year for O₃ and 25,100 (8,200, 35,800) deaths/year for PM_{2.5} in this
652 study, in contrast with 7,300 (3,600, 11,200) deaths/year for O₃ and 11,500 (8,800,
653 14,200) deaths/year for PM_{2.5} in Anenberg et al. (2009; 2014). These differences likely
654 result from different concentration-response functions and the use of 6 regions here vs.
655 4 by Anenberg et al. (2009; 2014). In addition, updated atmospheric models and
656 emissions inputs, as well as different atmospheric dynamics in the single years chosen
657 in TF-HTAP1 vs. TF-HTAP2 may contribute to the differences. In addition, updated
658 atmospheric models and emissions inputs, as well as different atmospheric dynamics in
659 the single years chosen in HTAP vs. HTAP2 may contribute to the differences. Overall,
660 whereas O₃ accounts for a higher percentage of the total deaths in foreign regions than
661 PM_{2.5}, PM_{2.5} leads to more deaths in general, which agrees well with the results of
662 Anenberg et al. (2009; 2014).

663 Using regional models in AQMEII3, driven by a single global model (C-IFS_v2),
664 Im et al. (2018) estimated that 20% domestic emission reductions would avoid 54,000
665 and 27,500 premature deaths (for O₃ and PM_{2.5} combined) in Europe and the U.S.,
666 respectively, as opposed to ~1,000 and 2,000 premature deaths due to foreign emission
667 reductions. These results are comparable to our estimates that 32,900 and 19,500
668 premature deaths result from 20% domestic emission reductions in Europe and the U.S.,
669 while 670 and 570 premature deaths result from foreign emission reductions. Although
670 our defined U.S. region is slightly bigger than Im et al. (2018), the majority of U.S.
671 emission sources and population are located within the region defined by Im et al.
672 (2018). This comparison shows that regional and global models show similar impacts
673 on mortality from air pollution transport.

674 Differences in our estimates of premature mortality attributable to air pollution
675 from three emission sectors (multiplied by 5) may be explained by methodological
676 differences relative to previous studies (Silva et al., 2016; Lelieveld et al., 2015),

677 including our use of 20% emission reductions versus the zero-out method in those
678 studies, different emission inventories, a multi-model ensemble versus single models,
679 and differences in baseline mortality rates, population, and concentration response
680 functions. Our finding that TRN emissions contribute the most avoided deaths for O₃
681 in most regions agrees well with the result by Silva et al (2016a), but differs for PM_{2.5}
682 mortality for which we find that PIN emissions cause the most deaths, while both Silva
683 et al (2016a) and Lelieveld et al (2015) find that RES emissions are responsible for the
684 most deaths. This discrepancy may be explained by different PM_{2.5} species included in
685 individual models, as we showed that changes in PM_{2.5} concentration to TRN emission
686 differ across models.

687 By using an ensemble of multi-model results here, we highlight the relative
688 importance of difference source-receptor pairs for mortality in a way that is more robust
689 than using a single model, particularly since some individual models yielded different
690 conclusions than the ensemble mean. The air pollutant concentration changes reported
691 by the HTAP2 models may be different among models, it may result from variety of
692 processes, e.g. atmospheric physical and chemical mechanisms, processing of natural
693 emissions, and transport time step, etc. (Table S1), but not anthropogenic emissions
694 since those were nearly identical among models. In addition, the coarse model
695 resolution used by global models may underestimate health effects by misaligning peak
696 concentration and population, particularly in urban areas and for PM_{2.5} (Punger and
697 West, 2013), but it is not known how model resolution would affect the relative
698 contributions of extra-regional and intraregional health benefits. Future research should
699 explore the possible bias from using coarse global models for extra-regional and
700 intraregional mortality estimates in metropolitan regions by comparing with finer-
701 resolution chemical transport models.

702 Another uncertainty in this paper (and other global studies) lies in applying the
703 same RRs worldwide, because of lack of long-term records of the chronic influences of
704 ambient air pollution on mortality outside of North America and Europe. We consider
705 only the population of adults ≥ 25 years old, ignoring possible mortality effects on the
706 younger population, and consequently we may underestimate premature mortality
707 overall. Likewise, the effects of air pollution on several morbidity endpoints are omitted.
708 We assume that all PM_{2.5} is equally toxic, for lack of clear evidence for greater toxicity
709 of some species. Inter-regional transport may also change the toxicity of PM_{2.5} by
710 changing the size distribution or chemical composition, where transport likely causes
711 particles to become more oxidized (West et al., 2016). Future research on PM_{2.5}-related
712 mortality should include estimating health effects for different PM_{2.5} chemical
713 components.

714

715 **5 Conclusions**

716 We estimate O₃- and PM_{2.5}-related premature mortality from simulations with 14
717 global CTMs participating in the TF-HTAP2 multi-model exercise for the year 2010.
718 An estimate of 290,000 (30,000, 600,000) global premature O₃-related deaths and 2.8
719 million (0.5 million, 4.6 million) global PM_{2.5}-related premature deaths is obtained
720 from the ensemble for the year 2010 in the baseline case. We focus on model
721 experiments simulating 20% regional air pollutant emission reductions (excluding
722 methane) in 6 regions, 3 sectors and 1 global domain. For regional scenarios, 6 source
723 emission reductions altogether can cause 84% of the global avoided O₃-related
724 premature deaths within the source region, ranging from 21 to 95% among 6 regions,
725 and 16% (5 to 79%) outside of the source region. For PM_{2.5}, 89% of global avoided
726 PM_{2.5}-related premature deaths are within the source region, ranging from 32 to 94%
727 among 6 regions, and 11% (6 to 68%) outside of the source region. While most avoided
728 mortality generally occurs within the source region, we find that emission reductions
729 from RBU (only for O₃) and MDE (for both O₃ and PM_{2.5}) can avoid more premature
730 deaths outside of these regions than within. Considering the effects of foreign emissions
731 on receptor regions, 20% foreign emission reductions lead to more avoided O₃-related
732 premature deaths in EUR, MDE and RBU than domestic reductions. Reductions from
733 all six regions in the transport of air pollution between regions are estimated to lead to
734 more avoided deaths through changes in PM_{2.5} (25,100 (8,200, 35,800) deaths/year)
735 than for O₃ (6,000 (-3,400, 15,500) deaths/year). For NAM and EUR, our estimates of
736 avoided mortality from regional and extra-regional emission reductions are comparable
737 to those estimated by regional models in AQMEII3 (Im et al., 2018) for these same
738 emission reduction experiments. Overall, the spread of modeled air pollutant
739 concentrations contributes most to the uncertainty in mortality estimates, highlighting
740 that using a single model may lead to erroneous conclusions and may underestimate
741 uncertainty in mortality estimates.

742 For sectoral emission reductions, reducing anthropogenic emissions by 20% in 3
743 sectors together avoids 48,500 (7,100, 108,000) O₃-related premature deaths and
744 243,000 (66,800, 357,000) PM_{2.5}-related premature deaths globally. Of the 3 sectors,
745 TRN had the greatest fraction (26-53%) of O₃-related premature deaths globally and in
746 most regions, except for EAS (58%) and RBU (38%) where PIN emissions dominate.
747 For PM_{2.5} mortality, PIN emissions cause the most deaths in most regions (38-78%),
748 except for SAS (45%) where the TRN emissions dominate.

749 In this study, we have gone beyond previous TF-HTAP1 studies that quantified
750 premature mortality from interregional air pollution transport, by using more source
751 regions, analyzing source emission sectors, and using updated atmospheric models and

752 health impact functions. The estimate of air transport premature mortality could vary
753 due to differences in exposure estimate (single model vs ensemble model), health
754 impact function, regional definitions, and grid resolutions. These discrepancies
755 highlight uncertainty estimated by different methods in previous studies. Despite
756 uncertainties, our results suggest that reducing pollution transported over a long
757 distance would be beneficial for health, with impacts from all foreign emission
758 reductions combined that may be comparable to or even exceed the impacts of emission
759 reductions within a region. Additionally, actions to reduce emissions should target
760 specific sectors within world regions, as different sectors dominate the health effects in
761 different regions. This work highlights the importance of long-range air pollution
762 transport, and suggests that estimates of the health benefits of emission reductions on
763 local, national, or continental scales may underestimate the overall health benefits
764 globally, when interregional transport is accounted for. International cooperation to
765 reduce air pollution transported over long distances may therefore be desirable.

766

767 **Acknowledgments** We sincerely acknowledge the contribution of modeling
768 groups from the second phase of Task Force on Hemispheric Transport of Air Pollution
769 (TF-HTAP2). This work was supported by a scholarship from the Taiwan Ministry of
770 Education, grants from NIEHS (1 R21 ES022600-01), and NASA (NNX16AQ30G and
771 NNX16AQ26G), funding from BEIS under the Hadley Centre Climate Programme
772 contract (GA01101) and from the European Union's Horizon 2020 research and
773 innovation programme under grant agreement no. 641816 (CRESCENDO). The
774 National Center for Atmospheric Research is sponsored by the National Science
775 Foundation. We thank Dr. Owen Cooper who provided the TOAR ground level O₃
776 observation dataset, and Michael Brauer for the GBD2013 ground level PM_{2.5}
777 observation dataset.

1076 Table 5. Annual avoided multi-model empirical mean O₃-related premature respiratory deaths with 95% CI from Monte-Carlo simulations in
 1077 parenthesis due to 20 % regional (NAM, EUR, SAS, MDE and RBU), sectoral (PIN, TRN and RES) and global (GLO) anthropogenic emission
 1078 reductions in each region and worldwide. The diagonal, showing the effect of each region on itself, is underlined. For regional reductions, we also
 1079 the RERER (eq. 4) as the percent of total avoided deaths in each receptor region that result from foreign emission reductions, as well as the percent
 1080 of global avoided deaths from emission reductions in each source region. All numbers are rounded to three significant figures or the nearest 10
 1081 deaths.

1088

1089 Table 7. Comparison of O₃ and PM_{2.5}-related premature deaths attributable to PIN,
 1090 TRN and RES emissions with previous studies. Results from this study (for 20%
 1091 reductions) are multiplied by 5. For Silva et al. (2016), we combine results for “Energy”
 1092 and “Industry” to represent PIN, and use “Land transportation” to represent TRN and
 1093 “Residential & Commercial” to represent RES. For Lelieveld et al. (2015), we combine
 1094 the “Power generation” and “Industry” sectors to represent PIN, and use “Land Traffic”
 1095 to represent TRN, and “Residential Energy” to represent RES.

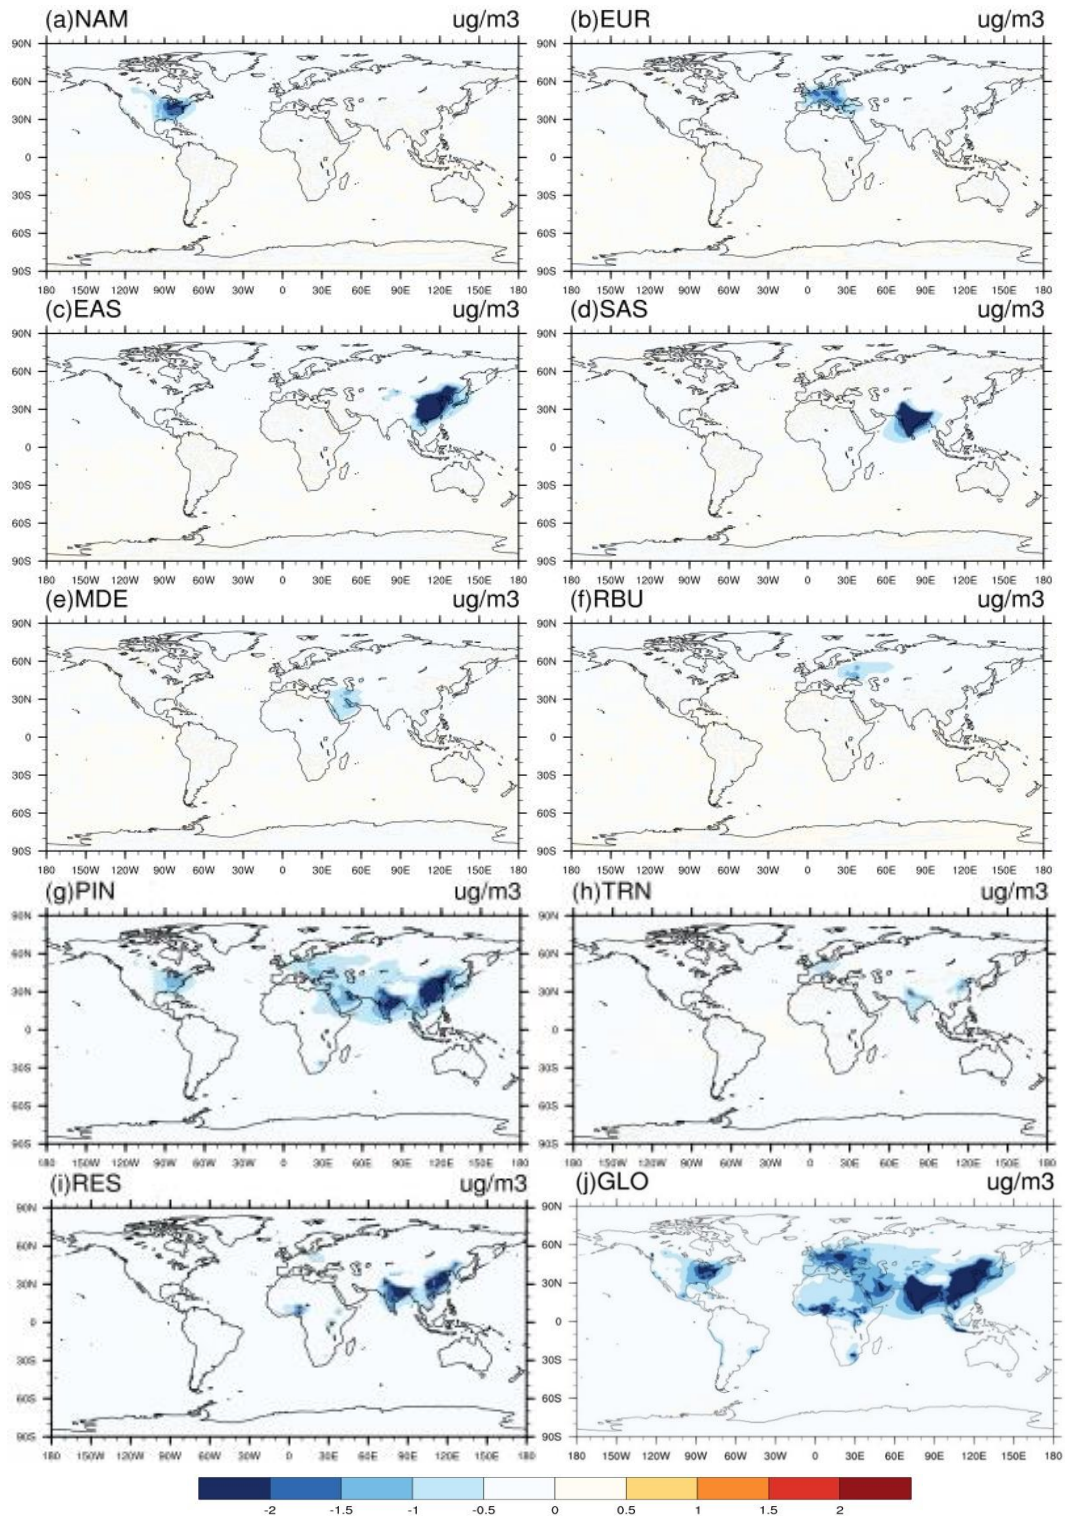

Emission source sector	This study	Silva et al. (2016)	Lelieveld et al. (2015)
PIN	O ₃ : 96,500 (7,000, 225,000) PM _{2.5} : 640,000 (208,000, 895,000)	O ₃ : 111,000 (23,200, 240,000) PM _{2.5} :613,000 (422,000, 816,000)	O ₃ + PM _{2.5} (692,000)
TRN	O ₃ : 94,000 (15,000, 208,000) PM _{2.5} : 160,000 (-82,500, 292,000)	O ₃ : 80,900 (17,400, 180,000) PM _{2.5} : 212,000 (114,000, 292,000)	O ₃ + PM _{2.5} (165,000)
RES	O ₃ : 52,000 (13,500, 106,000) PM _{2.5} :417,000 (209,000, 600,000)	O ₃ : 53,700(12,300, 116,000) PM _{2.5} :675,000 (428,000, 899,000)	O ₃ + PM _{2.5} (1,020,000)
