

## 32 **Abstract**

33

34 Mercury was measured onboard the IAGOS-CARIBIC passenger aircraft since May 2005  
35 until February 2016 during nearly monthly sequences of mostly four intercontinental  
36 flights from Germany to destinations in North and South America, Africa, and South and  
37 East Asia. Most of these mercury data were obtained using an internal default signal  
38 integration procedure of the Tekran instrument but since April 2014 more precise and  
39 accurate data were obtained using post-flight manual integration of the instrument raw  
40 signal. In this paper we use the latter data.

41

42 Elevated upper tropospheric total mercury (TM) concentrations due to large scale  
43 biomass burning were observed in the upper troposphere (UT) at the equator and  
44 southern latitudes during the flights to Latin America and South Africa in boreal autumn  
45 (SON) and boreal winter (DJF). TM concentrations in the lowermost stratosphere (LMS)  
46 decrease with altitude above the thermal tropopause but the gradient is less steep than  
47 reported before. Seasonal variation of the vertical TM distribution in the UT and LMS is  
48 similar to that of other trace gases with surface sources and stratospheric sinks. Using  
49 speciation experiments, we show that nearly identical TM and gaseous elementary  
50 mercury (GEM) concentrations exist at and below the tropopause. Above the thermal  
51 tropopause GEM concentrations are almost always smaller than those of TM and the TM  
52 – GEM (i.e.  $\text{Hg}^{2+}$ ) difference increases up to ~40% of TM at ~2 km and more above the  
53 thermal tropopause. Correlations with  $\text{N}_2\text{O}$  as a reference tracer suggest stratospheric  
54 lifetimes of  $72 \pm 37$  and  $74 \pm 27$  yr for TM and GEM, respectively, comparable to the  
55 stratospheric lifetime of COS. This coincidence, combined with pieces of evidence from  
56 us and other researchers, corroborates the hypothesis that  $\text{Hg}^{2+}$  formed by oxidation in the  
57 stratosphere attaches to sulfate particles formed mainly by oxidation of COS and is  
58 removed with them from the stratosphere by air mass exchange, gravitational  
59 sedimentation, and cloud scavenging processes.

60

## 61 **1 Introduction**

62

63 Mercury is a heavy metal whose high vapor pressure leads to significant emissions into  
64 the atmosphere. Moreover, due to its slow rate of oxidation and low solubility in water it  
65 can be transported over long distances. After oxidation to less volatile and more soluble  
66 compounds, mercury is thus deposited in remote areas. Its conversion to the highly  
67 neurotoxic methyl mercury which bioaccumulates in the aquatic nutritional chain to  
68 concentrations dangerous for humans and animals has motivated intensive research on  
69 the biogeochemical cycle of mercury (e.g. Mergler et al., 2007; Scheuhammer et al.,  
70 2007; Lindberg et al., 2007, AMAP/UNEP, 2013 and references therein).

71

72 Despite decades of research, the atmospheric mercury cycle is still not well understood  
73 (Lin et al., 2006; Lindberg et al., 2007, Ariya et al., 2015). Several mechanisms of  
74 elemental mercury oxidation in the gas phase have been proposed (Selin et al., 2007;  
75 Holmes et al., 2010; Dibble et al., 2012; Horowitz et al., 2017, Travnikov et al., 2017) but  
76 their relative importance is still unknown (Lin et al., 2006; Travnikov et al., 2017).  
77 Neither have the oxidation products been unequivocally identified so far because of the  
78 lack of speciation techniques for individual mercury compounds (Gustin et al., 2015;  
79 Ariya et al., 2015). In addition, attempts to constrain the atmospheric mercury cycle using  
80 different models had to rely almost exclusively on measurements at the surface in the  
81 northern hemisphere, which undermined these efforts. Measurements of mercury  
82 distribution in the troposphere and stratosphere by research aircraft are expensive and  
83 thus usually limited to short-term campaigns covering small regions of the globe  
84 (Ebinghaus and Slemr, 2000; Friedli et al., 2001, 2003a and 2004; Banic et al., 2003;  
85 Ebinghaus et al., 2007; Radke et al., 2007, Talbot et al., 2007a and b, Swartzendruber et  
86 al., 2008; Slemr et al., 2009; Lyman and Jaffe, 2012; Brooks et al., 2014, Slemr et al.,  
87 2014; Ambrose et al., 2015; Gratz et al., 2015; Weigelt et al., 2016a and b). These  
88 measurements have so far provided information about the emissions of mercury from  
89 biomass burning (Friedli et al., 2001, 2003a and b; Ebinghaus et al., 2007) and from  
90 industrial sources (Friedli et al., 2004; Talbot et al., 2007b; Swartzendruber et al., 2008,  
91 Slemr, et al., 2014; Ambrose et al., 2015; Weigelt et al., 2016b), with sometimes  
92 conflicting information about the vertical distribution of mercury (Ebinghaus and Slemr,  
93 2000; Radke et al., 2007; Talbot et al., 2007a and b; Slemr et al., 2009; Lyman and Jaffe,

94 2012; Brooks et al., 2014; Weigelt et al., 2016a; Bieser et al., 2017). In addition, a  
95 pronounced depletion of elemental mercury in air masses influenced by the stratosphere  
96 has been reported (Ebinghaus et al., 2007; Radke et al., 2007; Talbot et al., 2007a and b,  
97 Swartzendruber et al., 2008, Slemr et al., 2009; Lyman and Jaffe., 2012). Because of  
98 temporal and spatial limitations resulting from the costs of research aircraft hardly any  
99 information on seasonal variation of mercury concentrations in the upper troposphere  
100 (UT) and lowermost stratosphere (LMS) have been obtained so far.

101

102 IAGOS-CARIBIC (*In-service Aircraft for a Global Observing System - Civil Aircraft for*  
103 *Regular Investigation of the Atmosphere Based on an Instrumented Container*) project  
104 offers a possibility of regular large scale sounding of trace gas distributions in the UT/LS  
105 using an instrumented container flown onboard a passenger aircraft during  
106 intercontinental flights (Brenninkmeijer et al., 2007, [www.caribic-atmospheric.com](http://www.caribic-atmospheric.com)).  
107 From May 2005 until February 2016 mercury was measured with a modified Tekran  
108 instrument in combination with a large suite of other trace gases and particles onboard the  
109 CARIBIC aircraft (Brenninkmeijer et al., 2007, Slemr et al., 2009, 2014, 2016). The  
110 mercury data collected during nearly monthly sequences of mostly four intercontinental  
111 flights from Germany to destinations in North and South America, Africa, and East and  
112 South Asia represent the largest mercury data set obtained in the UT and LMS so far.  
113 Most mercury data were obtained using the Tekran internal default signal integration  
114 procedure but since April 2014 we manually integrated the Tekran raw signal after the  
115 flights. The post-flight integration of the raw signal substantially improved the detection  
116 limit and precision of the mercury measurements and removed negative bias of the  
117 default integration leading to occasional occurrence of zero concentrations in the data  
118 before April 2014 (Slemr et al., 2016; Ambrose, 2017). Raw signal data are available  
119 only since April 2014 and older data cannot be reintegrated. We use here the recent,  
120 smaller but higher quality dataset, to figure out the fate of mercury in the lowermost  
121 stratosphere.

122

## 123 **2 Experimental**

124

125 The CARIBIC container (Brenninkmeijer et al., 2007; [www.caribic-atmospheric.com](http://www.caribic-atmospheric.com))  
126 onboard an Airbus 340-600 of Lufthansa holds automated analyzers for gaseous mercury,  
127 CO, O<sub>3</sub>, NO, NO<sub>y</sub>, CO<sub>2</sub>, CH<sub>4</sub>, acetone, acetonitrile, water vapor (total, gaseous, isotope  
128 composition), and fine aerosol particles (three counters for particles with lower threshold  
129 diameters of 4 nm, 12 nm, and 18 nm, upper cut off about 2.0 μm), as well as an optical  
130 particle size spectrometer (OPSS) for particles with diameters > 150 nm. In addition,  
131 whole air and aerosol particle samples are taken in flight and subsequently analyzed for  
132 greenhouse gases, halocarbons, hydrocarbons, and particle elemental composition. The  
133 CARIBIC measurement container is usually deployed monthly during a sequence of four  
134 intercontinental flights.

135

136 The air inlet system and the mercury instrument are described in detail by  
137 Brenninkmeijer et al. (2007) and Slemr et al. (2016), respectively. Briefly, the trace gas  
138 inlet consists of a trace gas diffuser tube with a flow of more than 2000 volume-l min<sup>-1</sup>  
139 from which ~80 volume-l min<sup>-1</sup> is taken at a right angle to a manifold which supplies the  
140 trace gas analyzers in the container via a temperature controlled PFA lined supply line.  
141 The large air velocity in the trace gas diffuser tube and perpendicular sampling at much  
142 smaller velocity discriminate against particles larger than about one micrometer diameter  
143 (~50% aspiration efficiency, Baron and Willeke, 2001). A modified Tekran instrument  
144 (Tekran-Analyzer Model 2537 A, Tekran Inc., Toronto, Canada) samples 0.5 l (STP, i.e.  
145 1013.25 hPa and 273.15 K) min<sup>-1</sup> of air from the supply line manifold (heated to 40°C)  
146 using the 4 mm ID PFA tubing at about 30°C. The major modifications of the instrument  
147 were the addition of a second pump supporting the internal Tekran pump and of a  
148 computer which communicates with the container master computer and controls the  
149 automatic operation of the instrument. For the period August 2014 until February 2016 a  
150 quartz wool scrubber was installed in the instrument to filter out gaseous oxidized  
151 mercury (GOM).

152

153 To achieve an improved spatial resolution of ~ 75 km, the instrument was run with a  
154 sampling time of only 5 min. Despite an additional pump the nominal flow of 0.5 l (STP)  
155 min<sup>-1</sup> could not be sustained at the highest flight levels. Limited air flow, the short

156 sampling time, and low concentrations resulted in only  $\sim 2$  pg of mercury which is much  
157 smaller than 10 pg considered as minimum for bias-free internal default integration of the  
158 signal by the Tekran instrument (Swartzendruber et al., 2009; Slemr et al., 2016;  
159 Ambrose, 2017). The raw analyzer signals were thus processed post flight using a manual  
160 integration procedure described in detail by Slemr et al. (2016). The detection limit and  
161 precision with post-flight processing is estimated to be  $\sim 0.05$  ng m<sup>-3</sup>. The instrument is  
162 calibrated after every second flight sequence by comparison with a calibrated reference  
163 Tekran instrument in the laboratory. All concentrations are reported in ng Hg m<sup>-3</sup>(STP).  
164

165 As discussed in detail by Slemr et al. (2016) we can assume that our measurements  
166 encompass gaseous elemental mercury (GEM), gaseous oxidized mercury (GOM), and  
167 about 70% of particle bound mercury (PBM). Speciation experiments with soda lime and  
168 KCl coated quartz sand as GOM scrubbers made during several flights demonstrated that  
169 GOM passes through the CARIBIC sampling system. According to the extrapolation of  
170 the reported GOM/PBM (GOM and PBM are both assumed to be Hg<sup>2+</sup>, i.e. PBM + GOM  
171 = Hg<sup>2+</sup>) partitioning equilibria (Rutter and Schauer, 2007; Amos et al., 2012) from  
172 ambient temperatures near ground to  $\sim -50^\circ\text{C}$  around the tropopause, most of Hg<sup>2+</sup> will  
173 be attached to particles. Although the CARIBIC trace gas inlet is not optimized to collect  
174 particles, we estimated that particles with diameter of  $< 0.5$   $\mu\text{m}$  will pass through it,  
175 representing  $\sim 70\%$  of the aerosol mass. Despite of significant PBM concentrations in the  
176 stratosphere reported by Murphy et al. (1998, 2006), we were not able to detect mercury  
177 in aerosol samples collected by the CARIBIC impactor sampler downstream of the inlet  
178 optimized for quantitative particle sampling. Although not equipped with heaters, the air  
179 carrying particles will warm up to  $\sim +30^\circ$  on the way from the aerosol inlet to the  
180 impactor. Our inability to detect mercury in particle samples thus suggests that Hg<sup>2+</sup> on  
181 particles evaporates when the air sample is heated to  $\sim +30^\circ\text{C}$  in the inlet tubing and  
182 forms GOM. In summary, we assume that our measurements are close to total mercury  
183 (TM = GEM + Hg<sup>2+</sup> = GEM + GOM + PBM) concentration and we refer to them as such.  
184

185 In order to get information about the GOM fraction, sample air was passed through a  
186 quartz wool scrubber (Lyman and Jaffe, 2012) during the outbound flights between

187 August 2014 and February 2016. Quartz wool GOM scrubbers are claimed not to be  
188 influenced by ozone (Ambrose et al., 2013 and 2015) but can release GOM in humid air.  
189 Thus high UT/LMS ozone levels pose no problem and humidity effects are likely small  
190 or absent. The data collected with quartz wool scrubber are referred here as GEM.  
191 However, during half of the flights with quartz wool scrubber GEM concentrations were  
192 significantly higher than those of TM during the return flight at the beginning of the  
193 flight and the difference decreased during the flights indicating contamination of  
194 unknown origin. These data were eliminated from the data set. We note that the tracks  
195 and altitudes of the outbound and return flights differ sometimes substantially, especially  
196 in the case of the flights to North America (the flight tracks from Germany to North  
197 America tend to be substantially further north than those of the return flights). The TM  
198 and GEM data are thus not directly comparable even if they were measured on the same  
199 day.

200

201 The data reported here were obtained during flights between April 2014 and February  
202 2016 whose tracks are shown in Figure 1. All but one monthly flight sequences consisted  
203 of four individual intercontinental flights. The altitude of these flights varies typically  
204 from ~ 9 km at the beginning of the flight to 11 - 12 km at the end before the final  
205 descent. In addition to the meteorological data provided by the aircraft, meteorological  
206 parameters along the flight track were calculated from the ECMWF (European Centre for  
207 Medium Range Weather Forecasts) data (6-hourly, 60 model levels until February 2006  
208 and 90 model levels thereafter,  $1^\circ \times 1^\circ$  horizontal resolution). Eight day backward, 3-D  
209 kinematic trajectories were calculated with the KNMI model TRAJKS (Scheele et al.,  
210 1996, [http://projects.knmi.nl/campaign\\_support/CARIBIC/](http://projects.knmi.nl/campaign_support/CARIBIC/)) at one minute intervals along  
211 the flight path. Consequently, 5 trajectories were available for each mercury  
212 measurement. The data set consists of 33 and 17 individual flights with valid TM and  
213 GEM data, respectively.

214

215 For the data evaluation, the complementary continuous meteorological and chemical data  
216 were averaged over the sampling intervals of mercury measurements.

217

## 218 **3 Results and discussion**

219

### 220 3.1 Latitudinal TM distribution in the upper troposphere

221

222 Figure 2 shows latitudinal distribution of TM in the upper troposphere (defined as TM  
223 concentrations at potential vorticity (PV) of  $-1.5 \leq PV \leq 1.5$  PVU,  $1 \text{ PVU} = 10^{-6} \text{ K m}^2 \text{ kg}^{-1}$   
224  $\text{s}^{-1}$ ) observed during the flights to South America (Bogota, São Paulo, and Rio de  
225 Janeiro) in boreal summer (only July and August), fall (September, October, November),  
226 and winter (December, January, February). Corresponding latitudinal distributions of  
227 acetonitrile (AN), originating almost solely from biomass burning, and of CO and CH<sub>4</sub>  
228 with large emissions from biomass burning (Andreae and Merlet, 2001) are also shown.  
229 The lowest TM concentrations are observed in the latitude bands of 10 – 20°S and 20 –  
230 30°S in summer (JA) and the same applies for CO, CH<sub>4</sub>, and acetonitrile. The highest TM  
231 concentrations in 20-30°S latitude band are observed in fall (SON) and the TM  
232 concentrations decrease in winter (DJF) as do the CO and acetonitrile mixing ratios in the  
233 10 – 20°S latitude band. The highest CO and CH<sub>4</sub> mixing ratios at 20 – 30°S are observed  
234 in winter with mixing ratios in fall somewhat lower. Biomass burning in South America  
235 starts in June, peaks in September and ends in December (Duncan et al., 2003). TM  
236 concentrations in the southernmost latitude bands follow this seasonal variability as do  
237 the acetonitrile, CO and CH<sub>4</sub> mixing ratios at 10 – 20°S latitude. In the latitude band 20 –  
238 30°S the CO and CH<sub>4</sub> mixing ratios are higher in boreal winter than in fall. This might  
239 result from larger additional CO and CH<sub>4</sub> sources in boreal winter such as from oxidation  
240 of volatile organic compounds and wetlands. It is also worth noting that in boreal fall and  
241 boreal winter the acetonitrile and CO mixing ratios in the monitored part of the southern  
242 hemisphere are higher than in the northern hemisphere. In summary, Figure 2 illustrates  
243 the large-scale influence of biomass burning on the latitudinal TM distribution in the  
244 upper troposphere of the southern hemisphere.

245

246 The role of biomass burning is further illustrated by means of Figure 3, comparing the  
247 South America boreal winter profiles of the four trace constituents with those for South  
248 Africa (Cape Town). Acetonitrile and CO mixing ratios from flights to South Africa

249 show a pronounced bulge between 30°S and 20°N peaking around the equator. The same  
250 applies to results for the flights to South America, be it with somewhat lower values and  
251 more southern maximum for acetonitrile. For both flight routes CO and acetonitrile  
252 mixing ratios are higher in the southern than in the northern hemisphere. Boreal winter  
253 (DJF) is an intermediate season between biomass emissions peaking in September in  
254 southern Africa and in January in northern Africa (Duncan et al., 2003). The latitudinal  
255 pattern of CH<sub>4</sub> is less clear, with wetlands also being a major source. Finally, Figure 3  
256 shows a similarity between TM and the biomass burning indicators in the tropics at flight  
257 altitude.

258

259 Biomass burning plumes with enhanced mercury concentrations have been reported  
260 before (Brunke et al., 2001; Friedli et al., 2001, 2003a and b, Ebinghaus et al., 2007,  
261 Slemr et al., 2014, among others). With 675 Mg yr<sup>-1</sup> biomass burning is estimated to be  
262 the third largest source of atmospheric mercury after emissions from oceans (2682 Mg yr<sup>-1</sup>)  
263 and from fossil-fuel power plants (810 Mg yr<sup>-1</sup>; Friedli et al., 2009; Pirrone et al.,  
264 2010). Figures 2 and 3 illustrate the influence of biomass burning on the large scale  
265 distribution of TM in the southern hemispheric UT.

266

267 Acetonitrile mixing ratios in winter (DJF) in Figure 3 are the lowest in the northernmost  
268 latitude bands 20 – 50°N. The concomitant elevated TM concentrations and CO and CH<sub>4</sub>  
269 mixing ratios are thus mostly due to anthropogenic emissions. An exception is the highest  
270 TM concentration observed at 30 – 40°N (Figure 2) in summer (JA) which coincides with  
271 the peak of acetonitrile mixing ratio in the northern hemisphere. The respective data  
272 originate from the flight #475 from São Paulo to Munich on August 21, 2014. Two whole  
273 air samples were taken within this latitude band of which sample #12 coincides with the  
274 peak acetonitrile, acetone, CO, and CH<sub>4</sub> mixing ratios. In addition, sample #12 contains  
275 high ethane and propane mixing ratios (786 and 126 ppt, respectively) as well as  
276 somewhat elevated CH<sub>4</sub> and SF<sub>6</sub> mixing ratios. Sample #12 was taken over southwestern  
277 Spain and its 8 day backward trajectory crosses the Atlantic Ocean, eastern US, Great  
278 Lakes up to Californian Pacific coast. The complex composition of this sample indicates  
279 a mixture of anthropogenic pollution with emissions from biomass burning. The latter is

280 additionally supported by fire maps  
281 (<https://lance.modaps.eosdis.nasa.gov/imagery/firemaps>) reporting individual fire counts  
282 along the trajectory in North America and especially a large fire in northern California at  
283 the time of trajectory crossing.

284

285 3.2 Seasonal variation of the vertical TM distribution in the upper troposphere and  
286 lowermost stratosphere

287

288 Due to the geographical location of the airport of departure and the CARIBIC  
289 destinations it happens to be that half of the intersected air masses are above the  
290 tropopause. This allows a fairly representative mapping of measured trace species around  
291 the tropopause. Figure 4 shows the seasonal pattern of the average TM concentrations  
292 and CO, CH<sub>4</sub>, and O<sub>3</sub> mixing ratios relative to the thermal tropopause. The distance  
293 relative to the tropopause is based on CARIBIC ozone measurements. Basically, an  
294 ozone mixing ratio measured by CARIBIC is compared to representative data from ozone  
295 soundings. Because these soundings measure both thermal tropopause height and ozone,  
296 the distance relative to the tropopause is obtained (Sprung and Zahn, 2010). This value  
297 based on the CARIBIC ozone data is considered to be more accurate than PV (calculated  
298 from the ECMWF-model) based dynamical tropopause, especially in subtropical latitudes  
299 where the dynamical tropopause is not well defined by a constant PV threshold value  
300 (Kunz et al., 2011). Only measurements north of 20°N were considered for making this  
301 plot. The seasonal variation of the vertical distributions of the trace gases and TM reflect  
302 their source location and the Brewer-Dobson circulation with a maximum content of  
303 stratospheric air in the UT/LMS in spring (Holton et al., 1995; Gettelman et al., 2014).  
304 Ozone rich air, depleted in CO, CH<sub>4</sub>, and N<sub>2</sub>O descends in spring and the question is  
305 what happens to the mercury compounds.

306

307 The highest tropospheric TM concentrations of 1.4 – 1.7 ng m<sup>-3</sup> are encountered in  
308 September/October at 0.5 – 1.75 km below the thermal tropopause. About two thirds of  
309 these elevated TM data originate from flights from Tokio to Munich on October 30,  
310 2014, and Beijing to Munich on October 31, 2014, and were observed mostly within

311 ~1500 km of Tokio and Beijing. High TM concentrations are accompanied by elevated  
312 CO and CH<sub>4</sub> mixing ratios. Near Tokio and Beijing also elevated SF<sub>6</sub> mixing ratios were  
313 observed. Backward trajectories from these flight segments on October 30 and 31 point to  
314 surface contact in Tibet, Bangladesh, and northern India. Slightly elevated TM  
315 concentrations encountered near Munich on October 30 and 31 are most likely due  
316 emissions located in North America.

317

318 The lowest TM concentrations of 0.4 – 0.6 ng m<sup>-3</sup> were encountered during the flights  
319 Tokio to Munich (CARIBIC #502) on April 21, 2015, and Mexico to Munich (CARIBIC  
320 #504) on April 22, 2015. During both flights the lowest TM concentrations were  
321 accompanied by O<sub>3</sub> and H<sub>2</sub>O mixing ratios of > 400 ppb and < 10 ppm, respectively,  
322 characteristic of deeper stratospheric air. No CO data are available for the CARIBIC  
323 flight #502 but CO mixing ratios of < 30 ppb for the lowest TM values during the  
324 CARIBIC flight #504 also point to deep stratospheric origin of the air, as confirmed by  
325 the extremely low SF<sub>6</sub> and CH<sub>4</sub> mixing ratios in both flights.

326

### 327 3.3 Speciation in the UT and LMS

328

329 The reason to show only TM in Figure 4, and not GEM as well is that speciation failed  
330 for about half of the data due to contamination problems with the quartz wool GOM  
331 scrubber. For analyzing the GEM results, we divide the data set into boreal winter  
332 (December – May) and boreal summer (June – November). Figure 5 give the vertical  
333 distributions of TM and GEM in three different latitude bands for boreal winter (Figure  
334 5a) and summer (Figure 5b). The data points in these figures represent concentration  
335 averages and their standard errors. Although extreme individual values were eliminated  
336 using the Nalimov outlier test (Kaiser and Gottschalk, 1972), unedited data give very  
337 similar plots. We also note that TM and GEM data from all flights were used in these  
338 figures, altogether 1528 and 1349 TM measurements in winter and summer, respectively,  
339 as well 699 and 916 GEM measurements in winter and summer, respectively. As already  
340 mentioned GEM data were collected during the outward and TM data during the return  
341 flights. Because of different flight tracks and flight altitudes the GEM and TM data

342 cannot be directly compared even if measured on the same day. In addition, because of  
343 contamination problems valid GEM data are available only for about one half of the  
344 flights with TM data.

345

346 Winter vertical distribution in Figure 5a shows for 30 – 60°N a steep gradient of TM  
347 concentrations across the thermal tropopause from ~ 1.25 ng m<sup>-3</sup> in the UT to ~ 0.6 ng m<sup>-3</sup>  
348 <sup>3</sup> in the LMS. This gradient corresponds to the steep gradient of TM concentrations in  
349 January – May shown in Figure 4. The GEM gradient is steeper starting with  
350 concentrations of ~ 1.35 ng m<sup>-3</sup> and decreasing to concentrations of ~ 0.35 ng m<sup>-3</sup> in the  
351 LMS. The difference between TM and GEM concentrations at altitudes starting at 1 km  
352 above the tropopause is ~ 0.2 ng m<sup>-3</sup>, representing ~ 40% of TM concentration.

353

354 TM and GEM data between 30°S – 30°N cover essentially only the UT because the  
355 aircraft cruising altitude of 10 – 12 km is not sufficient to enter the tropical stratosphere.  
356 TM and GEM concentrations are essentially the same, but with ~1.2 ng m<sup>-3</sup> somewhat  
357 lower than in the UT at 30 – 60°N where most of the anthropogenic mercury sources are  
358 located.

359

360 In the northernmost latitude band (> 60°N) there are few UT data because the aircraft  
361 cruising altitude of 10 – 12 km has most of the time been above the tropopause. Starting  
362 at altitudes of 1 km above the tropopause, the TM concentrations around ~ 0.6 ng m<sup>-3</sup> are  
363 only slightly higher than GEM concentrations of 0.5 ng m<sup>-3</sup>. Larger difference between  
364 TM and GEM concentrations is observed only at the three highest altitudes above the  
365 tropopause.

366

367 Figure 5b shows the summer data which are generally higher than the winter data. In the  
368 tropical UT (30°S – 30°N GEM concentrations are with ~ 1.2 ng m<sup>-3</sup> somewhat lower  
369 than those of TM, but the difference is probably insignificant. In the northern  
370 midlatitudes the GEM concentrations measured in the UT are higher than TM This is not  
371 a contradiction because of the different tracks of outbound (GEM measurements) and

372 return (TM measurements) flights to North America and different influence of biomass  
373 burning on particular flights. It appears that in the LMS the differences are small.

374

375 At mid latitudes and north of 60°N, TM gradients around the tropopause are much less  
376 steep in summer than in winter (Figure 5a), which is consistent with the seasonal  
377 variation of TM concentrations in UT/LMS shown in Figure 4. There is not much  
378 difference between TM and GEM concentrations in the midlatitude LMS, but at >60°N at  
379 2 – 3 km above the tropopause GEM concentrations with  $\sim 0.6 \text{ ng m}^{-3}$  are consistently  
380 lower than those of TM with  $\sim 0.8 \text{ ng m}^{-3}$ .

381

382 In summary, TM concentrations are lowest (with  $\sim 0.5 \text{ ng m}^{-3}$ ) in stratosphere at the  
383 highest altitude above the tropopause (3 – 4 km). GEM concentrations are comparable to  
384 those of TM in the UT, but systematically smaller in the LMS at middle latitude in winter  
385 and at northernmost latitudes in summer.

386

387 Our notion about the behavior and speciation of mercury in the UT/LMS is quite limited  
388 and based on a few measurement reports. Swartzendruber et al. (2006) observed at Mount  
389 Bachelor higher GOM concentration in downslope air flow than in upslope flow which  
390 implies higher GOM concentrations in the free troposphere than in the planetary  
391 boundary layer. Talbot et al. (2007a) reported a total depletion of GEM in the UT/LMS.  
392 By extrapolation of measurements in stratospheric intrusions, Lyman and Jaffe (2012)  
393 derived an empirical model which predicts a total depletion of GEM at  $\sim 1 \text{ km}$  above the  
394 tropopause and of total mercury (including particle bound mercury, PBM) at some 2 km  
395 above the tropopause. The latter is inconsistent with observations of substantial PBM  
396 concentrations in the stratosphere up to an altitude of 8 km above the tropopause reported  
397 by Murphy et al. (1998, 2006). Brooks et al. (2014) reported decreasing GOM  
398 concentrations above GOM maxima at  $\sim 4 \text{ km}$  altitude above ground. They also found  
399 that GEM concentrations are independent of altitude between ground and 6 km altitude  
400 for most of the year. Only in April, May and June GEM concentrations decreased with  
401 increasing altitude possibly because of the intensive influx of stratospheric air in this

402 season. Gratz et al. (2015) observed in June 2013 high GOM concentrations in  
403 tropospheric air mass rich in BrO advected from the subtropical Pacific.

404

405 Opposite to the total GEM depletion reported by Talbot et al. (2007a) and predictions by  
406 Lyman and Jaffe (2012) our post-flight processed GEM and TM concentrations were  
407 never below the detection limit of  $\sim 0.05 \text{ ng m}^{-3}$ , even at 4 km altitude above the  
408 tropopause. However, when using the default Tekran software, small mercury peaks are  
409 occasionally not integrated resulting in erroneous zero concentrations. We thus surmise  
410 that the zero GEM concentrations reported by Talbot et al. (2007a) were not real but an  
411 artifact due to incorrect default integration of the Tekran raw signal (Swartzendruber et  
412 al., 2009; Slemr et al., 2016; Ambrose, 2017). We also note that Talbot et al. (2007a)  
413 attribute their measurements to GEM although their inlet system is very similar to that of  
414 CARIBIC (Slemr et al., 2014) with proven transmission of GOM. As for CARIBIC, the  
415 measurements by Talbot et al. (2007a) are thus more likely close to those of TM.

416

417 Based on TM and GEM measurements outside of a stratospheric intrusion, Lyman and  
418 Jaffe (2012) found  $\text{Hg}^{2+}$  ( $\text{GOM} + \text{PBM} = \text{TM} - \text{GEM}$ ) to be dominant mercury species at  
419 the tropopause. By extrapolation of the data using empirical correlations of TM and  $\text{Hg}^{2+}$   
420 with ozone, they predicted zero TM concentrations already at  $\sim 2 \text{ km}$  above the  
421 tropopause and speculated that this may generally apply for the UT/LMS. This is  
422 inconsistent with our measurements that show comparable GEM and TM concentrations  
423 in the UT with  $\text{Hg}^{2+}$  constituting at most  $\sim 50\%$  of TM up to 4 km above the tropopause.  
424 It is also inconsistent with regular vertical profiling of GEM, GOM, and PBM up to 6 km  
425 altitude above ground by Brooks et al. (2014). They report tropospheric GOM maxima of  
426 up to  $\sim 0.11 \text{ ng m}^{-3}$  at  $\sim 4 \text{ km}$  above ground and decreasing GOM concentrations above.  
427 Elevated  $\text{Hg}^{2+}$  concentrations in the UT during the NOMADDS (Nitrogen, Oxidants,  
428 Mercury and Aerosol Distributions, Sources and Sinks) campaign were reported by Gratz  
429 et al. (2015) but only for an advected tropospheric air mass with high BrO content (Gratz  
430 et al., 2015). We thus conclude that high GOM concentrations in the UT reported by  
431 Lyman and Jaffe (2012) are most likely an event phenomenon which cannot be  
432 generalized.

433

434 Zero TM concentrations at ~ 2 km above the tropopause from the empirical model of  
435 Lyman and Jaffe (2012) are, in addition, not conform to the observations of significant  
436 PBM concentrations in stratosphere by Murphy et al. (1998, 2006). Gaseous  $\text{Hg}^{2+}$  (GOM)  
437 is assumed to be in equilibrium with PBM. An extrapolation of the equilibria observed at  
438 ambient air temperatures near ground (Rutter and Schauer, 2007; Amos et al., 2012) to  
439 some  $-50^\circ\text{C}$  around the tropopause shows that almost all  $\text{Hg}^{2+}$  will be on particles.  
440 Substantial PBM concentrations observed by Murphy et al. (1998, 2006) up to 8 km  
441 above the tropopause together with our TM data obtained during some 500 CARIBIC  
442 flights (including those with default Tekran raw signal integration) thus exclude the  
443 possibility that TM disappears at ~ 2 km above the tropopause. We also note that Murphy  
444 et al. (1998, 2006) could not detect any PBM in the troposphere at and below 5 km above  
445 ground. Non-detectable PBM in equilibrium with GOM at still low air temperatures at  
446 these altitudes is another piece of evidence inconsistent with generally high GOM  
447 concentrations in the upper free troposphere.

448

449 In summary, it is plausible that our TM data currently provide the most representative  
450 picture of its UT/LS distribution and seasonal variation. Our GEM measurements rely on  
451 the performance of the GOM quartz wool traps and the difference between TM and GEM  
452 is statistically compromised by not being measured along exactly the same routes and  
453 altitudes above the tropopause. Despite this, our TM and GEM observations suggest only  
454 a small contribution of  $\text{Hg}^{2+}$  to TM in the UT and are consistent with the observations of  
455 substantial PBM concentrations in UT/LS by Murphy et al. (1998, 2006).

456

#### 457 3.4 Stratospheric lifetime of TM and GEM

458

459  $\text{N}_2\text{O}$  and  $\text{SF}_6$  measured in the whole air samples taken during the CARIBIC flights can be  
460 used as chronological tracers to estimate the stratospheric lifetime of TM and GEM. Here  
461 we use the relative approach described by Volk et al. (1997) using the CARIBIC  $\text{N}_2\text{O}$   
462 measurements (Assonov et al., 2013) as reference tracer.  $\text{N}_2\text{O}$ , with a lifetime of ~120 yr  
463 is nearly uniformly distributed in the troposphere, with little seasonal variation and is

464 only removed in the stratosphere (Nevison et al., 2011). In comparison with SF<sub>6</sub> as  
465 chronological tracer, N<sub>2</sub>O has the advantage of a much smaller latitudinal gradient in the  
466 troposphere and of nearly constant growth rate in the last two decades. Figure 6 shows  
467 winter (November – April) average stratospheric TM and GEM concentrations as a  
468 function of N<sub>2</sub>O mixing ratios. In this plot N<sub>2</sub>O mixing ratios were detrended using 2015  
469 as a reference year and the N<sub>2</sub>O growth rate of 0.844 ppb yr<sup>-1</sup> (Assonov et al., 2013).

470

471 TM and GEM concentrations in Figure 6 start at  $1.18 \pm 0.27$  (n = 48) and  $1.12 \pm 0.21$  (n =  
472 35) ng m<sup>-3</sup>, respectively, in the 325 – 330 ppb bin of N<sub>2</sub>O mixing ratios and they decrease  
473 substantially to  $0.59 \pm 0.13$  (n = 12) and  $0.42 \pm 0.10$  (n = 16) ng m<sup>-3</sup>, respectively, in the  
474 305 – 310 ppb bin. The difference between TM and GEM concentrations is not  
475 statistically significant in the 325 – 330 ppb bin of N<sub>2</sub>O mixing ratios, i.e. in the UT as  
476 already mentioned before. At lower N<sub>2</sub>O mixing ratios, however, GEM concentrations  
477 are systematically smaller than those of TM at the 99% significance level. The TM-GEM  
478 difference (i.e. Hg<sup>2+</sup> concentration in the gas phase (GOM) and on particles (PBM)) is  
479 increasing with decreasing N<sub>2</sub>O mixing ratios and levels off at  $\sim 0.17$  ng m<sup>-3</sup> at N<sub>2</sub>O  
480 mixing ratios below 315 ppb representing  $\sim 30\%$  of TM concentrations. As mentioned in  
481 the experimental section, the CARIBIC trace gas inlet is not optimized for quantitative  
482 collection of particles and, consequently, we presume to measure only  $\sim 70\%$  of Hg<sup>2+</sup> on  
483 particles. If all Hg<sup>2+</sup> (i.e. TM-GEM) were on particles as predicted by extrapolation of  
484 Hg<sup>2+</sup> gas-particle partitioning equilibrium (Rutter and Schauer, 2007; Amos et al., 2012)  
485 from ambient temperature to temperatures at the tropopause then the unbiased Hg<sup>2+</sup> and  
486 TM concentrations would be  $\sim 0.24$  and  $\sim 0.66$  ng m<sup>-3</sup>, respectively, at N<sub>2</sub>O mixing ratios  
487 below 310 ppb.

488

489 Small decrease of TM and GEM with decreasing N<sub>2</sub>O below 315 ppb suggests a long  
490 stratospheric lifetime of both TM and GEM. Correlations of all TM and GEM  
491 concentrations at N<sub>2</sub>O mixing ratios < 315 ppb vs N<sub>2</sub>O yield slopes of  $6.30 \pm 2.96$  pg m<sup>-3</sup>  
492 ppb<sup>-1</sup> (n = 46, R = 0.2947, significance > 95%) and  $6.13 \pm 1.82$  pg m<sup>-3</sup> ppb<sup>-1</sup> (n = 63, R =  
493 0.3909, significance > 99%), for TM and GEM, respectively. Using stratospheric N<sub>2</sub>O  
494 lifetime of  $122 \pm 24$  yr (Volk et al., 1997) we arrive at stratospheric TM and GEM

495 lifetimes of  $72 \pm 37$  and  $74 \pm 27$  yr, respectively. The uncertainties calculated from the  
496 slope uncertainties and the uncertainty of  $\text{N}_2\text{O}$  lifetime are probably lower limit because  
497 of the narrow range of encountered  $\text{N}_2\text{O}$  mixing ratios in cruising altitudes of the  
498 CARIBIC aircraft (Assonov et al., 2013). We note that our stratospheric TM and GEM  
499 lifetimes are not “relatively short” as claimed by Lyman and Jaffe (2012). We think that  
500 their TM and GEM concentrations were measured within the region of mixing of  
501 stratospheric with tropospheric air. Figure 6 shows that TM and GEM vs  $\text{N}_2\text{O}$   
502 correlations would result in much shorter lifetimes when data at  $\text{N}_2\text{O}$  mixing ratios larger  
503 than 315 ppb were included. With the calculated uncertainties the stratospheric TM  
504 lifetime cannot be distinguished from that of GEM. A more precise estimate of TM and  
505 GEM stratospheric lifetimes will require measurements with research aircraft capable of  
506 flying at higher altitudes.

507

508 Data in Figure 6 allow us to correlate  $\text{Hg}^{2+}$  (TM - GEM) with GEM as made by Lyman  
509 and Jaffe (2012).  $\text{Hg}^{2+}$  is negatively correlated with GEM with a slope of  $-0.13 \pm 0.04$  ( $n$   
510  $= 7$ ,  $R^2 = 0.712$ ) and  $-0.31 \pm 0.04$  ( $n = 7$ ,  $R^2 = 0.919$ ) when averages and medians are  
511 used, respectively. Chemical conversion of GEM into  $\text{Hg}^{2+}$  without any  $\text{Hg}^{2+}$  losses  
512 would yield a slope of -1 and slopes near this value were reported for the free troposphere  
513 by Swartzendruber et al. (2006) and for the UT by Lyman and Jaffe (2012). Our negative  
514 slopes in the stratosphere are substantially greater than -1 and somewhat greater than -  
515 0.53 reported by Lyman and Jaffe (2012) for stratosphere-influenced air masses.  
516 Negative slopes greater than -1 imply losses of  $\text{Hg}^{2+}$  ( $\text{Hg}^{2+}$  yield of GEM oxidation is  
517 smaller than the stoichiometry of the reaction) and result in decreasing TM  
518 concentrations with increasing  $\text{Hg}^{2+}$  concentrations in the stratosphere.

519

520 A reduction of TM concentration from  $\sim 1.2 \text{ ng m}^{-3}$  in tropospheric air to  $\sim 0.66 \text{ ng m}^{-3}$  in  
521 stratospheric air is too large to be explained by the aerosol bias induced by the  
522 incomplete particle sampling mentioned above and requires  $\text{Hg}^{2+}$  removal process. Such  
523 removal process requires an oxidation of GEM into  $\text{Hg}^{2+}$ , an attachment of  $\text{Hg}^{2+}$  to  
524 abundant stratospheric, mainly sulfate, particles, and their removal by gravitational  
525 sedimentation and/or scavenging by clouds (Menzies and Tratt, 1995; Rasch et al., 2008;

526 Lyman and Jaffe, 2012). We note that air mass exchange is also taking important part in  
527 removing the sulfate particles from the stratosphere but TM concentrations would not  
528 change without sedimentation and scavenging of  $\text{Hg}^{2+}$  on particles. The oxidation and  
529 subsequent attachment to particles could be a local process in the vicinity of extratropical  
530 tropopause layer (exTL) or a non-local process in the tropical upper troposphere (TTL)  
531 and during the transport from the TTL to the location of the IAGOS-CARIBIC  
532 measurements in the LMS. Lyman and Jaffe (2012) hypothesized that  $\text{Hg}^{2+}$  formed by  
533 GEM oxidation in the TTL and/or stratosphere will attach to sulfate particles formed in  
534 the stratosphere predominantly by COS oxidation and be removed with them (Wilson et  
535 al., 2008). This hypothesis is corroborated by our stratospheric TM and GEM lifetimes  
536 which are comparable to COS lifetime of  $64 \pm 21$  yr (Barkley et al., 2008). As pointed  
537 out by Lyman and Jaffe (2102), the hypothetical model of stratospheric mercury is thus  
538 similar and closely related to that of stratospheric sulfur (COS + sulfate particles) as  
539 described by Wilson et al. (2008).

540

## 541 **Conclusions and outlook**

542

543 The obvious implication of the long stratospheric TM and GEM lifetimes is that most  
544 atmospheric mercury is oxidized in the troposphere. The second direct implication is that  
545 if the lifetime of GEM in the stratosphere with its very high  $\text{O}_3$  mixing ratios (typically 1  
546 ppm and more) is quite long, then the GEM +  $\text{O}_3$  reaction cannot be important in the  
547 troposphere with its low  $\text{O}_3$  mixing ratios. This implies that either the reaction does not  
548 take place or that the primary reaction product is unstable. Moreover, with very low  
549 stratospheric  $\text{H}_2\text{O}$  mixing ratios below 10 ppm, also OH is an unlikely oxidant for GEM  
550 in the stratosphere. The most plausible remaining oxidants are Br atoms with a possible  
551 contribution of O atoms.

552

553 The regular intercontinental IAGOS-CARIBIC flights provide an insight into the large-  
554 scale distribution of TM and GEM in the UT/LMS and its seasonal variation. Post-flights  
555 processed data with better accuracy and higher precision reveal a seasonal variation of  
556 vertical TM distribution in the UT/LMS which is similar to most of the trace gases with

557 sources in the troposphere, such as CH<sub>4</sub> and CO. Importantly, even at altitudes of up to  
558 3.5 km above the thermal tropopause TM concentrations are still ~0.5 ng m<sup>-3</sup>, one order  
559 of magnitude above the instrumental detection limit. We have never observed zero TM or  
560 GEM concentrations and attribute earlier reports about them to an insufficiency in the  
561 default signal integration of the Tekran instrument.

562

563 Latitudinal TM distribution in the UT during the flights to South America and South  
564 Africa were found to be strongly influenced by biomass burning. Although TM and GEM  
565 were not measured at the same place and at the same time, the data collectively show that  
566 their concentrations in the UT are similar and the Hg<sup>2+</sup> concentrations are thus usually  
567 small. Recent reports on high GOM and Hg<sup>2+</sup> concentrations in the free troposphere are  
568 limited to middle tropospheric altitudes (Brooks et al., 2014), to an event with high BrO  
569 concentrations (Gratz et al., 2015) or to a stratospheric intrusion (Lyman and Jaffe, 2012)  
570 and are in view of our observational IAGOS-CARIBIC data set most likely not  
571 representative for large-scale UT distribution. Larger Hg<sup>2+</sup> (TM – GEM) concentrations  
572 of up to about half of TM concentrations were observed only in the LMS.

573

574 Lower TM concentrations were generally observed in LMS with the pronounced gradient  
575 just above the tropopause. We attribute this gradient to mixing of tropospheric air with  
576 stratospheric air depleted of mercury. The conservative character of TM measurements  
577 implicates a loss process by oxidation to Hg<sup>2+</sup>, its attachment to particles and their  
578 subsequent removal by gravitational sedimentation and/or scavenging by clouds.  
579 Substantial stratospheric PBM concentrations reported by Murphy et al. (1998, 2006) and  
580 GOM/PBM equilibria (Rutter and Schauer, 2007; Amos et al., 2012) extrapolated to  
581 temperatures in the LMS support this hypothesis.

582

583 Correlations of TM and GEM with N<sub>2</sub>O as a reference substance show statistically the  
584 same TM and GEM concentrations in the UT. In the N<sub>2</sub>O range of 330 and 315 ppb TM  
585 and GEM concentrations rapidly decrease with decreasing N<sub>2</sub>O mixing ratios due to  
586 mixing of tropospheric air with stratospheric air depleted of mercury. Below 315 ppb  
587 until 295 ppb of N<sub>2</sub>O TM and GEM concentrations hardly change. TM and GEM

588 lifetimes of  $72 \pm 37$  and  $74 \pm 27$  yr, respectively, were calculated from correlations of  
589 TM and GEM vs  $\text{N}_2\text{O}$  below 315 ppb, albeit with large uncertainties caused by the  
590 limited altitude range of commercial airliners and the resulting narrow range of  $\text{N}_2\text{O}$   
591 mixing ratios between 315 and 295 ppb. Measurements of TM, GEM, and  $\text{N}_2\text{O}$  to higher  
592 altitudes above the tropopause (i.e. to  $\text{N}_2\text{O}$  mixing ratios substantially below 290 ppb) are  
593 needed to better constrain the stratospheric TM and GEM lifetimes.

594

595 Stratospheric lifetimes of TM and GEM are comparable to the COS stratospheric lifetime  
596 of  $64 \pm 21$  yr (Barkley et al., 2008), which is in volcanically quiet periods the major  
597 precursor of sulfate particles in the stratosphere (Wilson et al., 2008). This coincidence  
598 corroborates the hypothesis of  $\text{Hg}^{2+}$  attachment to sulfate particles and their removal by  
599 gravitational sedimentation and scavenging by clouds. This hypothesis, first proposed by  
600 Lyman and Jaffe (2012), could be directly tested in future by quantitative measurements  
601 of Hg/S ratios on stratospheric particles. Such measurements would also better constrain  
602 the mercury fluxes across the tropopause.

603

604 Mercury measurements onboard IAGOS-CARIBIC were stopped in March 2016 and the  
605 space of the mercury instrument is now occupied by other instruments. The reason for the  
606 termination of the mercury measurements was the feeling that, with the present  
607 instrumentation, we will only reproduce the existing data. An improved instrumentation  
608 including reliable speciation technique is needed to gain new insights. Any institution  
609 capable of providing and maintaining such an instrument is welcomed to participate in  
610 future IAGOS-CARIBIC measurements. For details please consult the CARIBIC  
611 coordinator Andreas Zahn.

898

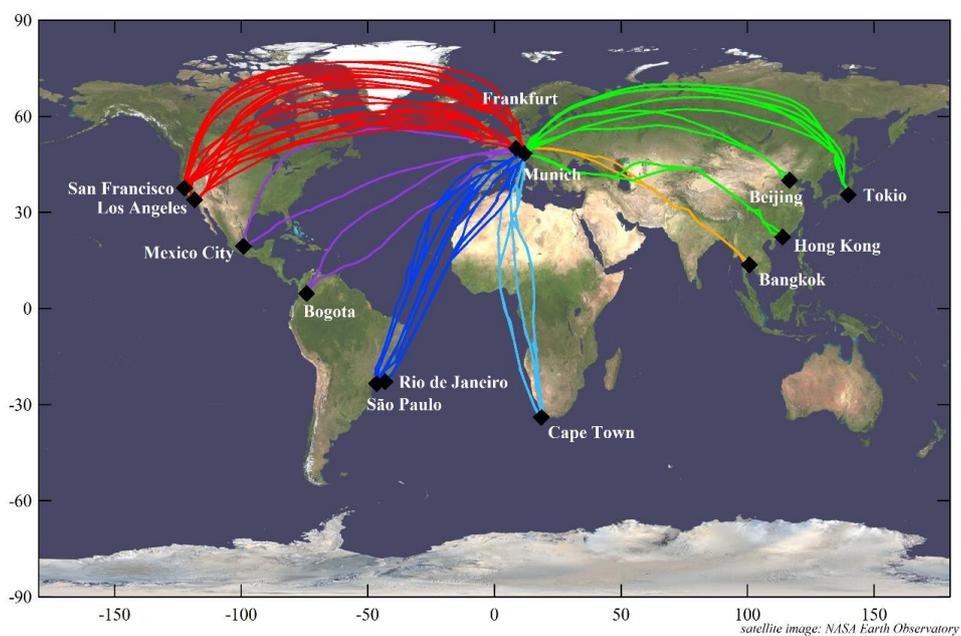

899 **Figures**

900

901 Figure 1: Tracks of the CARIBIC flights made between April 2014 and February 2016  
902 (CARIBIC flights #468-536). Mercury data for these flights were obtained by post-flight  
903 processing of the Tekran raw signal (Slemr et al., 2016).

904

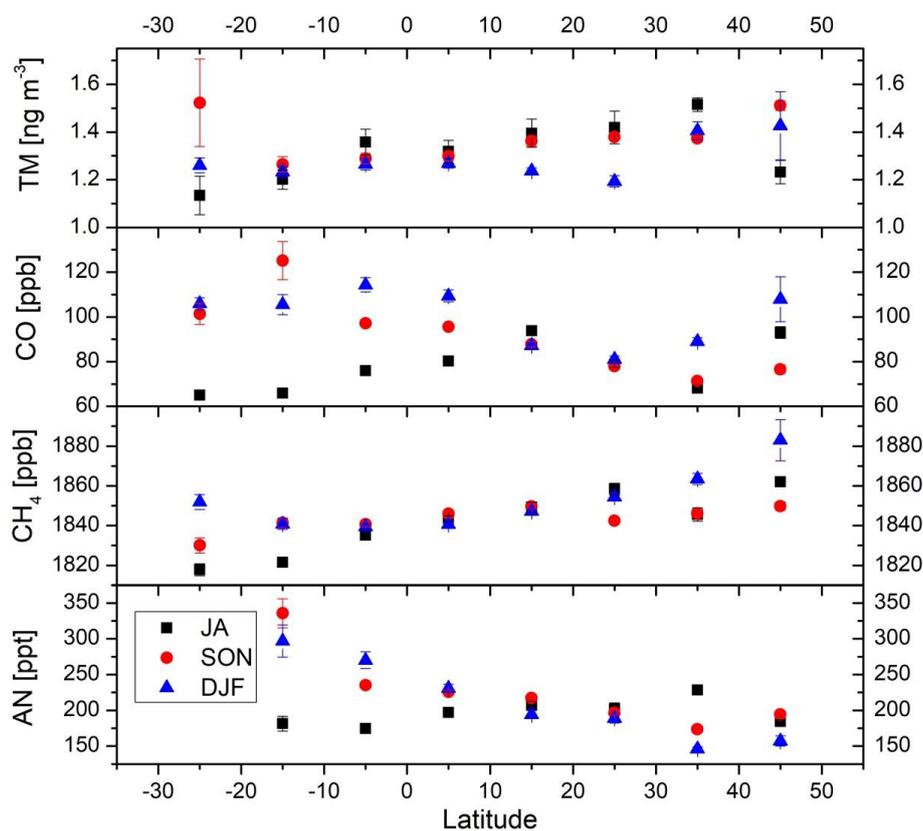

905

906

907

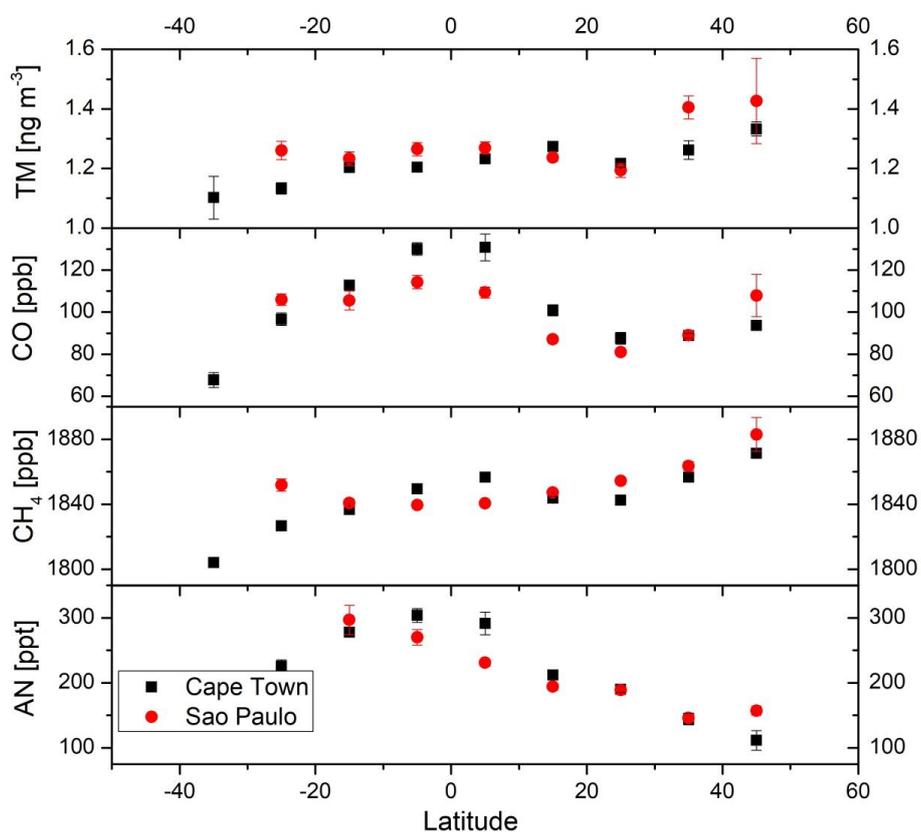

908 Figure 2: Latitudinal distributions of tropospheric ( $PV \leq 1.5$  PVU) TM, CO, CH<sub>4</sub>, and  
 909 acetonitrile (AN) during the flights from Bogota and São Paulo/Rio de Janeiro to Munich  
 910 in summer (only July and August, JA), autumn (September, October, and November,  
 911 SON) and winter (December, January, and February, DJF). The points represent averages  
 912 and the vertical bars their standard error. No acetonitrile data were available south of  
 913 20°S.  
 914

915  
 916  
 917

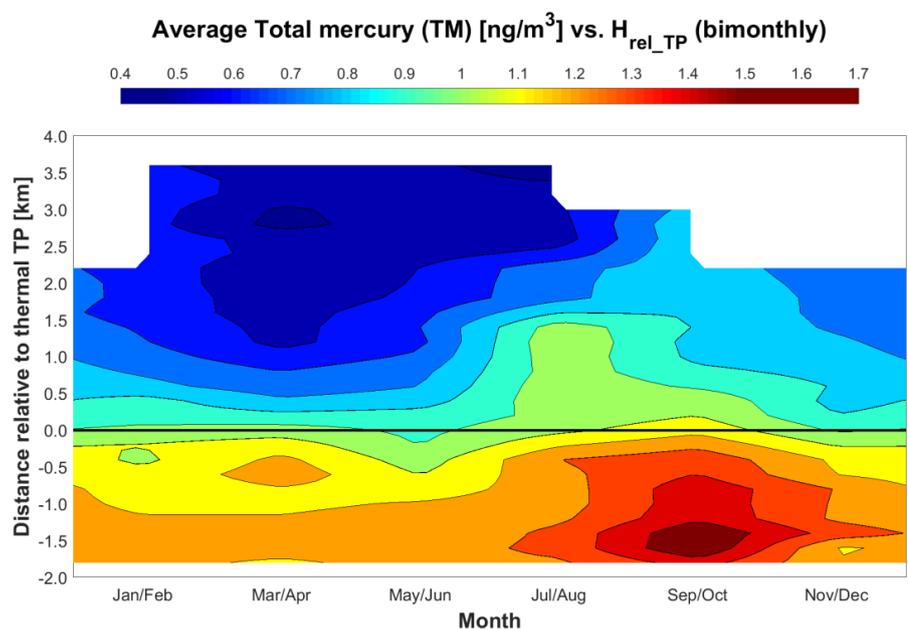

918 Figure 3: Latitudinal distributions of tropospheric TM, CO, CH<sub>4</sub>, and acetonitrile (AN) in  
 919 winter (December, January, and February, DJF) during the flights from Cape Town and  
 920 São Paulo to Munich. The points represent averages and the vertical bars their standard  
 921 error. No acetonitrile data are available south of 30°S and 20°S for flights to Cape Town  
 922 and São Paulo, respectively.  
 923

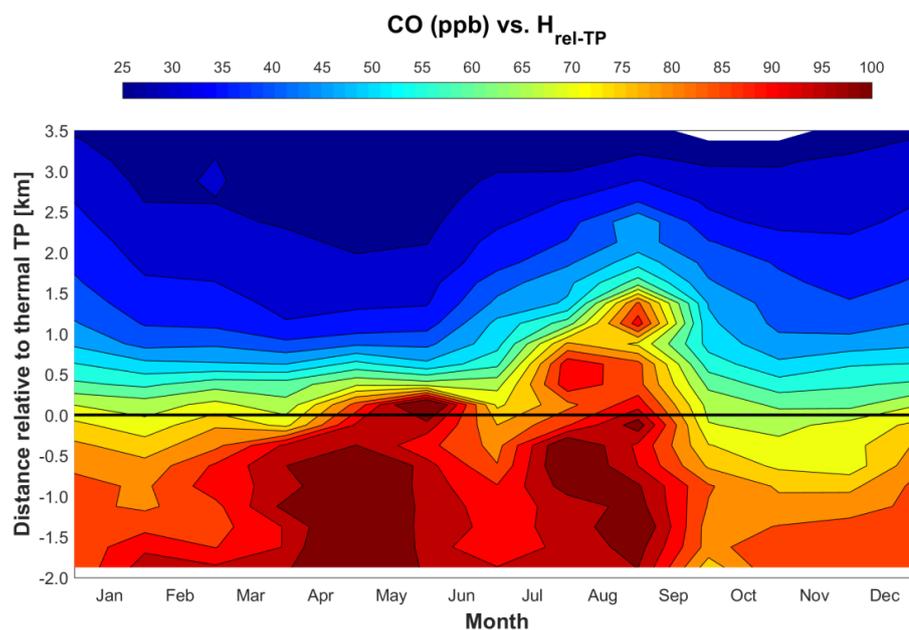

924  
925

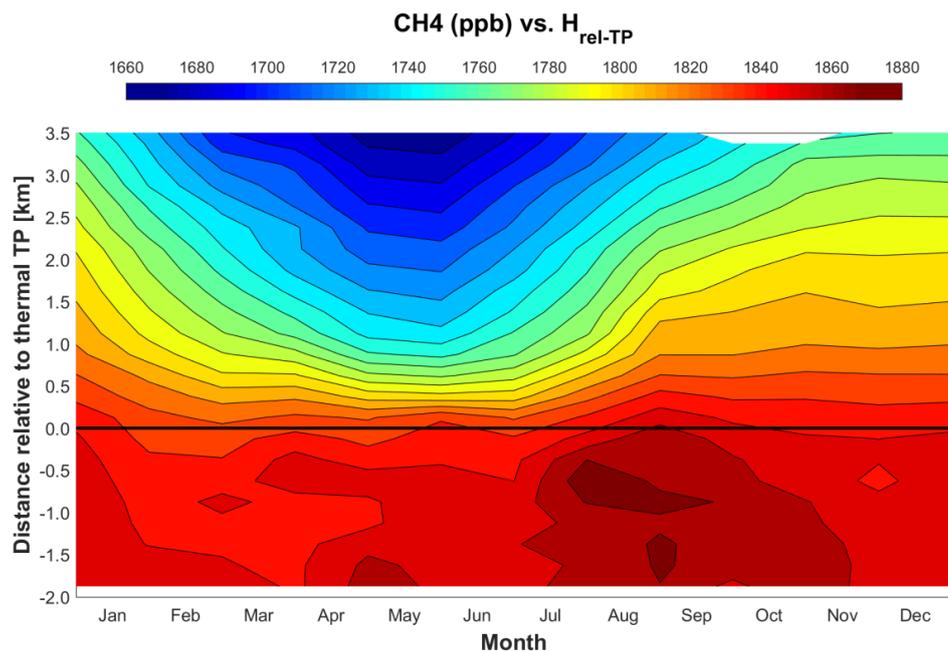

926 Figure 4: Seasonal variation of mean TM concentrations (a), CO (b), CH<sub>4</sub> (c) and O<sub>3</sub> (d)  
 927 mixing ratios in distance relative to the thermal tropopause derived from ozone soundings  
 928 according to Sprung and Zahn (2010). All TM data north of 20°N obtained between April  
 929 2014 and February 2016 were considered for this plot (2288 individual data points).  
 930

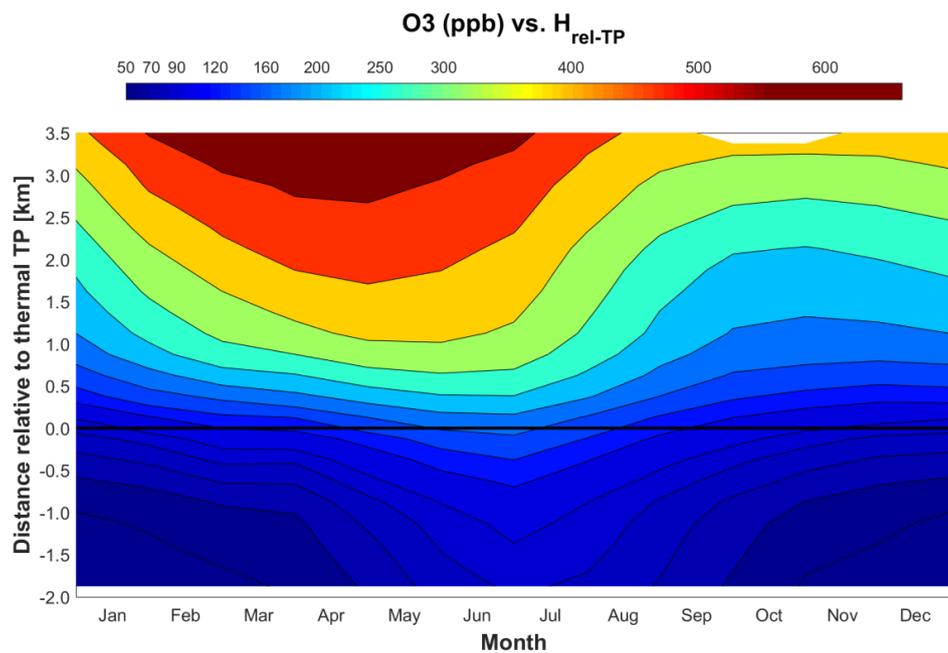

931  
932

936

937 Figure 5: Vertical TM and GEM distribution relative to the thermal tropopause in a)  
938 winter (December – May, upper panel) and b) in summer (June – November, lower  
939 panel). The data points represent averages and their standard errors, extreme values were  
940 eliminated using the Nalimov outlier test (Kaiser and Gottschalk, 1972).

945

946 Figure 6: Stratospheric average TM and GEM concentrations in boreal winter (November  
947 – April) are binned according to the N<sub>2</sub>O mixing ratio. N<sub>2</sub>O mixing ratios were detrended  
948 using 2015 as a reference year and the N<sub>2</sub>O growth rate of 0.844 ppb yr<sup>-1</sup> (Assonov et al.,  
949 2013). Vertical and horizontal bars represent the standard errors of the averages.
